Abstract. Nitrous oxide (N₂O) fluxes measured using the eddy-covariance method capture the spatial and temporal heterogeneity of N₂O emissions. Most closed-path trace-gas analyzers for eddy-covariance measurements have large-volume, multi-pass absorption cells that necessitate high flow rates for ample frequency response, thus requiring high-power sample pumps. Other sampling system components, including rain caps, filters, dryers, and tubing, can also degrade system frequency response. This field trial tested the performance of a closed-path eddy-covariance system for N₂O flux measurements with improvements to use less power while maintaining the frequency response. The new system consists of a thermoelectrically cooled tunable diode laser absorption spectrometer configured to measure both N₂O and carbon dioxide (CO₂). The system features a relatively small, single-pass sample cell (200 mL) that provides good frequency response with a lower-powered pump (~250 W). A new filterless intake removes particulates from the sample air stream with no additional mixing volume that could degrade frequency response. A single-tube dryer removes water vapour from the sample to avoid the need for density or spectroscopic corrections, while maintaining frequency response. This eddy-covariance system was collocated with a previous tunable diode laser absorption spectrometer model to compare N₂O and CO₂ flux measurements for two full growing seasons (May 2015 to October 2016) in a fertilized cornfield in Southern Ontario, Canada. Both spectrometers were placed outdoors at the base of the sampling tower, demonstrating ruggedness for a range of environmental conditions (minimum to maximum daily temperature range: −26.1 to 31.6 °C). The new system rarely required maintenance. An in situ frequency-

response test demonstrated that the cutoff frequency of the new system was better than the old system (3.5 Hz compared to 2.30 Hz) and similar to that of a closed-path CO₂ eddy-covariance system (4.05 Hz), using shorter tubing and no dryer, that was also collocated at the site. Values of the N₂O fluxes were similar between the two spectrometer systems (slope = 1.01, $r^2 = 0.96$); CO₂ fluxes as measured by the short-tubed eddy-covariance system and the two spectrometer systems correlated well (slope = 1.03, $r^2 = 0.998$). The new lower-powered tunable diode laser absorption spectrometer configuration with the filterless intake and single-tube dryer showed promise for deployment in remote areas.

1 Introduction

The concentration of N₂O in the atmosphere is rising and is of concern as N₂O has 298 times the global warming potential of CO₂ (IPCC, 2013). Agricultural systems contribute a significant proportion of total global N₂O emissions due to microbial soil processes (Davidson, 2009). The main drivers of microbial N₂O emissions are soil conditions (e.g., soil oxygen, carbon, and nitrogen levels), but distal drivers such as nitrogen fertilization, dry–wet, and freeze–thaw cycles also exert control and result in N₂O fluxes (F_{N_2O}) that are highly variable in time (“hot moments”) and in space (“hot spots”; Groffman et al., 2009; Molodovskaya et al., 2012). This sporadic nature of F_{N_2O} necessitates continuous measurements covering areas large enough to capture the spatial heterogeneity of the fluxes to sufficiently quantify total emissions from agricultural systems (Flechar et al., 2007; Jones et al., 2011; Shurpali et al., 2016). The eddy-covariance (EC)

technique gives long-term, continuous, and spatially integrated measurements, which can fully capture F_{N_2O} . Advances in technology for N_2O analyzers have increased the number of long-term N_2O measurement campaigns using EC methods (Mishurov and Kiely, 2010; Molodovskaya et al., 2012; Merbold et al., 2014; Huang et al., 2014; Rannik et al., 2015; Shurpali et al., 2016; Wang et al., 2016). However, the application has been limited to sites with high-quality power or short-term deployment. Locations with agricultural N_2O emissions are often rural areas where it may be impractical and expensive to install permanent power infrastructure for long-term F_{N_2O} EC flux measurements.

Gas analyzers used in EC systems require fast responses to distinguish the high frequencies of concentration fluctuations (McBean, 1972; Leuning and Judd, 1996). High-frequency concentration fluctuations can be attenuated by line averaging within the sample cell, as well as sample mixing within various system components, such as intake tubing, dryers, filters, and rain caps (Moore, 1986; Massman, 2000). Analyzer frequency response often represents a significant proportion of the total high-frequency losses (Horst, 1997; Kroon et al., 2010b), but these sampling system components may also significantly degrade system frequency response (Aubinet et al., 2016). Modern closed-path analyzers for CO_2 EC fluxes achieve high-frequency response with low-power pumps by using small sample cells (6 or 16 mL) that operate near ambient pressure (Burba et al., 2010; Novick et al., 2013). The volume of sampling system components is minimized to preserve the frequency response without excessive flow restriction that would increase power requirements for the pump or exceed the range of the sample-cell pressure sensor (Aubinet et al., 2016; Ma et al., 2017).

In contrast, all N_2O analyzers tested in a recent EC field intercomparison have large sample cells (~ 500 mL) that must operate at significantly reduced pressure (50 to 120 mb), necessitating high flow rates (12 to 17 L min⁻¹; Rannik et al., 2015). The high flow rate and low pressure require the use of a relatively high-power pump (500 to 1000 W). Reducing the volume of the sample cell and sampling system components is a means of maintaining good frequency response at a lower flow rate while reducing the power requirements of N_2O EC systems. Using a dryer on the intake line may degrade system frequency response but can eliminate uncertainties associated with spectroscopic corrections for line broadening due to water vapour (Neftel et al., 2010) and density corrections (Webb et al., 1980). The typically high sample flow rates require the use of multi-tube dryers to achieve an acceptable residual humidity. However, laminar flow within the dryer degrades system frequency response because air velocity varies from the centre to the wall of the tube (Leuning and Judd, 1996), and multi-tube dryers can further degrade frequency response if the flow varies among the individual tubes. This problem cannot be overcome by simply increasing flow because a higher flow would require a larger dryer. Alternatively, analyzers with smaller sample cells re-

quire lower sample flow, allowing the use of single-tube dryers and lower-powered pumps to achieve the frequency response required for EC measurements.

An upgraded version of a first-generation tunable diode laser absorption spectrometer (TDLAS; Edwards et al., 2003) has recently been made commercially available (TGA200A, Campbell Scientific Inc., Logan, Utah, USA). The previous model was suitable for long-term N_2O flux measurements for a variety of agricultural and forested sites (Scanlon and Kiely, 2003; Pihlatie et al., 2005; Pattey et al., 2006; Mishurov and Kiely, 2010; Molodovskaya et al., 2012). The upgraded model has been designed to reduce power consumption of EC measurement systems by reducing the volume of the sample cell. This was done without changing the path length, thereby preserving measurement precision. The smaller sample cell allows a lower flow rate, enabling the use of a single-tube dryer that maintains frequency response better than high-capacity, multi-tube dryers. Adapting a new vortex intake – originally developed for use with a CO_2/H_2O EC analyzer (Ma et al., 2017) – to the N_2O analyzer should further improve the frequency response as this device removes particulates from the air stream without adding a significant mixing volume. The vortex intake has the additional advantage of not requiring a traditional filter that can clog over time, restricting flow to the analyzer, and requiring maintenance. This is an important aspect of EC system design for long-term studies because, as stated by Nelson et al. (2004), all components need to be sufficiently rugged to withstand exposure to environmental conditions and run reliably for long time periods with minimal maintenance.

