Abstract. Due to technical and cost limitations, the monitoring of emissions from ships sailing in open water within ship emission control areas (ECAs) is relatively rare. The present study adopts a monitoring method involving an unmanned aerial vehicle (UAV) that takes off from a patrol boat to measure the concentrations of SO$_2$ and CO$_2$ within the plumes of sailing ships. Our method aims to provide a low-cost, remote approach for estimating the fuel sulfur content (FSC) of sailing ships in open water, which overcomes the limitations of ground-based and small-aircraft-based methods. The selected monitoring area was the Yangtze River estuary, a domestic ECA with an FSC limit of 0.5 % (m/m) implemented by the Chinese government. A total of 27 sailing ships were monitored, 12 of which were found to have an FSC of >0.5 % (m/m). Moreover, the FSCs of the sailing ships were found to be higher than those of berthing ships in the study area. Based upon the online monitoring results, four of the monitored ships were intercepted by maritime law enforcement, and fuel samples were collected and analyzed in a laboratory; the results confirmed that all four FSCs were >0.5 % (m/m). Among them, one offending ship was tracked down on 15 July 2019; this was the first time that a sailing ship had been caught for having failed the FSC regulations in China. Overall, the present study provides scientific support for evaluating the effectiveness of ECA policies and recommends that emissions from sailing ships be monitored more often in open water in the future.

1 Introduction

With the rapid development of the shipping industry (UNCTAD, 2017) over the past few decades, air pollution caused by ship emissions has received an increasing amount of attention (Eyring et al., 2010; Wan et al., 2016). The pollutant gases emitted by ships not only affect the global climate (Huiebert, 1999; Corbett, 2016), but also impact local air quality and human health (Yang et al., 2016; Wang et al., 2019). Shipping accounted for 15 %, 13 %, and 3 % of the annual global anthropogenic emissions of NO$_x$, SO$_x$, and CO$_2$ from 2007 to 2012, respectively (Smith et al., 2015). In Europe, estimated ship emissions were responsible for $3.0 \times 10^6$ t of NO$_x$, $1.2 \times 10^6$ t of SO$_x$, and $0.2 \times 10^6$ t of fine particulate matter (PM$_{2.5}$) in 2011 (Jalkanen et al., 2016). In East Asia, shipping emissions accounted for 16 % of global shipping CO$_2$ in 2013, whereas they only accounted for 4 %–7 % during the period from 2002 to 2005 (Liu et al., 2016).

To reduce the negative impacts of ship emissions, the International Maritime Organization (IMO) regulates emissions through the International Convention for the Prevention of Pollution from Ships and its Annex VI (MARPOL, 1997). The air pollution limits for shipping were adopted in 1997, but they only came into force in 2005. The global cap for the fuel sulfur content (FSC) of seagoing ships was set at 3.5 % (m/m) in 2012 and was reduced to 0.5 % (m/m) in 2020. To date, four emission control areas (ECAs), the Baltic Sea, the North Sea, the United States Caribbean, and the North Amer-
ican and United States Caribbean Sea, have been set up, and the corresponding FSC limit for seagoing ships in these areas was set at 0.1 % (m/m) in 2015 (IMO, 2017).

The IMO has not yet set up ECAs in East Asia, which is a region that is home to the world’s 10 largest container ports, including Shanghai, Ningbo-Zhoushan, and Shenzhen ports. To limit the air pollution caused by ship emissions, the Chinese government established three domestic emission control areas (DECAs) in 2015: the Yangtze River Delta, the Pearl River Delta, and the Bohai Sea. The DECAs have been expanded to cover a wider area since 2020 and now include most of the coastal ports, the Yangtze River main line, and the Xijiang River main line. The FSC limit for sailing and berthing ships in the DECAs has been set at 0.5 % (m/m) since 1 January 2019.

