**Abstract.** We measured the column-averaged atmospheric CO<sub>2</sub> mixing ratio (XCO<sub>2</sub>) to a variety of cloud tops with an airborne pulsed multi-wavelength integrated path differential absorption (IPDA) lidar during NASA's 2017 ASCENDS/ABoVE airborne campaign. Measurements of height-resolved atmospheric backscatter profiles allow this lidar to retrieve XCO<sub>2</sub> to cloud tops, as well as to the ground, with accurate knowledge of the photon path length. We validated these measurements with those from an onboard in situ CO<sub>2</sub> sensor during spiral-down maneuvers. These lidar measurements were 2–3 times better than those from previous airborne campaigns due to our using a wavelength step-locked laser transmitter and a high-efficiency detector for this campaign. Precisions of 0.6 parts per million (ppm) were achieved for 10 s average measurements to mid-level clouds and 0.9 ppm to low-level clouds at the top of the planetary boundary layer. This study demonstrates the lidar's capability to fill in XCO<sub>2</sub> measurement gaps in cloudy regions and to help resolve the vertical and horizontal distributions of atmospheric CO<sub>2</sub>. Future airborne campaigns and spaceborne missions with this capability can be used to improve atmospheric transport modeling, flux estimation and carbon data assimilation.

## 1 Introduction

Atmospheric carbon dioxide (CO<sub>2</sub>) is a long-lived greenhouse gas that is widely transported. Globally distributed atmospheric CO<sub>2</sub> concentration measurements with high pre-

cision, low bias, and full seasonal sampling are essential to advance carbon cycle sciences and to assess carbon-climate changes (Schimel et al., 2016). However, about two-thirds of the Earth's surface is usually covered by clouds. High-quality retrievals of column-averaged atmospheric CO<sub>2</sub> mixing ratio (XCO<sub>2</sub>) can only be attained from passive remote sensing measurements of CO<sub>2</sub> from space for clear-sky scenes without significant aerosol loading, where the path length of the Earth's surface reflected sunlight is accurately known. Hence passive measurements of XCO<sub>2</sub> are significantly limited in terms of spatial coverage and seasonal sampling, which may cause large uncertainty in regional and hemispheric carbon flux estimates (Chevallier et al. 2014; Reuter et al., 2014; Feng et al., 2009, 2016, 2017). New observations to fill these gaps can be used to improve carbon balance estimates (Palmer et al., 2019; Vekuri et al., 2023).

The NASA Goddard Space Flight Center developed the CO<sub>2</sub> Sounder, an airborne pulsed, integrated-path differential absorption (IPDA) lidar to measure XCO<sub>2</sub>, as a candidate for NASA's planned Active Sensing of CO<sub>2</sub> Emissions over Nights, Days, and Seasons (ASCENDS) orbital mission (Abshire et al., 2010; Kawa et al., 2010, 2018). Concurrent measurements of height-resolved atmospheric backscatter profiles allow this lidar technique to estimate XCO<sub>2</sub> and range to cloud tops in addition to those to the ground, with precise knowledge of the photon path length even in dense, broken and sometimes multi-layered atmospheric clouds (Ramanathan et al., 2015; Mao et al., 2018, 2021a). This is a major advantage of this lidar approach over passive ones for measuring greenhouse gases when the elevation of the re-

flecting surface is uncertain (e.g., due to rough terrain or tall trees) and when the atmosphere has significant optical scattering (Mao and Kawa, 2004; Aben et al., 2007).

The airborne version of our IPDA lidar has been flown on the NASA DC-8 aircraft five times since 2011 over a variety of sites in the US and Canada to demonstrate instrument measurement capabilities and for regional science campaigns (Abshire et al., 2013, 2014 and 2018). We previously demonstrated its capability to measure XCO<sub>2</sub> to cloud tops and the partial column XCO<sub>2</sub> between the ground and cloud tops by using a cloud-slicing approach with data from the 2011, 2013 and 2014 airborne campaigns over the western and Midwest regions of the US (Ramanathan et al., 2015; Mao et al., 2018). In 2014, we replaced the lidar's wavelength-swept seed laser source with a rapidly tunable step-locked seed laser (Numata et al., 2012). In 2016, we replaced the photomultiplier-based photon-counting receiver with a much more sensitive HgCdTe avalanche photodiode (APD)-based receiver (Sun et al., 2017). These updates substantially improved the lidar's dynamic range, stability and signal-to-noise ratio, reduced the measurement bias and increased precision (Abshire et al., 2018). This paper describes the lidar XCO<sub>2</sub> measurements made to cloud tops during the summer 2017 ASCENDS/ABOVE (Arctic Boreal Vulnerability Experiment) campaign using the most recent instrument configuration (Mao et al., 2019, 2021b). Most flights were based at Fairbanks, Alaska. The lidar's XCO<sub>2</sub> measurements are validated against those from onboard in situ sensors during spiral-down maneuvers that were made nearby.

## 2 Lidar measurements of XCO<sub>2</sub>

The airborne CO<sub>2</sub> Sounder lidar deployed in the 2017 airborne campaign used a tunable narrow-line-width laser to measure CO<sub>2</sub> absorption at 30 wavelengths distributed across the vibration–rotation line of CO<sub>2</sub> centered at 1572.335 nm. The parameters of the airborne CO<sub>2</sub> lidar for the 2017 flights are the same as those for the 2016 flights and have been summarized in previous publications (Abshire et al., 2018; Sun et al., 2021). Briefly, the laser emits 1 μs wide rectangular pulses at a rate of 10 kHz. The laser scans across the CO<sub>2</sub> line with 30 wavelengths at a 300 Hz rate. The laser wavelengths were offset-locked to the center of this CO<sub>2</sub> absorption line by using a reference gas cell at a pressure of 40 hPa and a temperature of 296 K (Numata et al., 2011 and 2012). The laser wavelength step size varied from 250 MHz near the line center to 2.75 GHz on the wing, which allowed for well-distributed samples across the line. The laser line width is approximately 30 MHz or 0.001 cm<sup>-1</sup>. The laser's spectral resolution is considerably higher than that of passive measurements, for example, GOSAT/GOSAT-2 (~0.2 cm<sup>-1</sup>; Kuze et al., 2009), OCO-2/OCO-3 (~0.3 cm<sup>-1</sup>; Crisp et al., 2004) and the ground-based Fourier transform spectrometers of the Total Carbon Column Observing Network (~0.02 cm<sup>-1</sup>;