Cutoff frequencies are often used to characterize the frequency response of EC analyzers and systems (McBean, 1972; Nelson et al., 2004; Detto et al., 2011; Rannik et al., 2015) and for correcting flux values for high-frequency losses (Moore, 1986; Horst, 1997; Aubinet et al., 2000; Massman, 2000; Massman and Lee, 2002). Determining frequency response using field-measured cospectra (Aubinet et al., 2000; Ibrom et al., 2007) is challenging for N_2O EC systems as this requires a strong concentration signal occurring simultaneously with environmental conditions appropriate for scaling with temperature spectra. Direct characterizations are more appropriate for N_2O analyzers since emission events may occur for only a few days in a year, reducing the likelihood of ideal conditions for cospectral analyses. Similarly, evaluating system lag times of closed-path N_2O analyzers used for EC flux processing with the standard cross-correlation method requires a strong signal (Kroon et al., 2010b; Neftel et al., 2010). Directly measuring lag times will give a better estimate of the tube delay for periods with low N_2O signals.

We present the first field trial of a new TDLAS with an optimized sampling system, operating at lower flow rates with a lower-powered pump. Continuous F_{N_2O} measurements are presented over two growing seasons for an agricultural site in a cold climate. The system was evaluated for overall perfor-

mance of the instrument in terms of ease of operation, data quality, and suitability for EC measurements. N_2O fluxes measured by the new TDLAS were compared to those measured by the previous-generation TDLAS and CO_2 fluxes (F_{CO_2}) were compared to fluxes measured by a short-tubed CO_2 analyzer. A novel method for determining EC system frequency response and lag time was conducted in situ to determine the analyzer frequency response under field operating conditions.

2 Methods

2.1 Study site

Flux measurements took place at the Elora Research Station, Elora, Ontario, Canada (43.3°27.8' N, 80.24°20.4' W), from May 2015 to October 2016 as a part of a four-plot flux-gradient study on the effect of nitrogen fertilizer management practices on $F_{\text{N}_2\text{O}}$. The four 4 ha plots were located within a larger 30 ha aerodynamically homogeneous and flat field (Fig. 1a) under the same crop management practices. The soil at the site was a Guelph silt loam (fine loamy, mixed, mesic *Glossoboric Hapludalf*). Corn was planted on 10 May 2015 and again on 5 May 2016. Urea fertilizer was broadcast-applied at the time of planting in both years at a rate of 150 kg ha⁻¹ to the plot where instrumentation was set up (Fig. 1a). Corn grew to a maximum height of approximately 2.5 m each summer. Harvest for 2015 started on 27 October and completion was delayed due to rain until 2 November. The field was tilled immediately afterwards, leaving a bare-soil surface from 2 November 2015 to 30 May 2016 when the corn emerged. Harvest in 2016 occurred on 7 October. The field plot was located 400 m from an Environment Canada weather station that measured supporting variables of mean wind direction, air temperature, pressure, and precipitation.

2.2 Eddy-covariance measurements

An EC system (CPEC200, Campbell Scientific Inc., Logan, Utah, USA) was installed in the southeast corner of the 4 ha plot (Fig. 1a, c) and was comprised of a sonic anemometer (CSAT3A) to measure three-dimensional wind and sonic temperature, a closed-path infrared gas analyzer (EC155) to measure mixing ratios of CO_2 and H_2O , and a data logger (CR3000). The sonic anemometer was oriented towards the predominant wind direction (270°; Fig. 1b). Two TDLAS were added to this system (TGA100A and TGA200A, Campbell Scientific Inc., Logan, Utah, USA; see details below). Each measured mixing ratios of N_2O and CO_2 . The analyzers include temperature-controlled, weatherproof cases that allowed them to be placed on two cinder blocks set on the ground at the base of the tower (Fig. 1c). Details on the operation of each gas analyzer are given below. The EC measurements were made at a height of 2.0 m when the surface was bare; the intakes and sonic anemometer were raised to

1.75 m above the canopy top throughout the growing seasons. Data from the sonic anemometer and all three analyzers were recorded at a sampling rate of 10 Hz. Each gas analyzer included a user-configurable digital filter set for a 5 Hz cutoff frequency to avoid aliasing.

2.3 Gas analyzers

The operating principles of the TDLAS used can be found in Edwards et al. (2003) and Wagner-Riddle et al. (2005). Briefly, a temperature-controlled laser emits a beam at an absorption wavelength of the gas species of interest. This beam is split and directed through the sample cell as well as a reference cell supplied with a known reference gas. The laser wavelength is swept across an individual absorption line by adjusting the laser current. This produces the absorption spectrum, measured by detectors at the ends of the reference and sample cells. The mixing ratio in the sample cell is calculated from the ratio of the spectral absorbance of the reference and sample cells. Both TDLASs are capable of simultaneous measurement of multiple trace gases on separate absorption lines (dual-ramp mode). For periods during this study, the analyzers were set to measure the absorption of N_2O and $^{13}\text{CO}_2$.

Table 1 lists the equipment and measurement mode used for each analyzer through the measurement campaign. Operating configurations of N_2O analyzers used in Rannik et al. (2015) are given for comparison. The analyzers included enclosure temperature controllers to maintain temperatures of 20 °C in winter and 40 °C in summer. Flow from the reference gas cylinders was set at 10 mL min⁻¹. Analyzer calibrations were performed shortly after the initial installation and repeated each time a reference cylinder was replaced. Additional information on calibration and correction of $^{13}\text{CO}_2$ to total CO_2 can be found in the Supplement.