A key problem regarding the implementation of the policy of the ECAs is the question of how to enforce the FSC of ships. Several studies have suggested estimating the FSC by measuring ship plumes (Berg et al., 2012; Balzani Lööv et al., 2014). At present, the main method to monitor the emissions of surrounding ships is to place monitoring equipment either on the wharf, shore, port area, or bridge (i.e., ground-based methods) (Alföldy et al., 2013; Pirjola et al., 2014; Beecken et al., 2015; Kattner et al., 2015; Mellqvist et al., 2017a; Cheng et al., 2019; Zhang et al., 2019). Although ground-based methods can provide continuous monitoring, the results obtained depend on the wind speed, wind direction, and the position of a ship relative to the monitoring equipment. Additionally, the boundaries of the ECAs that are designated by the IMO are 200 nautical miles from the coast (Viana et al., 2015); hence, ground-based methods are not able to monitor the fuel that is used on the open sea in ECAs because sailing ships are too far from the shore or bridges.

Therefore, some researchers have used sensors that are carried by small aircraft to monitor navigating ships within ECAs (Berg et al., 2012; Beecken et al., 2014). However, as this kind of monitoring method is costly, the monitoring of navigating ships is relatively rare. Beecken et al. (2015) observed 434 plumes using ground-based measurements and 32 plumes from a helicopter. Balzani Lööv et al. (2014) took 475 measurements using “sniffing” instruments from ground-based measurements, whereas only 25 measurements were obtained using this method from mobile platforms. In the study undertaken by Mellqvist et al. (2017b), 114 individual ships were measured effectively during 27 flight hours at a cost of approximately EUR 470 per ship, although this amount only included the aircraft cost and did not consider the ferry, operator, or instrument rental costs. Therefore, the high cost of flying precludes extensive monitoring of ship emissions.

As a result of the aforementioned factors, there is less monitoring of ships on the open water in ECAs. This is despite the fact that numerous studies (Pirjola et al., 2014; Kattner et al., 2015; Zhang et al., 2019) have shown that the FSC of ships has been significantly reduced by the implementation of the ECA policy. However, most of these studies did not involve the monitoring of ships on the open water, which could lead to nonrepresentative assessments regarding the implementation of policies. At the same time, the lack of open-sea monitoring results in a blind area for maritime enforcement and is not conducive to the implementation of ship ECA policy by maritime authority. The present study used an unmanned aerial vehicle (UAV) to monitor the FSC of sailing ships on the open sea in the Yangtze River estuary DECA. The method proposed in this study can be used to monitor ship emissions at a comparatively low cost in order to understand the FSCs of sailing ships in open waters. Although the cost of using patrol boats is not negligible, it is more convenient and cheaper for maritime authorities than using small aircraft.

2 Experimental methods

The research undertaken in the present study forms part of the “Monitoring and inspecting ship exhaust emissions in the Shanghai free-trade zone” (MISEE) project. In this project, a UAV system was designed and developed which mainly included a pod for measuring the exhaust gas from ships and a UAV to carry the pod. In previous research (Zhou et al., 2019), the plumes of 23 berthing ships were measured using the first-generation pod, and the deviation of the estimated FSC was < 0.03 % (m/m) for an FSC of between 0.035 % (m/m) and 0.24 % (m/m).

In the present monitoring for sailing ships, we developed the second-generation pod by optimizing the structure and layout of the first-generation pod to achieve a lighter weight and smaller volume. A short overview of the instrumentation is provided in Sect. 2.1. We measured the plumes of 11 berthing ships to verify the accuracy of the second-generation pod, and we measured the plumes of 27 sailing ships to estimate the FSC.

2.1 Instrumentation

The instrumentation that was used for measuring the FSC of sailing ships is shown in Fig. 1. The UAV was a MATRICE 600 PRO (SZ DJI Technology Co., Ltd., Shenzhen, China). This type of UAV cannot be used on rainy days or when the wind speed is higher than 8 m s⁻¹. The white box installed underneath the UAV in Fig. 1 is the aforementioned second-generation pod for measuring exhaust gas. When the UAV approaches a ship’s plume, the gas pump in the pod draws air using the gas probe. The water vapor, particles, and the soot in the gas are subsequently removed by a hose filter valve. The sensors detect the gas, and measurement information is sent out by communication modules. The pod has dimensions of 20 cm × 12 cm × 9 cm and weighs 900 g.