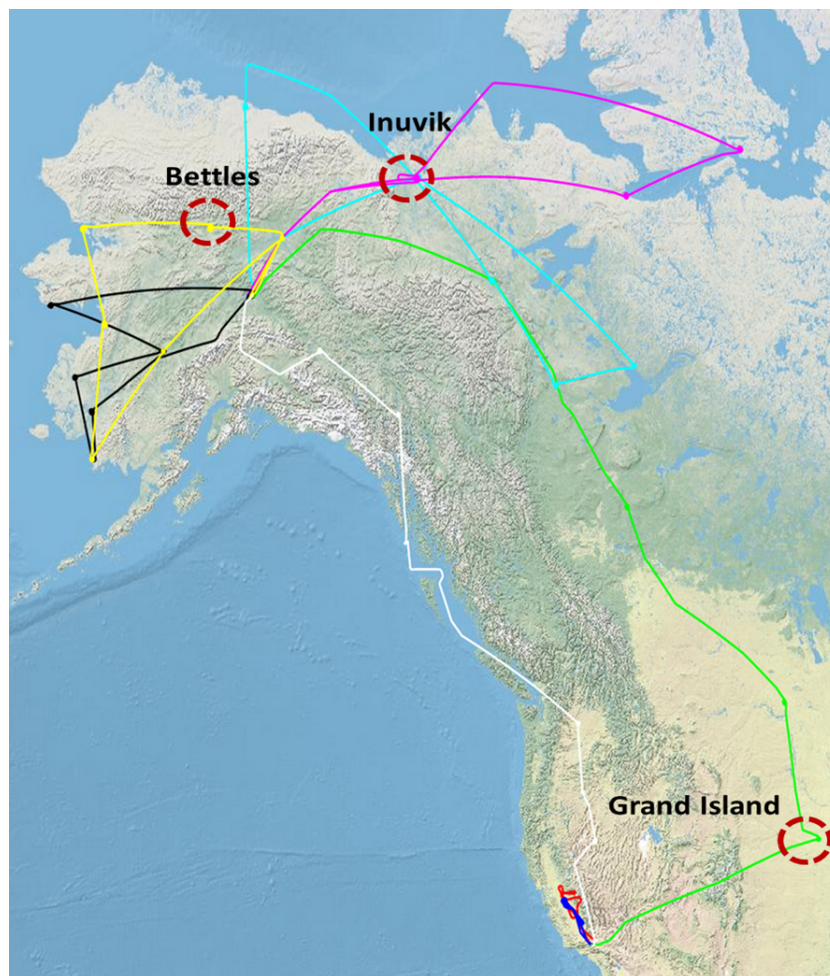

Wunch et al., 2011). The narrow laser line width allows the measured CO<sub>2</sub> line shape to be fully resolved, including the line width and the center wavelength (Ramanathan et al., 2013). The lidar's XCO<sub>2</sub> retrievals have sub-ppm sensitivity to CO<sub>2</sub> change in the measurement column and are independent of a priori CO<sub>2</sub> information, e.g., vertical distribution of CO<sub>2</sub> (Ramanathan et al., 2018).

The laser photons backscattered from the atmosphere and ground are collected by a 20 cm receiver telescope, pass through a narrow (~1 nm) band-pass filter, and then are focused onto the lidar's HgCdTe detector. The electrical bandwidth of the receiver is 8 MHz, and the receiver digitizer has a sampling period of 10 ns, providing accurate measurements of photon path lengths. Previous campaigns showed range measurements to better than 0.25 m to flat surfaces over a horizontal path from the laboratory and to better than 3 m to water surfaces on a near-nadir path from the aircraft (Amediek et al., 2013). To reduce the data volume, the backscatter profile data are re-sampled with 100 ns (15 m) bin width. The range-resolved backscatter profiles are computed from off-line laser wavelengths after averaging data over 1 s to improve the signal-to-noise ratio (SNR).

The lidar retrieval algorithm to estimate XCO<sub>2</sub> uses a weighted least-squares fit of the calculated CO<sub>2</sub> absorption line shape to the 30 wavelengths of the lidar measurement (Ramanathan et al., 2018; Sun et al., 2021). The fitting approach also allows the retrieval to simultaneously solve for Doppler frequency shift, surface reflectance at the off-line wavelengths and the non-uniformity in the lidar's spectral response, which minimizes potential biases. The high spectral resolution and high measurement sensitivity of this approach allow XCO<sub>2</sub> retrievals to be insensitive to a priori CO<sub>2</sub> information, e.g., vertical profile of CO<sub>2</sub>, and inversion constraints.

In the retrieval's forward calculations, the HITRAN 2008 spectroscopy database (Rothman et al., 2009) and the line-by-line radiative transfer model (Clough et al., 1992; Clough and Iacono, 1995) V12.1 were used to calculate CO<sub>2</sub> optical depth for a prior with a vertically uniform CO<sub>2</sub> concentration of 400 ppm. The retrieval algorithm calculates the best-fit XCO<sub>2</sub> by comparing the calculated absorption line shapes to the lidar sampled line shapes and by uniformly scaling the calculated line shape to minimize the fit error. Note that the averaging kernel in our retrieval is based on that defined in Borsdorff et al. (2014) for profile scaling-based retrieval, giving a measure of the sensitivity of the column scale factor to the XCO<sub>2</sub> in each layer. We used the averaging kernel for a uniform a priori CO<sub>2</sub> profile to compute the in situ XCO<sub>2</sub> with the in situ vertical profile of CO<sub>2</sub> to validate the lidar XCO<sub>2</sub> retrievals during spiral-down maneuvers.

For this campaign where the measurements were near a spiral-down location, the retrievals used the DC-8 aircraft housekeeping data for the vertical profiles of atmospheric pressure and temperature and water vapor profiles from an onboard engineering test version of the diode laser hygrom-

**Figure 1.** Map of flight ground tracks for the 2017 ASCENDS/ABOVE airborne science campaign with NASA DC-8 aircraft (© Google Maps 2019). The colors of the track indicate a total of eight flights from 20 July to 8 August. The three spiral maneuvers are marked with red circles for the three cases described in this study over Grand Island, Nebraska, on 27 July; Inuvik, Northwest Territories of Canada, on 3 August; and Bettles, Alaska, on 6 August.

eter (DLH; Diskin et al., 2002). When co-located radiosonde measurements were available within  $\pm 3$  h flight time, the radiosonde data of vertical profiles of atmospheric temperature, pressure and water vapor were used for forward calculations since a radiosonde provides the most accurate data about the vertical structure of the atmospheric state.