The “legacy” TDLAS (TGA100A, manufactured in 2005, hereafter referred to as TDLAS-LN) used a cryogenically cooled, lead salt diode laser operating at 83.5 K and 2243.11 cm⁻¹ (N_2O) and 2243.585 cm⁻¹ (CO_2). The TDLAS-LN required twice-weekly filling of the laser dewar with liquid nitrogen. This analyzer was operated in a dual-ramp mode measuring both N_2O and CO_2 throughout the measurement campaign, following a typical air-sampling configuration for EC measurements (Fig. 1d; see also Mammarella et al., 2010; Mishurov and Kiely, 2010; Molodovskaya, 2012; Rannik et al., 2015). Air was sampled through a 6 mL rain-shielded intake (part number 17882, Campbell Scientific, Inc., Logan, Utah, USA) and a dryer assembly (PD1000, Campbell Scientific, Inc., Logan, Utah, USA), which included a 2 µm polypropylene filter element in a low-volume, high-flow filter holder, and a multi-tube dryer (200-tube, 1.2 m NafionTM dryer element; Perma Pure, Lakewood, New Jersey, USA). A tee fitting and needle valves split the flow between dryer purge (3 L min⁻¹) and sample flow directed to the analyzer (14.5 L min⁻¹; Fig. 1d). Tub-

ing between the intake, dryer assembly, and the analyzer was 4.3 mm ID SynflexTM tubing. The total length of tubing (plus dryer) from the intake to the analyzer was 6 m from 10 May to 8 July 2015, at which time the tubing length was increased to 10 m to accommodate the increase in canopy height. A 950 W rotary vane pump (RB0021, Busch Vacuum Technics, Inc., Boisbriand, Québec, Canada) was connected to the analyzer using ~ 50 m of 25.4 mm ID PVC suction hose (Tigerflex K100, Kuri Tec, Brantford, Ontario, Canada), to draw air through the analyzer and the dryer purge (Fig. 1d). The volume of the sample cell of TDLAS-LN was 480 mL. This setup is similar to the TGA100A used by Rannik et al. (2015), although for the present study the original filter holder (Gelman 1235, Pall Corp.), included as part of the dryer assembly, was updated to a newer design (part number 20553, Campbell Scientific, Inc., Logan, Utah, USA) with lower volume (5 mL compared to 20 mL). Filter elements

were replaced approximately every 2 weeks. The nominal sample-cell pressure was 58 mb throughout the measurement campaign.

The new N_2O analyzer (TGA200A, hereafter referred to as TDLAS-TE) was similar to the TDLAS-LN with two major upgrades: a smaller-diameter sample cell and a room-temperature laser. It used a distributed feedback interband cascade laser (DFB ICL, nanoplus Nanosystems and Technologies GmbH, Gerbrunn, Germany) that was cooled thermoelectrically as opposed to with liquid nitrogen. The laser temperature was set to -1°C and the laser current was tuned to measure N_2O at 2237.7 cm^{-1} and CO_2 at 2237.3 cm^{-1} from 10 to 29 May 2015, when the laser was configured to measure N_2O at 2235.5 cm^{-1} to assess performance of the laser in single-ramp mode for approximately 2 months. On 31 July 2015, the laser was switched back to dual-ramp mode until 31 March 2016. On this date, a new N_2O -only laser was

Table 1. Sampling system details for each analyzer throughout the measurement campaign. Changes to equipment during the experimental period are indicated. Operating configurations of N₂O analyzers used in Rannik et al. (2015) are given for comparison.

installed in the TDLAS-TE. This laser operated at -2.4°C at 2208.6 cm^{-1} .

The sample cell of TDLAS-TE has a similar length (1.5 m) compared to the TDLAS-LN, but a smaller inner diameter (12.7 mm compared to 18.8 mm). The smaller inner diameter gives the newer sample cell a volume of 200 mL, a reduction of 280 mL from the original size. From 10 May to 22 June 2015 the TDLAS-TE sampling system (intake assembly, dryer, and pump) was similar to that of the TDLAS-LN. The TDLAS-TE sampling system was replaced on 24 June 2015 with a new prototype design including a vortex intake and single-tube dryer (Fig. 1e), optimized to take advantage of the smaller sample-cell volume. The intake assembly and filter were replaced with a vortex intake that removes particulates without a traditional filter (US patent no. 9 217 692). The vortex intake was adapted for this application by extending the length of the sample tube (2.2 mm ID stainless steel) to 1.1 m and by providing a separate high-capacity filter (Numatics PXB-02, ASCO Numatics, Florham Park, New Jersey, USA) and diaphragm pump (E163-11-120, Parker-Hannifin, Inc. Hollis, NH) for the bypass flow. On 24 December 2015 this pump was replaced by one designed for long-term continuous use (L061B-11, Parker-Hannifin, Inc. Hollis, New Hampshire, USA). The multi-tube dryer was replaced with a prototype design using a single Nafion[®] tube (2.2 mm ID, 7.3 m long TT-110, Perma Pure LLC, Lakewood, New Jersey, USA). The tube was housed in a large-

diameter (25.4 mm) flexible shell to allow it to be purged in reflux mode with little pressure drop. A needle valve at the outlet of the dryer controlled the sample-flow rate to 3.5 L min^{-1} . The total length of the intake assembly and dryer was 9.1 m. A short (0.1 m) tube (4.3 mm ID Synflex[™]) connected the needle valve to the analyzer inlet. A lower-powered (250 W) dry scroll pump (nXDS6i, Edwards Ltd., West Sussex, UK) pulled the sample air through the intake assembly, dryer, and analyzer via approximately 50 m of 25.4 mm ID PVC suction hose (Tigerflex K100, Kuri Tec, Brantford, Ontario, Canada; Fig. 1e). The nominal sample-cell pressure was 59 mb at the start of the measurement campaign and set to 35 mb after the new sampling system was installed on 24 June 2015.

CO₂ and H₂O fluxes were measured with a closed-path EC system (CPEC200) that included the gas analyzer (EC155) and sonic anemometer (CSAT3A), as well as the sample pump, enclosures, and mounting hardware. Details on the EC155 analyzer can be found in Novick et al. (2013). This CPEC200 system was configured with the manufacturer's valve module for automatic zero and span, as well as a scrub module to supply dry, CO₂-free air for setting zero on the analyzer (see details in the Supplement). The system was configured to automatically set the analyzer to zero and CO₂ span daily at 01:00. The EC155 was reconfigured on 10 February 2016 with the production version of the vortex intake/sample-cell prototype that was tested by Ma et

al. (2017). Nominal flow settings of 8 L min^{-1} total flow, with 6 L min^{-1} through the EC155 sample cell and 2 L min^{-1} for the vortex bypass, were used.

2.4 Frequency-response test

The impulse response method (Sargent, 2012) was used in situ to measure the frequency response of each EC system and derive the tube delay (t_{del}), cutoff frequency (f_c), and effective time constant (τ_e). Briefly, this method entails injecting an impulse of high N_2O and CO_2 concentration into the sample air stream. Measuring the response to this impulse and taking the Fourier transform of this result gives the frequency response. This gives a conservative estimate of the frequency response of the system, as any attenuation of high frequencies caused by the test method is included in the system frequency response.