The sensors used were able to measure both SO₂ and CO₂ and were purchased from Shenzhen Singoan Electronic
Figure 1. Image of the UAV system. A gas probe, camera, and pod are installed under the unmanned aerial vehicle (UAV). The gas probe is used to collect the ship’s exhaust gas, and the camera is used to assist in finding the ship’s funnel mouth during flight. The pod is used to carry a gas pump, gas circuit, filter, small motor, sensors for \( \text{SO}_2 \) and \( \text{CO}_2 \), and communication modules.

Technology Co., Ltd., China. The \( \text{SO}_2 \) sensor is based on the electrochemical method and has a measuring range of 0–10 ppm, an accuracy of \( \pm 3\% \) (0.3 ppm), and a response time \( (T_{90}) \) of \( \leq 30 \text{ s} \). The \( \text{CO}_2 \) sensor is based on the nondispersive infrared analyzer method and has a measuring range of 0–10,000 ppm, an accuracy of \( \pm 3\% \) (300 ppm), and a \( T_{90} \) of \( \leq 30 \text{ s} \). The \( T_{90} \) represents the time taken to reach 90% of the stable response following a full range change in the sample concentration. These sensor characteristics were provided by the instrument manufacturer and were ensured to be within the tolerances by calibration. The zero and full scales are usually calibrated by a standard mixed gas when the equipment is used on a daily basis. The major parameters of the UAV system are listed in Table 1.

2.2 Monitoring region

As illustrated in Fig. 2, the monitoring region was the channel of the Yangtze River estuary, near the Waigaoqiao port area to the north of Shanghai. The Yangtze River is the longest river in China and the third-longest river in the world. Shanghai is one of the most prosperous cities in the world and had a permanent resident population of approximately 24 million people at the end of 2017 (Shanghai Municipal Bureau of Statistics, 2017). The Waigaoqiao port area is only 20 km from the city center, and the air pollution caused by ship emissions directly affects the urban air environment and the health of residents (Wang et al., 2019; Feng et al., 2019). The experimental area of the MISEE project is mainly within the Waigaoqiao port and the Yangtze River estuary.

Figure 2. Monitoring regions in the channel of Yangtze River estuary, which belong to the Chinese domestic emission control areas (DECAs). This area is to the north of Shanghai, on the southwest side of Changxing Island. The distance between the two sides is \( \sim 6–7 \text{ km} \). Ships leave the Yangtze River and sail into the East China Sea through this channel. Map data: © MapWorld (http://www.tianditu.gov.cn, last access: 5 March 2020).

2.3 Measurement method

During the experiment, the operator took a patrol boat to the channel and selected a target ship at random. After identifying the target ship for monitoring, the patrol boat would accelerate to a few hundred meters to the left or right ahead of the vessel. The patrol boat would then stop and the UAV would take off from its deck and fly towards the plume of the target ship to measure the concentrations of \( \text{SO}_2 \) and \( \text{CO}_2 \) in the plume (Fig. 3).

During the measurements, the operator adjusted the position of the UAV to ensure that it was in the ship’s plume. Real-time measurements of \( \text{SO}_2 \) and \( \text{CO}_2 \) were made such...

that the pod could effectively detect the plume. Generally, it was necessary for the UAV to follow the ship’s funnel mouth for approximately 5 min, as illustrated in Fig. 4. The target ship continued to move during the measurements; hence, it was followed by the patrol boat in order to avoid the UAV moving too far away from the operator. When the operator was sure that valid data had been collected, the patrol boat stopped and the UAV returned and landed back on the deck.