There is a weak isotopic water vapor (HDO) line centered at 1572.253 nm on the shoulder of the 1572.335 nm CO<sub>2</sub> line. Depending on atmospheric water vapor content, this can distort the CO<sub>2</sub> line shape and could significantly impact the value of the XCO<sub>2</sub> retrieval. Therefore, the real-time water vapor absorption was calculated and added to CO<sub>2</sub> absorption for the best absorption line shape fitting in the retrieval. The XCO<sub>2</sub> retrievals were primarily processed based on 1 s averaged lidar data. Since the DC-8 aircraft traveled horizontally at an average speed of 240 m s<sup>-1</sup>, this resulted in a horizontal resolution of 240 m along the ground track. When the

DC-8 aircraft was in a spiral-down maneuver, it descended at 7–8 m s<sup>-1</sup>.

### 3 The 2017 ASCENDS/ABOVE airborne campaign

During July and August 2017, NASA conducted the ASCENDS/ABOVE airborne campaign using the NASA DC-8 aircraft. The flights occurred between 20 July and 8 August 2017 over the ground tracks shown in Fig. 1. In all, eight flights were conducted over the Central Valley of California and over the US Midwest then moved to Fairbanks, AK, and over the Northwest Territories in Canada and over south and central Alaska (Mao et al., 2019, 2021b) before returning to California. This was the first time that airborne XCO<sub>2</sub> lidar measurements had been made over the Arctic region.

Compared to previous airborne campaigns, the 2017 airborne campaign was conducted in much more dynamic atmo-

**Figure 2.** Time series of the range-corrected attenuated backscatter profiles measured for the flight over the Rocky Mountains and spiral down over Grand Island, NE, on 27 July 2017. The measurements have 1 s time resolution and a vertical resolution of 15 m. The GPS flight altitudes are marked in a white line, and the ground elevation is shown in the red and yellow band. The lidar returns are averaged for off-line wavelengths or wave pulses nos. 2, 3, 4, 27, 28, 29 and 30 on the wings of the CO<sub>2</sub> absorption line. The strong returns from the ground and clouds are colored in yellow and red, while the lidar returns from aerosols and cirrus clouds are weaker and plotted in light blue.

sphere conditions over the Northwest Territories of Canada and over Alaska, and it overflow more clouds at multiple levels, as well as smoke plumes from wildfires. The CO<sub>2</sub> Sounder lidar continuously measured column absorption of CO<sub>2</sub> from the aircraft altitude to the ground and to cloud tops, along with height-resolved backscatter profiles (Sun et al., 2021).

During the campaign, a total of 47 vertical spiral-down maneuvers were conducted over a variety of atmospheres and surface types like desert, vegetation, permafrost, and the Arctic and Pacific Oceans. The purpose of these vertical spiral maneuvers was to compare the lidar XCO<sub>2</sub> retrievals with those computed from the onboard in situ CO<sub>2</sub> sensors.

The XCO<sub>2</sub> retrievals from the lidar measurements were validated against those computed from CO<sub>2</sub> vertical profiles measured in situ by the AVOCET sensor (Vay et al., 2011) during the spiral down maneuvers. AVOCET has a stated precision of  $\pm 0.1$  ppm ( $1\sigma$ ) and an accuracy of  $\pm 0.25$  ppm (Halliday et al., 2019). The DC-8 aircraft housekeeping data provided temperature, pressure, geolocation, and positioning such as altitude and pitch or roll angles at flight altitude. The aircraft radar altimeter also provided an independent range measurement to ground under all conditions since the radar measurement penetrates clouds and dense smoke plumes. Using the radar altimeter data with aircraft housekeeping data allows us to calculate the radar-measured surface elevation. This allows distinguishing of the cloud tops from ground or ocean surface in the processing and analysis of the lidar measurements.

**Figure 3.** Time series of XCO<sub>2</sub> retrievals from lidar measurements made surrounding the spiral at Grand Island, NE, on 27 July 2017 using 1 s averaging. The black dots are the retrievals from the lidar measurements to the ground, and the blue dots are those made to the tops of altocumulus clouds.

#### 4 Case studies

Three case studies with spiral-down maneuvers near cloudy regions were selected and analyzed for this study. These are the flight segments over Grand Island, Nebraska, on 27 July; Inuvik, Northwest Territories of Canada, on 3 August; and over Bettles, Alaska, on 6 August.

**Figure 4.** Comparison of cloud-free lidar XCO<sub>2</sub> retrievals to the ground with those from in situ measurements made during the spiral maneuver at Grand Island, NE, on 27 July 2017. These are computed as a function of flight altitude for averages in every 1 km vertical layer of atmosphere above 4 km. The XCO<sub>2</sub> computed from in situ values are marked with blue squares, and the values of the lidar XCO<sub>2</sub> retrievals are marked with red squares. The red error bars for the lidar XCO<sub>2</sub> retrievals are  $\pm 1$  standard deviation. One of the normalized vertical averaging kernels for the lidar XCO<sub>2</sub> retrievals for this profile segment is shown on the right. The ground is marked with a thick dashed black line at the bottom, and the flight altitude is marked with a dotted blue line at the top.

#### 4.1 Resolving vertical gradient of atmospheric CO<sub>2</sub>

We conducted a 9.4 h long south-to-north flight on 27 July 2017, transiting from Palmdale, CA, to Fairbanks, AK. We conducted spiral-down maneuvers at four local airports during the flight. The first spiral-down maneuver had a duration of about 20 min and was conducted over Grand Island, NE, at 18:12 UTC or 1:12 PM local time from a flight altitude of 10 km to near ground. The backscatter profile for this segment of the flights is shown in Fig. 2 and a subsection of the XCO<sub>2</sub> in Fig. 3. A very significant drawdown of CO<sub>2</sub> ( $\sim 30$  ppm) was observed near the surface at this site; the CO<sub>2</sub> mixing ratio at the surface was as low as 376 ppm, while the average CO<sub>2</sub> mixing ratio in the free troposphere was 406 ppm (Fig. 4). Some cirrocumulus clouds were near the aircraft altitude prior to the spiral maneuver, while, during the spiral down, the sky was clear. During the flight out from Grand Island, the aircraft flew over altocumulus clouds for about 30 min (18:48–19:18 UTC or 1:48–2:18 PM local time). The cloud top heights of these mid-level clouds ranged from 5 to 7 km, as seen in Fig. 2.

##### 4.1.1 XCO<sub>2</sub> measurements to the ground

Figure 4 shows the comparison of lidar XCO<sub>2</sub> retrievals to the ground with those from the AVOCET in situ sensor during this spiral-down maneuver. The AVOCET instrument

sampled the CO<sub>2</sub> mixing ratio outside the aircraft every second. The lidar XCO<sub>2</sub> retrievals were based on 1 s averaged lidar data. The in situ XCO<sub>2</sub> was computed from the integral of the AVOCET CO<sub>2</sub> vertical profile using the vertical averaging kernel of the lidar XCO<sub>2</sub> retrieval made from the same altitude. The comparisons were made for averages in every 1 km vertical layer of atmosphere with more than 100 samples as DC-8 aircraft spiraled downward at about 7–8 m s<sup>-1</sup>.