The impulse responses were measured in situ for each analyzer by injecting high-concentration (2500 ppm N_2O and 30 000 ppm CO_2) gas directly into the intake with a fast-acting solenoid valve (VHS micro dispense valve, The Lee Co., Westbrook, Connecticut, USA) driven with a spike-and-hold driver (part number IECX0501350AA, The Lee Co.) every 10 s, as controlled by a data logger. For the TDLAS-TE and EC155, which were equipped with the vortex intake, the dispense valve nozzle was inserted into the rain cap end for a test of the complete system. The TDLAS-LN used a rain cap that did not permit this direct injection. This rain cap was removed and replaced with a small adapter to mount the valve. The dispense valve was driven open for less than 5 ms for each pulse. For the N_2O analyzers, frequency response was measured at various pressures, including the standard operating pressure (TDLAS-LN: 29, 38, 45, and 58 mb; TDLAS-TE: 28, 30, 35, and 43 mb). These pressures were achieved by adjusting the needle valve that sets the sample flow. The EC155 frequency response was measured with the production version of the vortex intake assembly. The concentration data and the voltages to the solenoid valve were recorded at 20 Hz for 20 min per test.

The impulse response was calculated by subtracting the average ambient background N_2O or CO_2 concentrations from the data, overlaying the multiple 10 s periods, and then taking an average of the responses. The t_{del} was calculated as the delay from the valve open signal to the peak of the impulse response, minus processing time for the analyzer (750, 372, and 800 ms, respectively, for TDLAS-LN, TDLAS-TE, and EC155). This tube delay represents the physical travel time through the sampling system and into the analyzer sample cell.

The frequency response was calculated as the normalized amplitude of the Fourier transform of the impulse response. The f_c was determined graphically as the frequency at which the frequency response reached a value of $1/\sqrt{2}$. Following common practice, we compared this frequency response to a linear, first-order system (Moore, 1986; Horst, 1997; Mass-

man, 2000; Massman and Lee, 2002; Ibrom et al., 2007). This transfer function is often related to electronic circuits, but it also describes transfer function of an ideal mixing volume (Horst, 1997). The amplitude of the transfer function (T_{FR}) is

$$T_{\text{FR}} = \frac{1}{\sqrt{1 + \left(\frac{f}{f_c}\right)^2}}. \quad (1)$$

Alternately, the transfer function may be parametrized by an effective time constant (τ_e), calculated using

$$\tau_e = \frac{1}{2\pi f_c}. \quad (2)$$

Theoretical residence times (τ_{res}) of the analyzer sample cells were calculated based on the sample-cell volume, pressure, and flow rates from Table 1. Theoretical cutoff frequencies ($f_{c,t}$) and corresponding theoretical effective time constants ($\tau_{e,t}$) were calculated from τ_{res} using different models for multi-pass and single-pass sample cells. Multi-pass sample cells, which tend to be relatively short for a given volume with low length-to-diameter ratios, are often modelled with the assumption of perfect mixing ($\tau_{e,t} = \tau_{\text{res}}$; Nelson et al., 2004). In contrast, EC155, TDLAS-LN, and TDLAS-TE have higher length-to-diameter ratios and have relatively long, narrow sample cells. For these analyzers the theoretical frequency response is modelled assuming no mixing in the sample cell, which is analogous to line averaging in a sonic anemometer when the sonic path is aligned with the wind vector. The amplitude transfer function for line averaging is (Mitsuta, 1966)

$$T_{\text{LA}} = \sqrt{\sin^2(\pi \tau_{\text{res}} f) / (\pi \tau_{\text{res}} f)^2}. \quad (3)$$

This transfer function has an approximate cutoff frequency of

$$f_{c,t} = \frac{2.78}{2\pi \tau_{\text{res}}}. \quad (4)$$

The corresponding effective time constant from Eq. (2) is

$$\tau_{e,t} = \frac{1}{2\pi f_{c,t}} = \frac{\tau_{\text{res}}}{2.78}. \quad (5)$$

2.5 Flux calculations

Fluxes were calculated as the covariance between fluctuations of the scalar concentration (s) and the vertical wind velocity (w):

$$F_s = \overline{w's'}, \quad (6)$$

where s is the mixing ratio of either N_2O or CO_2 .

Fluxes were calculated for 30 min time intervals in MatlabTM using modifications to functions from Sturm et al. (2012). The vertical wind was despiked and then rotated using a double rotation (Aubinet et al., 2012; Kaimal and Finnigan, 1994). The high-frequency concentration data for all analyzers were despiked and filtered according to instrument diagnostic codes. Concentration measurements from both N₂O analyzers were filtered for periods of equipment maintenance or malfunction. All concentrations measured by TDLAS-TE and the EC155 were linearly detrended. Concentration data from TDLAS-LN were linearly detrended until winter of 2016 when the concentration signal periodically indicated optical fringing of the laser. A Chebyshev filter was used to detrend and remove the artificial low-frequency fluctuations for those 30 min periods. The 30 min flux values were filtered for low wind speed conditions (friction velocity (u_*) $< 0.1 \text{ m s}^{-1}$) and wind direction of 60 to 120° (shadow of instrument tower). Vibrations from strong winds against the side of TDLAS-LN caused increased concentration noise. This occurred during periods when the field was bare and mean wind speeds were greater than 5 m s^{-1} from 200 to 360°. Data from these periods were filtered out. Flux data from TDLAS-TE were not affected by the strong winds as it was sheltered by TDLAS-LN for southwest to northerly wind directions, and data with winds against the side of TDLAS-TE were already filtered out due to tower interference (Fig. 1).

Cumulative gap-filled seasonal emission rates (planting to harvest) were calculated for each year. Daily mean emissions were estimated by extrapolating the mean of the available 30 min fluxes for each day to $\text{g N}_2\text{O-N ha}^{-1}$. Linear interpolation was used to fill periods with missing data (Abalos et al., 2015).

Lag times (t_l) for analyzers measuring CO₂ concentration (TDLAS-TE when operated under dual-ramp mode; TDLAS-LN and EC155) were calculated using cross-correlation such that t_l was the time delay that maximized the covariance between the concentration and w signals. CO₂ concentrations were used for the t_l calculation as the N₂O signal was too weak for cross-correlations for the majority of time periods, as was also observed by Kroon et al. (2010a). This was determined on a day-by-day basis as the conditions that affected concentration signal delays (e.g., pump performance, filter clogging) remained relatively consistent on a daily timescale. For the daily lag value, t_l was calculated for individual 30 min periods per day with the strongest F_{CO_2} as determined from raw 30 min flux values. An average of six lag times for each analyzer was used for a given day. Lag times ranged from 0.5 to 1.0 s for the TDLAS-TE and 0.6 to 1.2 s for the TDLAS-LN; t_l for the EC155 was consistent at 0.1 s. Processing delays in the sonic anemometer and the gas analyzers were subtracted from these lag times to calculate tube delays for comparison with t_{del} derived from the frequency-response test. Values for t_l derived from t_{del}

and sonic processing delays were used for periods when the TDLAS-TE was setup to measure only N₂O concentrations.