2.4 Calculation

The FSC in this study was obtained directly by sampling the gas concentrations in the ship plumes using the UAV. The enhancements of SO₂ and CO₂ in measurements that were affected by exhaust gases were calculated, and the ratio of these SO₂ and CO₂ peaks was used to calculate the FSC (Eqs. 1, 2). This method has been widely used to calculate the FSC in related studies (Alföldy et al., 2013; Pirjola et al., 2014; Balzani Lööv et al., 2014; Beecken et al., 2014, 2015; Kattner et al., 2015; Zhou et al., 2019). In the calculation, the molecular weights of carbon and sulfur are 12 and 32, respectively.
32 g mol\(^{-1}\), respectively, and the carbon mass percent in the fuel is 87 ± 1.5 % (Cooper et al., 2003). By assuming that 100% of the carbon content of the fuel is emitted as CO\(_2\) and sulfur is emitted as SO\(_2\) and other forms, the FSC mass percent can be determined using Eq. (1):

\[
\text{FSC}[^\%] = \frac{5 \text{[kg]}}{\text{fuel [kg]}} = \frac{\text{SO}_2 \text{[ppm]} \cdot A(S)}{\text{CO}_2 \text{[ppm]} \cdot A(C)} \cdot 87[^\%] + R
\]

\[
= 0.232 \frac{\int (\text{SO}_2\text{peak} - \text{SO}_2\text{bkg}) \, d[ppb]}{\int (\text{CO}_2\text{peak} - \text{CO}_2\text{bkg}) \, d[ppm]} \, [%] + R
\]

\[
= \frac{1}{20} \text{EF} \left(\text{SO}_2 \text{kg}_{\text{fuel}}^{-1}\right) + R,
\]

where \(R\) represents the sulfur content that is emitted in forms other than SO\(_2\), as preliminary studies have shown that 1–19% of the sulfur in fuel is emitted in other forms, possibly SO\(_3\) or SO\(_4\) (Schlager et al., 2006; Alföldy et al., 2013; Balzani Lööv et al., 2014). EF is the emission factor, and bkg represents background. In Eq. (1), if the sensors measuring SO\(_2\) and CO\(_2\) have approximately the same response time and can be set to be synchronized, the peak concentrations of SO\(_2\) and CO\(_2\) can be used to calculate the FSC; otherwise, integrals need to be used. In our research, the sampling rates of the SO\(_2\) and CO\(_2\) sensors were 1 s, and integrals were used because the two sensors could not be completely synchronized.

The continuous measurement data for two typical plumes (2019-4-15B and 2019-3-29A) are exhibited in Fig. 5. The data for plume 2019-4-15B (Fig. 5a) were considered to be “good” quality, whereas those for plume 2019-3-29A (Fig. 5c) were considered to be “poor” quality. Data were determined to be good quality when obvious, easily distinguished peak values were observed, whereas less obvious peaks that still corresponded to a result were considered to be poor-quality data. Meanwhile, the correlation between the SO\(_2\) and CO\(_2\) time series is a key factor in judging quality. Assuming that the gas is completely mixed, the variation trend of the SO\(_2\) and CO\(_2\) measurements should be the same (although there may be some deviation because the corresponding time of the sensors was not consistent) and can be identified in the peak area.

The selection of peak values leads to uncertainty because when the area ratio is selected for the calculation, the starting and ending time points of the area are still associated with substantial uncertainty. Figure 5b and d depict the average concentrations of the SO\(_2\) and CO\(_2\) measurements (from Fig. 5a and c, respectively) for 10 s periods. The peak value of each average concentration was selected for the calculation. This process is equivalent to selecting the area ratio of SO\(_2\) to CO\(_2\) within 10 s for the calculation, as shown in Eq. (2).