As the figure shows, the lidar's averaging kernel peaks in the planetary boundary layer, which means the lidar XCO<sub>2</sub> retrievals have the most weighting for CO<sub>2</sub> at the bottom atmospheric layers, allowing good sensitivity to surface fluxes. As shown in Fig. 3, there was a significant difference between the lidar XCO<sub>2</sub> retrievals made to the ground and those to cloud tops. Both in situ and lidar XCO<sub>2</sub> showed a strong vertical gradient, caused by a significant surface drawdown in this area that was covered with growing corn and soybeans crops. When DC-8 aircraft flew away from this area, the lidar-measured XCO<sub>2</sub> increased steadily.

The retrievals with the highest precision (lowest standard deviation from the least-squares fit) were from flight altitudes of 7–9 km, indicating the lidar's optimal operating altitude. This optimum is a result of the combined effect of CO<sub>2</sub> differential absorption and the number of returned laser photons. At higher flight altitudes, there is more CO<sub>2</sub> absorption, but there are fewer received laser photons. This causes a lower signal-to-noise ratio and noisier XCO<sub>2</sub> retrievals that

**Figure 5.** Same as Fig. 4 but for the comparison of the lidar XCO<sub>2</sub> retrievals to cloud tops with those from in situ measurements during the flight ascent from Grand Island, NE. The ground is marked in a thick dashed black line at the bottom, and the average cloud top height is marked in a thick dashed green line.

have larger standard deviations. At lower flight altitudes the received laser return is greater, but the photon path lengths are shorter, and the CO<sub>2</sub> absorption is much weaker, also causing the XCO<sub>2</sub> retrievals to have larger standard deviations. The 7–9 km altitude range is where there is the best balance between the line absorption and the number of received signal photons for this instrument.

Compared to the in situ XCO<sub>2</sub> from AVOCET, the lidar XCO<sub>2</sub> had an average bias of 0.1 ppm for flight altitudes above 5 km. These results are based on 1 s averaged lidar data which typically have a standard deviation of 1.2 ppm. When the lidar data averaging time is increased to 10 s, the standard deviation of lidar XCO<sub>2</sub> retrievals to the ground was 0.7 ppm. For 10 s flight time, the length of the aircraft's ground track was typically 2.4 km. The longer averaging time improves the signal-to-noise ratio of the lidar data; however, it also increases the lidar range variation for non-flat surfaces, e.g., vegetation cover and cloud tops, which makes XCO<sub>2</sub> retrievals have larger standard deviations (Mao et al., 2018). The overall benefit of a longer data averaging time is to improve the precision of lidar XCO<sub>2</sub> retrievals, especially over flat surfaces like deserts and oceans. Longer averaging times also benefit lidar XCO<sub>2</sub> retrievals to cloud tops, as shown in the next section.

#### 4.1.2 XCO<sub>2</sub> measurements to cloud tops

During the flight out from the Grand Island spiral, the DC-8 flew for about 30 min over extended altocumulus clouds, with cloud top heights between 5 to 7 km. As shown in Fig. 3, the difference between the lidar XCO<sub>2</sub> retrievals to the

ground and those to cloud tops was significant due to the surface drawdown in this area. As the DC-8 aircraft flew away from this area, the lidar XCO<sub>2</sub> increased steadily. Figure 5 shows the comparison of lidar XCO<sub>2</sub> retrievals to these mid-level cloud tops during the flight out with those from the in situ vertical profiles of CO<sub>2</sub> measured during the spiral-down segment for the flight altitudes above 7 km. The lidar range to cloud tops was between 2 to 4 km. This was shorter than the optimum range for this lidar. From the flight altitudes of 7–9 km, the lidar XCO<sub>2</sub> retrievals to cloud tops had an average difference of +0.8 ppm compared to those measured by the in situ sensor during the spiral.

When DC-8 aircraft flew further away from Grand Island, this difference increased to +2.9 ppm. These larger differences are thought to result from significant horizontal differences in the atmosphere (temperature, pressure, water vapor and CO<sub>2</sub> profiles) between the region of the spiral-down maneuver and that for the flight-out segment. Note that the optical depth look-up tables of CO<sub>2</sub> and H<sub>2</sub>O used for retrievals were based on the vertical profiles of atmosphere measured during the spiral down. Retrievals of XCO<sub>2</sub> to cloud tops during the flight out were made using the same look-up tables for the spiral down. However, the actual conditions are expected to be somewhat different because the atmospheric conditions and CO<sub>2</sub> concentrations during summer are expected to have significant gradients in this area.

The retrievals of XCO<sub>2</sub> to these cloud tops had a standard deviation of 3–4 ppm for 1 s averaged data, which was about 3 times larger than that for the retrievals to the ground. One reason for this is that the cloud reflectance at the lidar wave-

length was typically about 5 %, a factor of 4–5 times lower than that from vegetated surfaces (Mao et al., 2018). Calculations from the lidar data showed that median reflectance of these mid-level clouds at Grand Island was only 2.7 %, while the median value of ground reflectance at Grand Island was 27 %. Additionally, there was less CO<sub>2</sub> absorption in the shorter range, and the effects together caused these lidar retrievals to be noisier. In addition, the variability in the elevation of the cloud tops reduces the precision of the XCO<sub>2</sub> retrievals. The cloud top altitude used to calculate the photon path length in the retrieval is taken as the centroid of the cloud top altitudes calculated from time-averaged lidar range measurements. These range measurements are averaged over a longer time (1 s or 10 s); the difference in range results in an additional error in the XCO<sub>2</sub> retrievals (Mao et al., 2018).

When the data were averaged over 10 s, the standard deviation of XCO<sub>2</sub> retrievals to these altocumulus cloud tops at Grand Island improved to 1.3 ppm. This measurement precision for partial column XCO<sub>2</sub> to cloud tops is at least 2 times better than those from the 2011, 2013 and 2014 airborne campaigns (Abshire et al., 2014; Mao et al., 2018). This improvement was caused by the utilization of the step-locked seeder laser diode source in the transmitter and the high-sensitivity detector for this campaign (Abshire et al., 2018).

#### 4.2 Validation of lidar XCO<sub>2</sub> measurements to the tops of mid-level clouds

After the flight from Palmdale, CA, to Fairbanks, AK, we conducted two flights based out of Fairbanks to the Northwest Territories of Canada (NWT). Both flights targeted a northern loop of the area, including the Arctic Ocean. Figure 6 shows the ground track, satellite image and lidar backscatter profiles for the second flight in NWT on 3 August, UTC time. This flight started late on 2 August and went from Fairbanks to Inuvik, then east, then back north along the Arctic Ocean back to Inuvik, then back to Fairbanks. We again used spiral-down maneuvers for comparing the lidar measurements of XCO<sub>2</sub> against those from the in situ CO<sub>2</sub> profiles above the airports at Inuvik, Kugluktuk, Cambridge Bay, Inuvik again and then Fairbanks.