The τ_e derived from the frequency-response test was used to calculate corrections for high-frequency losses using the simplified formula given by Horst (1997):

$$T_r = \frac{1}{1 + \left(2\pi n_m \frac{U}{z} \tau_e\right)^\alpha}, \quad (7)$$

where U is the mean wind speed, z is the measurement height, and n_m and α are constants determined from the idealized spectra of Kaimal et al. (1972) using values for unstable and stable conditions as presented by Horst (1997).

2.6 Flux comparisons

Half-hourly $F_{\text{N}_2\text{O}}$ and F_{CO_2} obtained with the two TDLAS were compared over the whole measurement period, and F_{CO_2} from both TDLASs was also compared to the EC155. Agreement was evaluated based on r^2 and slope of the linear regression between values from the different analyzers. Cumulative $F_{\text{N}_2\text{O}}$ over the measurement period for each TDLAS were calculated. No gap filling was applied to the time series, so totals do not represent absolute emissions for this site. Emissions were accumulated using only 30 min $F_{\text{N}_2\text{O}}$ when data were available from both analyzers and converted from $\text{ng N}_2\text{O-N m}^{-2} \text{ s}^{-1}$ to $\text{g N}_2\text{O-N ha}^{-1}$.

Random errors of each of the individual 30 min $F_{\text{N}_2\text{O}}$ (δ_F) as measured by the TDLAS-LN and TDLAS-TE, were calculated using the filtering method of Salesky et al. (2012). This method was preferred over those requiring an estimate of the turbulent integral timescale (e.g., Finkelstein and Sims, 2001) as timescales can vary depending on definition (Dias et al., 2004). Salesky et al. (2012) showed that error estimates from the filtering method compared well to those using integral scales. Briefly, this method entailed repeatedly applying filters of increasing width (Δt) to the high-frequency instantaneous fluxes from each 30 min period. Standard deviations of each set of filtered data were fit to $\Delta t^{-1/2}$. These successive power law fits were then fit to the entire averaging period to estimate the 30 min δ_F . Propagation of δ_F was then used to calculate the confidence intervals ($p = 0.05$) of the total cumulative $F_{\text{N}_2\text{O}}$ for the TDLAS-TE and TDLAS-LN time series.

Flux detection limits (δF) were calculated using the method described in Blomquist et al. (2010) and Yang et al. (2016) where the detection limit is calculated using the instrument noise and the variability of the concentration signal:

$$\delta F = \frac{2\sigma_w}{\sqrt{T_f}} \left[\sigma_{C_a}^2 \tau_{wc} + \frac{\varphi C_n}{4} \right]^{1/2}, \quad (8)$$

such that σ_w is the standard deviation of w , T_f is the flux-averaging period, $\sigma_{C_a}^2$ is the ambient variance of the concentration signal, τ_{wc} is the integral timescale for the ambient

concentration variance, and ϕ_{C_n} is the band-limited analyzer noise. ϕ_{C_n} was calculated as the mean of the variance spectra from 1 to 5 Hz. Values of $\sigma_{C_a}^2$ were calculated as the second point of the autocovariance of the concentration signal (Yang et al., 2016). Blomquist et al. (2010) estimated τ_{wc} using the peak frequency of the variance cospectrum. Peak frequencies here were modelled via the equation given in Horst (1997).

3 Results

3.1 N₂O fluxes and data coverage

Measurements of fluxes covered two growing seasons (May to October in 2015 and 2016), one post-harvest period (November to December 2015), winter (January to February 2016), and early spring (March to April 2016). Winter was classified as the period when nighttime temperatures were consistently below freezing. Figure 2 displays the mean daily air temperatures and precipitation for 2015 and 2016. Mean hourly air temperatures ranged from -26.1 to 31.6 °C. Winter of 2016 was on average 3 °C warmer than 30-year normals and the maximum snow depth was relatively low at 8 cm. Precipitation totals were close to 30-year normal values for both years; however, May of 2015 received only 17 mm of rainfall until 31 May, which was considerably less than the normal amount of 89 mm. Rainfall was lower than normal in May, June and July of 2016 with monthly totals 50 % lower than the 30-year monthly normals.

Non-gap-filled mean daily N₂O fluxes obtained with the TDLAS are shown in Fig. 3. One major N₂O flux event occurred in 2015, one day after the first significant rainfall after planting and fertilizer application (8 and 9 June 2015, day of year (DOY) 159 and 160 in Fig. 3a). The daily mean 30 min F_{N_2O} values for this event as measured by both analyzers were $600 \text{ ng N}_2\text{O-N m}^{-2} \text{ s}^{-1}$ with the 30 min fluxes during the daytime and exceeding $800 \text{ ng N}_2\text{O-N m}^{-2} \text{ s}^{-1}$ for several hours. Two subsequent post-fertilizer flux events occurred after rainfall on 16 and 28 June 2015 (DOY 167 and 179; Fig. 2a) and were smaller in magnitude with daily average fluxes of $100 \text{ ng N}_2\text{O-N m}^{-2} \text{ s}^{-1}$. Throughout the remainder of the growing season of 2015 and post-harvest period of 2015, mean daily fluxes were small and varied between -10 and $10 \text{ ng N}_2\text{O-N m}^{-2} \text{ s}^{-1}$. The warmer-than-average winter in 2016 limited flux emissions from freeze-thaw processes that have been typically observed at this site (Furon et al., 2008; Risk et al., 2013; Abalos et al., 2015; Congreves et al., 2017; Wagner-Riddle et al., 2017) with average daily fluxes ranging from 0 to $30 \text{ ng N}_2\text{O-N m}^{-2} \text{ s}^{-1}$ (Fig. 3b). The abnormally dry spring in 2016 prevented any significant N₂O flux events associated with fertilizer application. Peak post-fertilizer daily flux values from 5 May to 13 June 2016 (DOY 126 to 165 in Fig. 3c) averaged $25 \text{ ng N}_2\text{O-N m}^{-2} \text{ s}^{-1}$. Daily flux values in the summer period of 2016 remained small ($\sim 5 \text{ ng N}_2\text{O-N m}^{-2} \text{ s}^{-1}$; Fig. 3c) but pre-

dominantly positive throughout the summer. Mean gap-filled daily emissions as measured by each analyzer were averaged together. This gave total seasonal (planting to harvest) cumulative emissions of 3.34 and $1.20 \text{ kg N}_2\text{O-N ha}^{-1}$ for the growing seasons of 2015 and 2016, respectively. This is within the range of seasonal emissions typically observed at this site (Wagner-Riddle et al., 2007; Abalos et al., 2015) and represented a loss of 2.2 and 0.8 % of the applied N.