\[
\text{FSC}[^\%] = 0.232 \frac{\int (\text{SO}_2\text{peak} - \text{SO}_2\text{bkg}) \, d[ppb]}{\int (\text{CO}_2\text{peak} - \text{CO}_2\text{bkg}) \, d[ppm]} \, [%] + R
\]

\[
\approx 0.232 \frac{\text{AVG}(\text{SO}_2\text{peak}) - \text{AVG}(\text{SO}_2\text{bkg})}{\text{AVG}(\text{CO}_2\text{peak}) - \text{AVG}(\text{CO}_2\text{bkg})} [%], \quad (2)
\]

where \(\text{AVG}(\cdot)\) is the calculated function for the average measurement value within 10 s; hence, the data in this study are the average values of measurements in 10 s. When the UAV took off from the patrol boat and flew high into the air, the SO\(_2\) and CO\(_2\) concentrations were relatively low. The background values were obtained at this stage as the minimum SO\(_2\) and CO\(_2\) concentrations. As the UAV flew into the plume, the measured concentrations of SO\(_2\) and CO\(_2\) increased. The obvious, stable maximum values in the observations of the average measurement values should be selected as the peak values. It can be seen that using the average values of measurements within 10 s makes it easier to select the peak values, especially with respect to poor-quality data. However, as there can still be several options for peak values, the data treatment methods reported by Zhou et al. (2019) were incorporated in this study to select the most appropriate peak values. In Fig. 5b, the time point of selected peak values is at 10:19:11 LT (local time). The measurement values from 10:19:57 to 10:20:15 LT were not used because the CO\(_2\) concentration covered the full range. In Fig. 5d, the time point of the selected peak values is at 10:38:27 LT. The measurement values from 10:39:57 to 10:41:41 LT were not used because we excluded data exhibiting either dramatic changes or errors in continuous observations. The details for selecting the peak values are given in Table 2.

### 2.5 Uncertainties

In previous research (Zhou et al., 2019), the main uncertainties of UAV measurements were summarized as sensor uncertainty, measurement uncertainty, calculation uncertainty, and exhaust uncertainty. The instrument calibration method, UAV flight procedures, and the data treatment methods were designed to reduce these uncertainties. However, some uncertainties remain, as discussed below.

To make the UAV lightweight and convenient, the second-generation pod was only equipped with SO\(_2\) and CO\(_2\) sensors and a simple filter. We did not account for the interference that some factors might have caused, including interference due to (1) the cross-sensitivity of the SO\(_2\) sensor to NO\(_2\), (2) the impact of a large temperature change in the exhaust plume, and (3) water vapor and/or particle contamination of the instruments.

The average gas concentration within 10 s was chosen for the FSC calculations; however, this does not mean that 9 or 11 s could not have been selected. To demonstrate this, a comparison calculation was carried out using both 9 and 11 s, which showed that these led to very little difference in
Figure 5. Typical measurement data for SO$_2$ and CO$_2$ concentrations, and their corresponding average values within 10 s. (a, b) Good-quality data from plume 2019-4-15B. (c, d) Poor-quality data from plume 2019-3-29A. There are some errors in the measurements from 10:11:06 to 10:12:02 LT in panel (a), which may have been caused by sensor uncertainty. These data were excluded and did not affect the calculation results. After selection, the peak values are circled in purple.

Nevertheless, it is necessary to ensure that the gradient of the gas measurements is stable within the sampling time (the interval length of the integral). Moreover, the interval length cannot be too short (e.g., 2 s) or too long (e.g., 20 s). If the interval length is too short, it is difficult to determine whether the measurements are stable and undisturbed over time. Similarly, if the interval length is too long, it is also difficult to ensure that all of the measurements in the integral interval are stable and undisturbed. In addition, during the flight of the UAV in this study, the time available for measuring the plume was $\sim$ 5 min. As both the ship and the UAV were moving at this time, it was virtually impossible to ensure that the UAV was flying consistently within the plume and obtaining stable measurements. Accordingly, 10 s is also a relatively appropriate value for the measurement process.