As shown in Fig. 6, the atmospheric conditions from Fairbanks to Inuvik varied from mostly cloudy to broken clouds at multiple levels on the return leg. These cloud layers provided opportunities for lidar cloud slicing (Ramanathan et al., 2015). There were several occurrences of thick cirrus clouds below the DC-8 aircraft that attenuated the lidar signal and caused some data outages. The path over the Arctic Ocean was also very cloudy, and the vertical structure of the clouds in this path was complex.

Also shown in Fig. 6 are dense smoke plumes from wildfires in the south seen after the spiral-down maneuvers at Inuvik and Cambridge Bay. The atmospheric scattering and attenuation caused by the smoke would significantly degrade or completely screen out any retrievals from passive

spectrometers on satellites (Mao and Kawa, 2004; Aben et al., 2007; Butz et al., 2009; Uchino et al., 2012; Guerlet et al., 2013). In contrast, the lidar can accurately measure CO<sub>2</sub> enhancements from wildfires through dense smoke plumes, as demonstrated earlier for the large wildfires in the Canadian Rockies during this airborne campaign (Mao et al., 2021a). Measurements of height-resolved atmospheric backscatter profiles allow this lidar approach to accurately estimate XCO<sub>2</sub> and range to terrain and water surfaces, even in the presence of wildfire smoke.

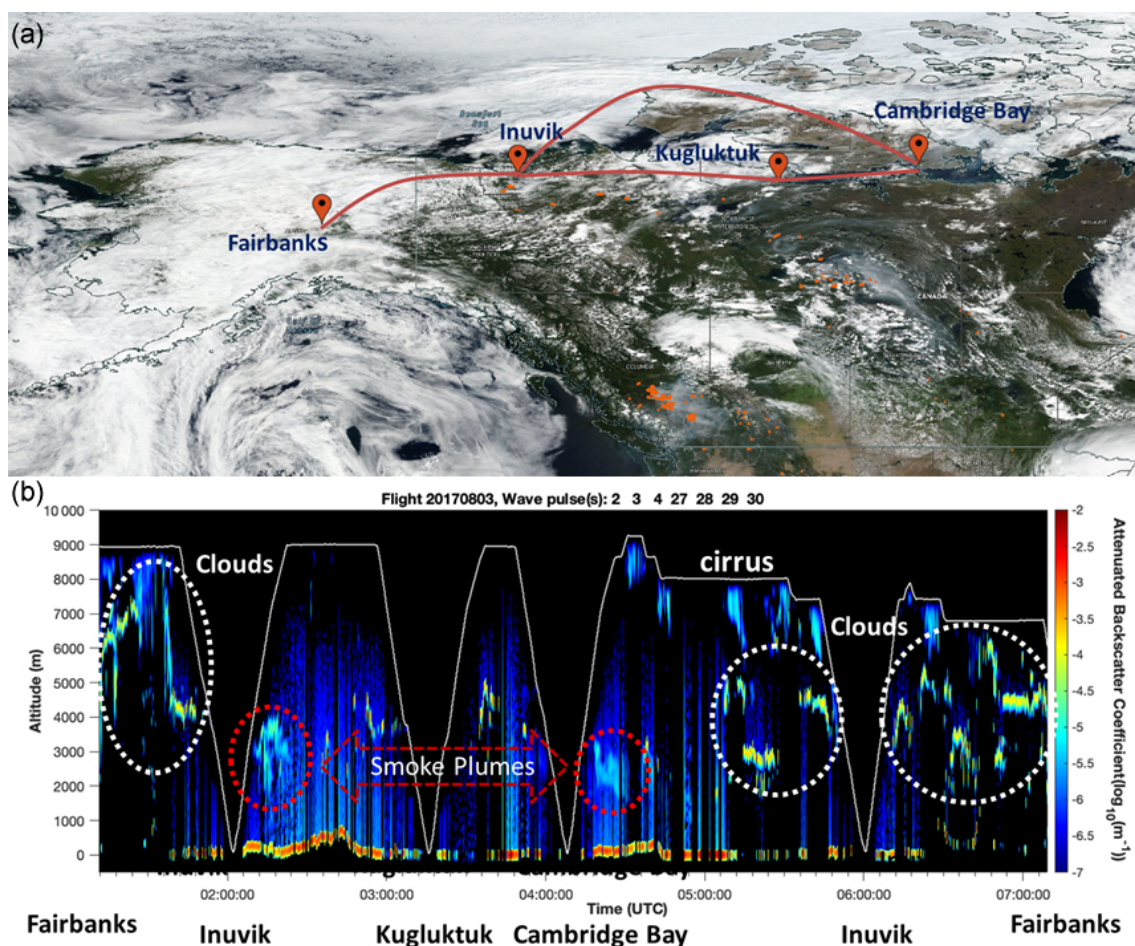

During the first spiral-down maneuver of the flight at Inuvik, NT, we overflew some altocumulus clouds with cloud tops around 4.5 km a.m.s.l. (Fig. 6). Figure 7 shows the comparison of both XCO<sub>2</sub> retrievals to the ground and to these mid-level cloud tops against those from the in situ CO<sub>2</sub> profiles. The measurement local time was around 20:00, and evidence of a small surface sink was noticeable. The differences between the lidar XCO<sub>2</sub> retrievals to the ground and to the altocumulus cloud tops were  $-0.1$  and  $+0.4$  ppm, respectively, compared to those from the in situ CO<sub>2</sub> profile. The standard deviation of the lidar XCO<sub>2</sub> retrievals to the ground from flight altitudes of 7–8 km was 1.3 ppm, while the standard deviation of XCO<sub>2</sub> retrievals to cloud tops from flight altitudes of 8–9 km was 1.7 ppm. On average, the lidar range to cloud tops was 4 km for this segment. The lidar measurements showed that the ground reflectance at Inuvik airport was 30 % at the lidar wavelength and that to the tops of the altocumulus clouds was 5.6 %, more than twice that of clouds over Grand Island. This higher reflectance improved the precision of the lidar measurements of XCO<sub>2</sub> to these clouds.

These retrieval results were based on 1 s averaged lidar data. When the lidar data averaging time was increased to 10 s, the standard deviation for both retrievals to the ground and to cloud tops decreased to 0.6 ppm. The lidar's measurement precision to cloud tops indicates the benefit of these measurements over persistent cloud cover, which occurs, for example, over the west coasts of continents with marine layered clouds and over the Southern Ocean. These results show that averaging lidar measurements to cloud tops for a longer distance in these regions can fill these significant gaps with high-precision measurements.