Both analyzers performed well throughout the measurement period and maintenance requirements were minimal for both. Of the total number of 30 min periods for the whole measurement period, 44 % of the 30 min flux values were filtered out due to low friction velocity, wind direction and footprint criteria, warnings from the sonic anemometer from precipitation, disruption from field operations, and power outages. Further filtering based on analyzer operation and diagnostics resulted in an additional removal of 16 (TDLAS-TE) and 28 % (TDLAS-LN) of the fluxes due to equipment failure and periods of equipment reconfiguration. Longer data gaps occurred mostly for the TDLAS-LN due to pump malfunction, a faulty power supply, and an electronic module failure. Data outage for the TDLAS-TE in September 2015 was due to failure of the diaphragm pump providing bypass flow for the vortex intake before a model designed for long-term use was installed. Intermittent periods of data losses for both TDLASs also occurred when the enclosure temperature settings prevented the heaters from maintaining a constant temperature. This occurred at night during spring and fall periods when differences between daytime and nighttime temperatures were greatest and midday in the summer months when air temperatures exceeded 30 °C.

3.2 Frequency-response test

The in situ frequency-response test characterized the frequency response and tube delay for the three analyzers under the operating pressures tested. Impulse response peaks were at minimum 5 ppm (N₂O) and 600 ppm (CO₂) above ambient concentrations. The peaks were consistent throughout each of the 20 min tests with an average coefficient of variation of 1.8 %. The precision of the impulse responses was further improved by averaging the 120 peaks in each test. Frequency-response curves for each analyzer obtained at the nominal cell pressure (Table 1) are given in Fig. 4. The frequency-response curve for the EC155 drops steeply at 5 Hz as expected due to its digital anti-aliasing filter. The effect of the digital filters is not distinctly visible for the N₂O analyzers, but all three analyzers have little or no response at or near the Nyquist frequency (10 Hz), giving confidence that the frequency-response curves are not contaminated by aliasing. Table 2 contains the corresponding cutoff frequencies and effective time constants. The EC155 showed the best frequency response ($f_c = 4.05 \text{ Hz}$ and $\tau_e = 39 \text{ ms}$) for CO₂ (Table 2). The frequency response to N₂O of TDLAS-TE was nearly as good as the EC155 ($f_c = 3.5 \text{ Hz}$, $\tau_e = 45 \text{ ms}$), while

Figure 2. Daily precipitation and temperature for 2015 and 2016. Rain values (mm) are the total rainfall per day, and snow values (cm) are the depth of snow present.

Table 2. Analyzer frequency-response characteristics from this study and that of Rannik et al. (2015). Residence times (τ_{res}) were calculated from values given in Table 1. $f_{c,t}$ is the theoretical best-case cutoff frequency, assuming no mixing for the single-pass sample cells and complete mixing for the multi-pass sample cells, and $\tau_{e,t}$ is the corresponding effective time constant. f_c and τ_e are results from the impulse response test. Results ($\tau_{e,s}$ and $f_{c,s}$) from Rannik et al. (2015) were derived from cospectral analyses. The tube delays t_{del} are the measured total delay minus the processing delay. Time constants and t_{del} are in units of milliseconds and cutoff frequencies are in hertz.

TDLAS-LN showed lower-frequency response ($f_c = 2.3$ Hz and $\tau_e = 69$ ms). TDLAS-LN measured both N₂O and CO₂ during the frequency-response test; results for CO₂ were identical to those for N₂O (data not shown). These measured f_c were used in Eq. 1 to calculate T_{FR} , which are shown for comparison in Fig. 4. Spectral losses (Eq. 7) calculated with the f_c were on average 5 % of the measured flux for the TDLAS-TE and 7 % for the TDLAS-LN. All measured f_c values were lower than the best-case theoretical cutoff frequencies ($f_{c,t}$) calculated from τ_{res} (Table 2), indicating some attenuation of high frequencies in the sampling system components and sample cells, as expected. Frequency responses for both N₂O analyzers were tested at a range of pressures as varying field conditions can cause pressures to drift with pump performance and, in the case of TDLAS-LN, filter clogging. The TDLAS-LN f_c increased significantly with pressure (1.1 Hz at 29 mb to 2.3 Hz at 58 mb), whereas the response of the TDLAS-TE showed less varia-

tion (3.1 Hz at 28 mb to 3.65 Hz at 43 mb; data not shown). Response times calculated using measured cospectra are included in the Supplement.

Tube delays determined from the impulse responses at the nominal cell pressure for the three analyzers are given in Table 2. As expected, the EC155 had the shortest t_{del} at 100 ms. The tube delay of TDLAS-TE was longer (578 ms) due to the greater tubing length and lower flow rate. The tube delay for TDLAS-LN was longest at 720 ms, despite its higher flow rate, due to the larger volumes for its tubing, filter, and dryer. Tube delays for the N₂O analyzers over the range of operating pressures showed a decrease in t_{del} with increasing cell pressure (Fig. 5). Decreases in flow rate with pressure for TDLAS-LN acted to increase t_{del} to a greater degree than for the TDLAS-TE. Tube delays determined from the cross-correlation of CO₂ with w ranged from 650 to 1450 ms for TDLAS-LN and 550 to 1050 ms for TDLAS-TE and were

Figure 3. Mean daily fluxes of $\text{N}_2\text{O-N}$ measured by each analyzer. Panel (a) shows the period of high N_2O fluxes in the post-fertilization period of 2015 and the fluxes measured throughout the growing season. Panel (b) shows the fluxes measured during the post-harvest period of 2015 and winter of 2016. The dotted line in panel (b) demarcates the separation between years 2015 and 2016. Panel (c) shows fluxes measured from early spring to the end of the growing season of 2016.

Figure 4. Results of the frequency-response test of TDLAS-LN and TDLAS-TE for N_2O and the EC155 (CO_2) under normal operating conditions (solid lines); dashed lines are modelled T_{FR} calculated using the measured f_c in Eq. (1).

consistent with those determined from the impulse response (Fig. 5).