Nevertheless, there is also some uncertainty associated with choosing the peak values. After ruling out the peak values across the full range as well as those corresponding to dramatic changes, the global maximum values were selected as the peak values to calculate the FSC. The maximum values probably correspond to the measurements taken in the center of the ship’s plume. At that location, the measurement values were relatively stable, and the probability of interference from other factors was lower. Furthermore, the higher the peak value is, the greater the proportion of exhaust gas is; hence, the impact from the incomplete mixing of the exhaust gas with clean air is relatively small.

In summary, the obvious and stable maximum values are selected as peak values to calculate the FSC. There are, of course, situations where multiple similar peaks can occur simultaneously. In this case, their calculated FSCs may be very
Table 2. All peak values and their corresponding FSC results. The background values of plume 2019-4-15B were 0 ppm and 310 ppm for SO\textsubscript{2} and CO\textsubscript{2}, respectively. The background values of plume 2019-3-29A were 0 and 329 ppm for SO\textsubscript{2} and CO\textsubscript{2}, respectively. The remarks indicate the reason for choosing or not choosing the peak. It can be seen that the peak value of plume 2019-4-15B was more obvious and that the results obtained by multiple alternative peaks were similar. The peak of plume 2019-3-29A was less obvious and there were fewer alternative peaks. This was also the basis for distinguishing data as being good or poor quality. The FSC result of selected peak values are marked as “√”. As the sensor response time was inconsistent, only the SO\textsubscript{2} peak time points are listed (the CO\textsubscript{2} peak time points had a delay of several seconds).

The deviation of the estimated FSC value obtained by the first-generation pod was < 0.035 % (m/m) for an FSC level ranging from 0.035 % (m/m) to 0.24 % (m/m) (Zhou et al., 2019). The second-generation pod was also verified on berthing ships by using this method at a similar FSC level, and the accuracy was approximately the same (see Sect. 3.1). These verifications of the deviation were based on the FSC measurement of berthing ships, which did not exceed the Chinese DECA FSC limit of 0.5 % (m/m). However, some of the sailing ships did exceed this limit. It should be noted that the deviations for different FSC levels were not the same. Based on previous studies, the deviation of the FSC obtained from high-sulfur plume should be greater; for example, Van Roy and Scheldeman (2016a, b) estimated relative uncer-
3 Results

3.1 Berthing ships

Before monitoring the sailing ships, we first monitored 11 berthing ships between March and April 2019 in the Waigaoqiao port to verify the accuracy of the second-generation pod. While one person operated the UAV to monitor one of the plumes, two maritime law enforcement officers boarded the corresponding ship to collect a fuel sample. Both processes took approximately 10–20 min. The fuel samples, which are considered to represent the true FSC values, were then sent for chemical analysis in a laboratory. The estimated (UAV) and true FSC values are listed in Table 3 along with the identification number of each plume and the time and serial number. Table 3 shows that the deviation generally did not exceed 0.03 % (m/m) for an FSC level of between 0.03 % (m/m) and 0.22 % (m/m), except for plumes 2019-3-22A and 2019-3-3B. Additionally, when the FSC of a target ship was low, for example, when light diesel fuel was used, the measured \(\text{SO}_2\) concentrations were mostly zero. When this occurred, the FSC was generally < 0.02 % (m/m), as seen for plumes 2019-4-3A and 2019-4-12A.

### Table 3. Comparison and verification of the estimated (UAV) and true (sampled fuel) values of the FSC from 11 berthing ships. “N” means the deviation has no a specific value, but it is less than 0.020 % (m/m).