Figure 8 shows the time series of the lidar XCO<sub>2</sub> retrievals made to the ground and to the altocumulus cloud tops during this spiral down using 10 s data averaging. While the XCO<sub>2</sub> measurements to cloud tops were steady during this segment, the measurements to the ground exhibited lower values of XCO<sub>2</sub>. This small 1.3 ppm difference between these two sets of measurements indicates slightly lower atmospheric carbon below clouds.

#### 4.3 Validation of lidar XCO<sub>2</sub> measurements to low-level clouds

Measurements of XCO<sub>2</sub> to the ground and to the tops of nearby clouds at the top of the planetary boundary layer pro-

**Figure 6.** True-color image from Aqua/MODIS (a; NASA Worldview) and time series of the lidar's attenuated backscatter profiles (b) for the flight over the Northwest Territories, Canada, on 3 August 2017. Clouds are white, and wildfires are marked with red dots in the MODIS color image. Clouds, including cirrus, and wildfire smoke plumes are circled and labeled in the lidar profiles. The flight ground track is marked in a red line in the top image, and the aircraft GPS flight altitude is marked in a white line in the bottom plot. The locations of spiral maneuvers are labeled. The lidar range-corrected attenuated backscatter profiles were sampled at a vertical resolution of 15 m and averaged over 1 s. Several occurrences of cirrus clouds are clearly seen as light-blue regions just below the aircraft altitude.

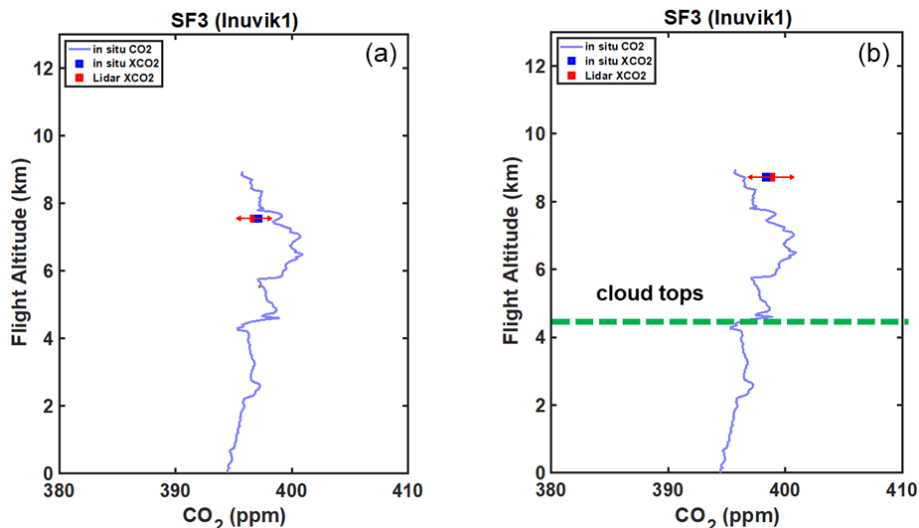

vide information to help separate the carbon processes at the Earth's surface from the carbon transport in the free troposphere (Mao et al., 2018; Shi et al., 2021). In earlier airborne campaigns we made measurements to broken cumulus clouds and demonstrated a lidar cloud-slicing approach to estimate partial column XCO<sub>2</sub> in the planetary boundary layer (Ramanathan et al., 2015). However, the results from the earlier version of this airborne lidar had larger biases and larger standard deviations even though the lidar data were aggregated over 10 or even 100 s (Abshire et al., 2014; Ramanathan et al., 2015; Mao et al., 2018). The lidar used in the 2017 campaign had several instrument improvements that resulted in improved measurement performance.

After the two flights in the Northwest Territories of Canada, we conducted two flights in southern and central Alaska. On 6 August the flight track went in a counterclockwise direction from Fairbanks westward to Kotzebue, then

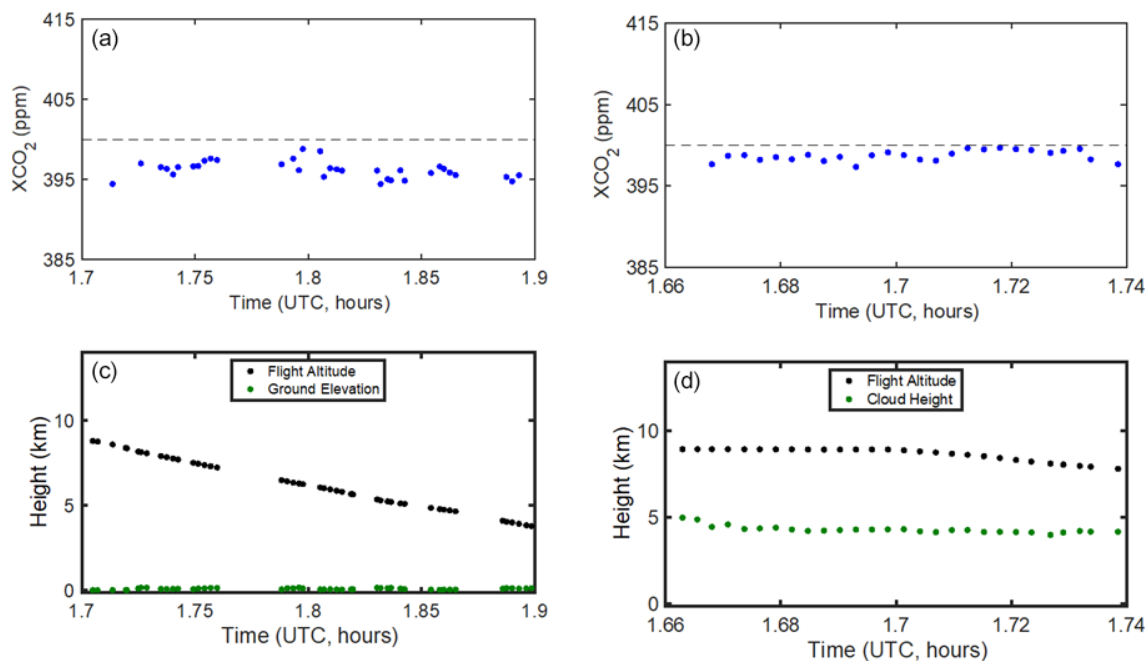

almost due south and on a diagonal path back toward Fairbanks (Fig. 1). We again used spiral-down maneuvers above the airports at Bettles, Kotzebue, Unalakleet, Platinum, McGrath, Fort Yukon and Fairbanks to validate the lidar XCO<sub>2</sub> measurements.