3.3 Flux comparison

Comparison of $F_{\text{N}_2\text{O}}$ showed similar values for both TDLASs on short and long timescales. Figure 6a shows the agreement between 30 min $F_{\text{N}_2\text{O}}$ values measured

Figure 5. Tube delay (t_{del}) determined from the frequency-response test (solid symbols) and from the cross-correlation between the CO_2 and w (open symbols) across the range of operating pressures. Error bars are the standard deviation of the mean cell pressure associated with each value.

by each analyzer ($r^2 = 0.97$, slope = 1.01). The majority (86 %) of 30 min N_2O fluxes were small and below $20 \text{ ng N}_2\text{O-N m}^{-2} \text{ s}^{-1}$. The general correspondence between the TDLAS-LN and TDLAS-TE flux values remained for the small flux values (Fig. 6b). Scatter in the low $F_{\text{N}_2\text{O}}$ (Fig. 6b) was related to instrument noise. Both analyzers showed excellent agreement with the CO_2 fluxes measured using the EC155. The slope and correlation coefficient of the linear regression between the EC155 and TDLAS-TE were, respectively, 1.03 and 0.998 (Fig. 6c). Similarly, the slope and correlation coefficient of the linear regression between the EC155 and TDLAS-LN were 1.03 and 0.998 (data not shown).

Figure 7 shows the mean variance spectra of the N_2O signals from each TDLAS analyzer for a period of 10 days where no N_2O fluxes were observed (29 June to 9 July 2016). The variance spectra of both analyzers were dominated by instrument noise as N_2O emissions were at background levels. Values of ϕ_{C_n} were $0.28 \text{ ppb}^2 \text{ Hz}^{-1}$ for the TDLAS-TE and $0.22 \text{ ppb}^2 \text{ Hz}^{-1}$ for the TDLAS-LN. When considering only instrument noise, detection limits with mean conditions of $U = 3.5 \text{ m s}^{-1}$, $z = 4 \text{ m}$, and $\sigma_w = 0.5 \text{ m s}^{-1}$ were $6.6 \text{ ng N}_2\text{O-N m}^{-2} \text{ s}^{-1}$ for the TDLAS-TE and $5.2 \text{ ng N}_2\text{O-N m}^{-2} \text{ s}^{-1}$ for the TDLAS-LN. Incorporating signal noise increased $\delta F_{\text{N}_2\text{O}}$ to $9.9 \text{ ng N}_2\text{O-N m}^{-2} \text{ s}^{-1}$ for the TDLAS-TE and $19.6 \text{ ng N}_2\text{O-N m}^{-2} \text{ s}^{-1}$ for the TDLAS-LN. Despite the lower instrument noise, concentration signals of the TDLAS-LN were less steady than the TDLAS-TE during the period evaluated ($\sigma_{C_a}^2$ of 0.27 and 0.042 ppb^2 , respectively).

Emissions were accumulated over the measurement period to evaluate the long-term comparison of the total $F_{\text{N}_2\text{O}}$ (Fig. 8). No gap filling was applied for the comparison of cumulated sums between analyzers. From planting of 2015 to harvest of 2016, TDLAS-TE measured total emissions of $1247 \pm 11.3 \text{ g N}_2\text{O-N ha}^{-1}$ and TDLAS-LN measured $1272 \pm 9.3 \text{ g N}_2\text{O-N ha}^{-1}$, where uncertainties are the propagated random errors.

Figure 6. Comparison of 30 min fluxes measured by each analyzer. Panel (a) displays the comparison of $\text{N}_2\text{O-N}$ fluxes ($\text{ng N}_2\text{O-N m}^{-2}\text{s}^{-1}$) for the entire data set, panel (b) shows the same $\text{N}_2\text{O-N}$ flux data set ($\text{ng N}_2\text{O-N m}^{-2}\text{s}^{-1}$) but centred on the low flux values. The green “x” markers in panel (b) are the fluxes measured when the standard deviation of background N_2O concentrations for both analyzers was less than 2 ppb N_2O . Panel (c) is the comparison of F_{CO_2} between TDLAS-TE and EC155 ($\mu\text{g CO}_2 \text{ m}^{-2} \text{ s}^{-1}$).

4 Discussion

Both N_2O analyzers were well suited for the long-term and continuous measurement of $F_{\text{N}_2\text{O}}$ that are required to fully capture the temporal dynamics of N_2O emissions (Savage et al., 2014; Shurpali et al., 2016). Both operated continuously for over 1.5 years through the various environmental conditions encountered in Southern Ontario. Data gaps were caused by problems with sample pumps, a power supply failure, and from reconfigurations for the intercomparison experiment, (e.g., frequency-response testing, swapping lasers, and reconfiguring the sampling systems). Disregarding these time periods, data coverage of 56 % was typical for EC measurements at that site after typical EC filtering for rainy periods, low wind speeds, and wind direction (Santos et al., 2011; Brown et al., 2013). Further steps can be taken to reduce data losses attributable to the TDLAS operation, including adjusting the analyzer’s internal-temperature set point more frequently (seasonally to monthly) and protecting the analyzer from strong winds. A simple baffle the height of the analyzer (0.55 m) along the side of the analyzer facing the mean wind direction would provide sufficient shelter from strong winds ($U > 5 \text{ m s}^{-1}$).

The older TDLAS-LN system required periodic maintenance including liquid nitrogen fills (twice weekly), replacing filter elements (twice monthly), and changing pump oil (monthly). The TDLAS-TE system with the vortex intake and dry scroll pump required no routine maintenance. The

Figure 7. Mean N_2O variance spectra of each TDLAS analyzer from 29 June to 9 July 2016.

Figure 8. Cumulative (not gap-filled) $\text{N}_2\text{O-N}$ emissions. Shaded areas represent the $p = 0.05$ confidence intervals calculated using the random error calculations.

TDLAS-TE also operated using less power for the sample pump than the TDLAS-LN (250 W versus 950 W). The ruggedness and low maintenance of TDLAS-TE through all seasons showed the suitability of the analyzer for capturing post-fertilizer and freeze–thaw emissions.