3.2 Sailing ships and comparison with berthing ships

Between March and December 2019, effective monitoring of 27 sailing ships was undertaken using the UAV that took off from the patrol boat (Table 4). The FSC of 23 berthing ships measured by the first-generation monitoring equipment and the FSC of 11 berthing ships (Table 3) measured by the second-generation monitoring equipment in this study were taken as the FSC monitoring results for berthing ships. We compared the distribution of the FSCs of these 34 berthing ships with those of the 27 sailing ships. Figure 6 shows that the FSCs of the sailing ships were considerably higher than those of the berthing ships; the FSC of all 27 sailing ships exceeded 0.1 % (m/m), and the FSC of 12 of these ships exceeded the Chinese DECA FCS limit of 0.5 % (m/m), which included five exceedances of 1.5 % (m/m). The uncertainty in the assessment is not small; however, the results thus far do not lead to optimism with respect to the FSC used by ships sailing in the area. The reason for this is that although berthing ships are sometimes boarded by maritime law enforcement officers for examination, an effective approach for monitoring the FSC of sailing ships in open water that led to prosecution by China’s maritime authorities did not existed prior to the present study.

According to the monitoring results, law enforcement officers of the Pudong Maritime Safety Administration intercepted four sailing ships for which the UAV FSC results were of a good quality and exceeded 1.5 % (m/m). The officers boarded these ships for inspection on 15 July, 14 August, 20 August, and 27 September 2019, respectively, and took fuel samples, which were sent for chemical analysis in a laboratory. The FSC of all four respective fuels was also found to exceed 0.5 % (m/m); 0.534 % (m/m), 0.744 % (m/m), 0.813 % (m/m), and 1.991 % (m/m) (in chronological order). The reason that three of these laboratory results did not exceed 1.5 % (m/m) was related to the fact that ships cannot stop immediately in the channel for inspection and have to sail to the anchorage point; when the officers boarded the ships to take samples they found the crew taking various measures to drain the high-sulfur fuel in the main engine fuel oil pipeline. This means that the chemical analysis results of the sampled fuels were obviously lower than those of the UAV monitoring. Nevertheless, the four inspections success-
**Table 4.** Estimated (UAV) values of the FSC from 27 sailing ships. “∗” indicates that the ship was boarded by the maritime authority for inspection, and the value in parentheses is the result of the chemical examination of the fuel.

**Figure 6.** Comparison between the monitoring results of berthing ships and sailing ships.

fully confirmed that the FSC of the fuels exceeded the standard for sailing ships. The inspection on 15 July 2019 was the first time that a sailing ship’s FSC failed to meet Chinese regulations, and this aroused wide concern in the shipping community.

### 4 Conclusions

In this research, we used a UAV that took off from a patrol boat to monitor emissions from sailing ships in open water. Of the 27 sailing ships that were successfully monitored, 12 were found to have an FSC that exceeded 0.5 % (m/m) and 5 exceeded 1.5 % (m/m). Based on the monitoring results, law enforcement officers of the Pudong Maritime Safety Administration caught the first case of excessive FSC for a sailing ship and confirmed three other cases. Additionally, the UAV monitoring results demonstrated that the FSC values of sailing ships in the waters surrounding Waigaoqiao port were higher than those determined for berthing ships in the port. While the sample size was relatively small, Fig. 6 suggests that the data are still convincing.

Although a global cap on the FSC in marine fuel was set at 3.5 % (m/m) in 2012 following the IMO regulation, this was reduced to 0.5 % (m/m) in 2020 and has already been implemented in China. According to our monitoring results, the current situation for meeting the 0.5 % (m/m) limit is not optimistic. Successful compliance with this regulation by ship

Atmos. Meas. Tech., 13, 4899–4909, 2020
owners involves many challenges. We conclude that there is a need for further monitoring data on sailing ships in open water to ascertain the degree of exceedance and work toward compliance.

In addition, there are still some improvements to be made to the UAV system. Currently, 4G transmission is the communication method for detecting information transmission; hence, in locations without a 4G signal (e.g., offshore), the receiving equipment cannot obtain real-time measurement results. Potential solutions include setting up smallbase stations on patrol boats or using satellite transmission. Although carrying an infrared camera on the UAV would make it easier to find the plume, this would require replacing the camera in Fig. 1 with an infrared camera and establishing new data communication.