The takeoff time of the 6 August flight was 07:45 local time, and the spiral down at Bettles, AK, started around 08:45 local time or at 16:54 UTC. As shown in Fig. 9, the DC-8 aircraft flew over broken cumulus clouds for about 35 min prior to and during the Bettles spiral down. The heights of cumulus cloud tops ranged from 2 to 2.5 km a.m.s.l. at the top of the planetary boundary layer. As shown in Fig. 10, the in situ sensor showed that the CO<sub>2</sub> concentration near the surface was as high as 436 ppm in the morning, which was confined within the lowest 100 m layer. Above that layer the CO<sub>2</sub> concentration increased with altitude in the bottom 4 km and remained almost uniform in the upper layers. The XCO<sub>2</sub>

**Figure 7.** Comparison of XCO<sub>2</sub> retrievals from lidar measurements made to the ground (a) and to cloud tops (b) during the first spiral-down maneuver at Inuvik, NT, on 3 August 2017. The CO<sub>2</sub> profile measured with the in situ sensor is plotted with the blue line. The lidar measurements used a 1 s average. The in situ XCO<sub>2</sub> values are marked with blue squares, and the lidar XCO<sub>2</sub> retrieval values are marked with red squares. XCO<sub>2</sub> values were binned into the top 1 km vertical layer of atmosphere. The red error bars for the lidar XCO<sub>2</sub> retrievals are ± 1 standard deviation. In the plot on the right, the average cloud top height is marked as a dashed green line.

**Figure 8.** XCO<sub>2</sub> retrievals from lidar measurements during the spiral-down maneuver at Inuvik, NT, on 3 August 2017, using 10 s averaging. (a) The time series of the XCO<sub>2</sub> retrievals made to the ground (blue dots). (c) DC-8 aircraft altitudes and ground elevation for the same segment. Panels (b) and (d) are the same as the left plots but for the lidar XCO<sub>2</sub> retrievals made to cloud tops (blue dots). In the lower figures the flight altitudes are plotted with black dots, and the elevation of the ground and cloud tops used for the lidar XCO<sub>2</sub> retrievals are plotted with green dots.

**Figure 9.** Time series of the lidar's range-corrected attenuated backscatter profiles measured for the flight segment over Bettles, AK, on 6 August 2017. The lidar measurements are averaged over 1 s and have a vertical resolution of 15 m. The lidar returns from cloud tops are comparable to those from the ground, as indicated by their red and yellow color scale of the attenuated backscatter coefficients. The aircraft's flight altitude is marked as a white line.

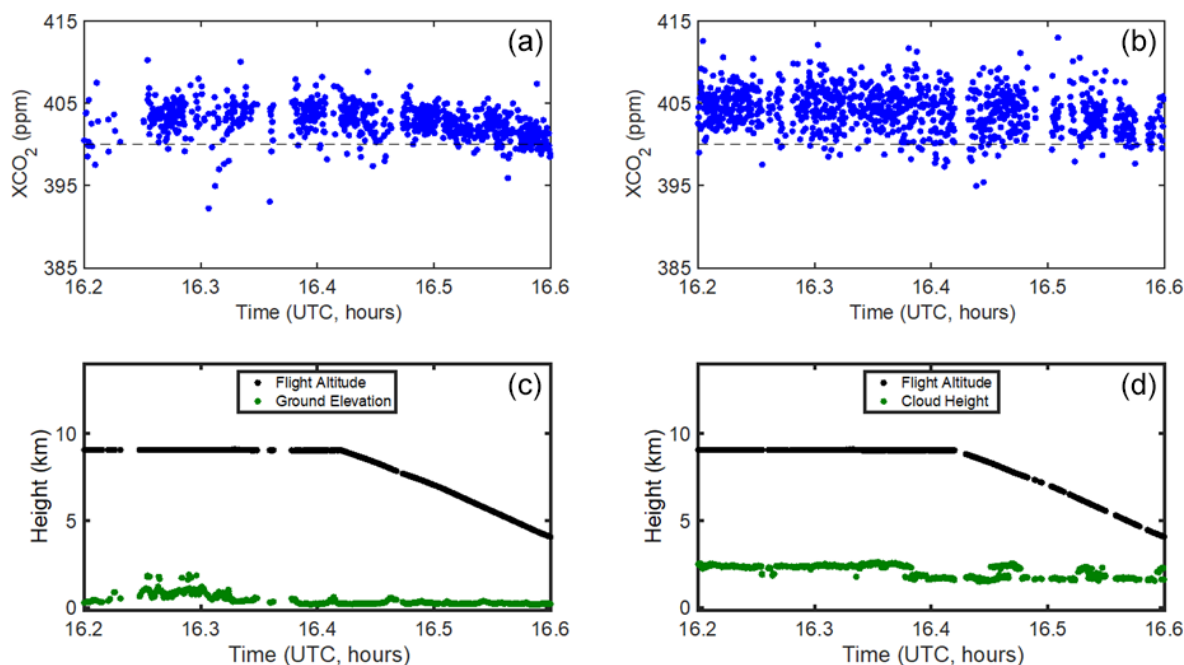

**Figure 10.** XCO<sub>2</sub> retrievals from lidar measurements near the spiral down over Bettles, AK, on 6 August 2017. The XCO<sub>2</sub> retrieved from 1 s averaged lidar measurements to the ground is on the left, and the lidar XCO<sub>2</sub> retrievals to cloud tops are on the right. The CO<sub>2</sub> profile measured from the in situ sensor during the spiral-down maneuver is plotted with the blue line. The XCO<sub>2</sub> values computed from the in situ measurements are marked with blue squares, and the lidar's XCO<sub>2</sub> retrieval values are marked with red squares. XCO<sub>2</sub> values were binned into every 1 km vertical layer of atmosphere above 5 km. The red error bars for the lidar retrievals are  $\pm 1$  standard deviation. In the plot on the right, the average cloud top height is marked as a dashed green line.

values measured to the ground and to the tops of cumulus cloud for flight altitudes above 5 km were about the same.

Figure 10 shows the profile comparison with the in situ measurements. The XCO<sub>2</sub> retrievals from lidar measurements to the ground and to the tops of cumulus clouds showed an average bias of +0.2 and −0.4 ppm, respectively, for flight altitudes above 5 km compared to the in situ mea-

surements. The standard deviations of XCO<sub>2</sub> measurements to the ground and to cloud tops were 1.5 and 2.5 ppm, respectively, for 1 s average lidar data. In this case, the lidar reflectance of cumulus clouds was 6 %, while the ground reflectance near the Bettles airport was 25 %.