The TDLAS-TE system, with smaller sample-cell volume, single-tube dryer, and vortex intake had better frequency response ($f_c = 3.5 \text{ Hz}$) than the TDLAS-LN system ($f_c = 2.30 \text{ Hz}$), while operating at lower flow rates (3.5 compared to 14.5 L min^{-1}) and with lower sample pump power consumption. The TDLAS-TE cutoff frequency of 3.5 Hz was only slightly lower than that of the short-tubed EC155 closed-path analyzer ($f_c = 4.05 \text{ Hz}$). The frequency response of the TDLAS-TE system was affected less by changes in pressure and flow rate than the TDLAS-LN, which helped to maintain constancy of f_c with the slight variations in pressure that occur during long-term field operations. The frequency response of TDLAS-LN was still adequate for EC measurements (McBean, 1972; Eugster et al., 2007). Rannik et al. (2015) reported EC system time constants calculated from cospectra ($\tau_{e,s}$) for several N_2O analyzers, which are summarized in Table 2. The same model N_2O analyzer (TGA100A) with a similar sampling system at similar flow (17 L min^{-1}) and pressure (50 mb) had a $\tau_{e,s}$ of 120 ms. The lower τ_e in this study (69 ms) is likely related to the shorter tube and newer lower-volume filter holder as com-

pared to the higher-volume filter holder used in the Rannik et al. (2015) study or discrepancies between our direct frequency-response assessment compared to deriving τ_e from cospectral analyses. Rannik et al. (2015) found a disagreement of almost a factor of 2 in the N_2O and CO_2 time constants for a system that measured both gases, opting to use the value measured for CO_2 for spectral corrections of both gases. However, it is difficult to directly compare the absolute values of the frequency-response τ_e with the commonly used cospectra method (Detto et al., 2011; Peltola et al., 2014; Rannik et al., 2015; Aubinet et al., 2016). The cospectral method is highly dependent on the adherence of the spectra to similarity scaling and is also affected by sensor separation and by imperfect synchronization of the scalar with vertical wind. The frequency-response test provided a direct assessment of sampling system response times, as it eliminates the possibility of response times being affected by artefacts of the temperature or w spectra.

Analyzer sample cell and sampling system design both have an impact on system frequency response. Multi-pass sample cells tend to be much shorter but with larger diameters compared to single-pass sample cells; therefore, the air flow tends to behave as a mixing volume. Measured τ_e for analyzers with multi-pass sampling cells are generally greater than the τ_{res} of the sample cell. Nelson et al. (2004) directly measured the frequency response of an analyzer with a multi-pass sample cell using an exponential fit to measurements of a step change in concentration. Their τ_e of 63 ms was slightly greater than the theoretical time constant ($\tau_{\text{res}} = 54$ ms). Neftel et al. (2010) measured the time constant for an EC system with a similar sample cell using the same step-change technique. The measured τ_e of 400 ms was more than twice the theoretical time constant ($\tau_{\text{res}} = 175$ ms) of the sample cell, likely due to the long tube (30 m) and other sampling components. Single-pass sample cells, which tend to be long and narrow, have less mixing as the air flows through the cell, giving them a theoretical advantage of a factor of 2.78 compared to multi-pass sample cells. The TDLAS-TE τ_e was within 15 % of this theoretical $\tau_{e,t}$, indicating near ideal performance in the sample cell and sampling system. The EC155 τ_e was a factor of 2 larger than the theoretical $\tau_{e,t}$. This is likely due to mixing in the sample cell, which has a length/diameter ratio of 15, compared to 110 for the TDLAS-TE. TDLAS-LN has a diameter/length ratio of 75, suggesting its performance should also approach the ideal. However, the TDLAS-LN τ_e was 40 % greater than $\tau_{e,t}$, compared to 15 % for TDLAS-TE. This additional frequency-response degradation was most likely caused by attenuation in the multi-tube dryer. Ratios of $\tau_e / \tau_{e,t}$ from similar analyzers operating without driers (Table 2) were comparable to those of the TDLAS-LN and TDLAS-TE systems, although not directly as spectral calculations of τ_e were used in that study.

Operating the N_2O systems with driers prevented uncertainties from spectroscopic and density corrections. Improper

application of the WPL (Webb–Pearman–Leuning) corrections, as well as variations in flux processing steps, can affect flux values (Aubinet et al., 2012; Mammarella et al., 2016). For fluxes close to zero, WPL corrections for fluctuations in water vapour can be greater than the value of the scalar flux, and uncertainty of the correction can be of similar magnitude to the small fluxes (Detto et al., 2011). Line broadening caused by moisture in the sample can also cause significant errors in $F_{\text{N}_2\text{O}}$ (Neftel et al., 2010).

Lag times can be difficult to determine using cross-correlation methods on data with weak signals, which is often the case for N_2O (Pihlatie et al., 2005; Neftel et al., 2010). Inaccurate lag times can lead to underestimations of flux values. The t_{del} from the impulse response tests corresponded well with the t_l obtained for CO_2 using the cross-correlation method. The t_{del} measured with the impulse response method reduced uncertainty in the N_2O lag times used in the flux processing in the absence of a CO_2 signal. This approach is useful for long-term studies measuring agricultural N_2O fluxes when signals are too weak for automatic covariance maximization and when variations in operating conditions preclude the use of a constant lag value. Tube delay of the TDLAS-TE (0.6 s at 35 mb) was lower than that of the TDLAS-LN (0.8 s at 58 mb), showing the improved transit time of the upgraded intake system. These values were comparable to tube delay values of analyzers operated without driers (Rannik et al., 2015), showing how the TDLAS systems used here (with driers) could be optimized for fast response, while also avoiding corrections associated with lack of air drying.

5 Conclusions

The field trial of the new TDLAS-TE analyzer with the optimized sampling system consisting of a vortex intake, single-tube drier, and lower-power pump demonstrated the ability of this analyzer to operate continuously through several field seasons with minimal maintenance with the frequency response needed for EC measurements. The frequency response was comparable to that of a short-tubed CO_2 EC system and was better than published reports of N_2O EC systems operating without driers.

The legacy TDLAS-LN analyzer presented a lower cutoff frequency and higher tube delay than the TDLAS-TE and EC155 but showed improvement over previous reports due to the use of a shorter intake tube and a lower volume filter holder. The 30 min F_{CO_2} and $F_{\text{N}_2\text{O}}$ values measured by the TDLAS systems compared well; F_{CO_2} values measured by these systems were also comparable with the EC155.

More studies of long-term, multi-season N_2O fluxes are needed to improve global estimates of agricultural N_2O emissions (Reay et al., 2012; Wagner-Riddle et al., 2017). The optimal performance combined with its lower power and low maintenance requirements make the TDLAS-TE suitable

for N₂O flux measurements under rugged field conditions in remote or rural areas where power quality can be a concern.

Data availability. Any persons requiring the dataset can request it by contacting the authors.

The Supplement related to this article is available online at <https://doi.org/10.5194/amt-11-1583-2018-supplement>.

Competing interests. Steve Sargent is employed by Campbell Scientific Inc., the manufacturer of several instruments mentioned in this study.

Acknowledgements. This work was funded by the Natural Science and Engineering Research Council of Canada and Fertilizer Canada. Technical support was provided by Sean Jordan.