Figure 11 shows the time series of lidar measurements. It shows that the lidar XCO<sub>2</sub> retrievals to cloud tops were more

**Figure 11.** Time series of the lidar XCO<sub>2</sub> retrievals during the spiral-down maneuver over Bettles, AK, on 6 August 2017. (a) The blue dots are the XCO<sub>2</sub> retrievals to the ground for 1 s averaged lidar data. (c) The DC-8 aircraft altitudes and ground elevation. Panels (b) and (d) are the same as the left plots but for the XCO<sub>2</sub> retrievals to cloud tops (blue dots). In the lower figures the flight altitudes are plotted with black dots, and the ground elevations and cloud top heights are plotted with green dots.

scattered than those to the ground, which is mainly caused by the lower reflectance of clouds at the lidar measurement wavelength. Compared to the XCO<sub>2</sub> measurements to the mid-level altocumulus cloud tops, the XCO<sub>2</sub> measurements to the boundary layer cumulus cloud tops were significantly noisier due to the puffy cumulus cloud tops and the longer range from aircraft to cloud tops (Mao et al., 2018).

When the lidar data are averaged over 10 s, the standard deviation of XCO<sub>2</sub> measurements to the ground is 0.8 ppm, and the standard deviation for XCO<sub>2</sub> to the cumulus cloud tops is reduced to 0.9 ppm. These lidar XCO<sub>2</sub> measurements to the tops of the low-level clouds from the 2017 airborne campaign are 2–3 times better than those from our previous airborne campaigns using the earlier version of the lidar (Mao et al., 2018).

## 5 Discussion and summary

The 2017 ASCENDS/ABOVE airborne campaign was the first time that lidar measurements of XCO<sub>2</sub> had been extended to the Arctic region. The summertime Arctic atmosphere contained a variety of cloud types whose tops were at different elevations. These conditions allowed the opportunity to perform lidar XCO<sub>2</sub> retrievals to cloud tops and to validate these measurements with those from the onboard in situ sensor during spiral-down maneuvers.

The results showed that the standard deviation of the lidar XCO<sub>2</sub> retrievals to cloud tops for 1 s average data from this campaign was equivalent to that for 10 s average data from previous campaigns in 2011, 2013 and 2014. The improvement in data precision for this campaign enabled the utilization of a step-locked seeder laser diode source and the higher-sensitivity lidar detector.

When the data averaging time was increased to 10 s, the standard deviations of the lidar retrievals improved to 0.6 ppm for the mid-level clouds and 0.9 ppm for the low-level clouds at the top of the planetary boundary layer. The precision of XCO<sub>2</sub> measurements to cloud tops was typically 2–3 times lower than those to the ground due to the lower reflectance of clouds at the 1572 nm lidar wavelength. During the 2017 airborne campaign, most flight altitudes were below 10 km, and so the lidar ranges to cloud tops were relatively short. There were many occurrences of cirrus clouds during the flights; however, the ranges from the aircraft to the tops of these cirrus clouds were short, resulting in weak CO<sub>2</sub> absorption and poor retrievals. For future space-based lidar measurements, the longer atmospheric path length to cirrus clouds should allow useful XCO<sub>2</sub> measurements to cirrus clouds as well.

These results indicate the significant benefit of the lidar's measurements to cloud tops, particularly those made over persistent cloud cover, e.g., the Intertropical Convergence Zone, the western coasts of continents with marine layered

clouds, the Southern Ocean with low-level clouds and the Arctic. These are important areas with active carbon cycling but where measurements from passive satellite-based spectrometers are sparse or unavailable.

This study demonstrated that this lidar's XCO<sub>2</sub> measurements to cloud tops, along with those to the ground, can be used to help resolve vertical and horizontal gradients of CO<sub>2</sub>. This lidar capability can be used to fill significant measurement gaps left by passive spectrometer missions and to help resolve the vertical distribution of atmospheric CO<sub>2</sub>. Future airborne campaigns and spaceborne missions with this lidar's measurement capability, like NASA's planned ASCENDS mission (Kawa et al., 2018), would improve carbon data assimilation, atmospheric transport modeling and flux estimation and would advance carbon cycle science.

*Data availability.* The lidar XCO<sub>2</sub> retrievals for the clear sky from the 2017 airborne campaign are available from the NASA Airborne Science Data for Atmospheric Composition website, <https://www-air.larc.nasa.gov/cgi-bin/ArcView/ascends.2017#ABSHIRE.JAMES/> (NASA Langley Research Center, 2020). The lidar XCO<sub>2</sub> retrievals to cloud tops used in this work are available from the primary authors.

*Author contributions.* JM led the paper writing and the airborne campaign data processing and analysis. JBA was the principal investigator of the CO<sub>2</sub> Sounder lidar development, led the 2017 ASCENDS/ABOVE airborne campaign, and contributed to the analysis and paper. SRK contributed to the 2017 airborne campaign, the campaign data processing and analysis, and the paper editing. XS contributed to the CO<sub>2</sub> Sounder lidar development, the lidar data analysis and the paper editing. HR contributed to the CO<sub>2</sub> Sounder lidar development, the 2017 airborne campaign, and the campaign data processing and analysis.

*Competing interests.* The contact author has declared that none of the authors has any competing interests.

*Disclaimer.* Publisher's note: Copernicus Publications remains neutral with regard to jurisdictional claims made in the text, published maps, institutional affiliations, or any other geographical representation in this paper. While Copernicus Publications makes every effort to include appropriate place names, the final responsibility lies with the authors.

*Acknowledgements.* We appreciate the work of Graham Allan, Kenji Numata and Jeffrey Chen from NASA Goddard Space Flight Center in supporting the CO<sub>2</sub> Sounder lidar, as well as Joshua P. DiGangi, Glenn Diskin and Yonghoon Choi from NASA Langley Research Center for participating in the airborne campaign and for providing the in situ CO<sub>2</sub> and H<sub>2</sub>O data. We gratefully acknowledge the work of the DC-8 aircraft team at NASA's Armstrong

Flight Center in helping to plan and conduct the flight campaign. We thank Paul T. Kolbeck from the University of Maryland at College Park for the lidar backscatter data processing. We acknowledge the use of imagery from the NASA Worldview application (<https://worldview.earthdata.nasa.gov/>, last access: 25 April 2023), part of the NASA Earth Observing System Data and Information System (EOSDIS). We also would like to thank two anonymous reviewers for their helpful reviews and recommendations.

*Financial support.* This research was supported by the NASA ABoVE project, the NASA ASCENDS mission pre-formulation activity, the NASA Earth Sciences Technology Office and NASA's Airborne Science Program.

*Review statement.* This paper was edited by Christoph Kiemle and reviewed by two anonymous referees.
