**Abstract.** Radiocarbon (<sup>14</sup>C) is an optimal tracer of methane emissions, as <sup>14</sup>C measurements enable distinguishing between fossil methane and biogenic methane (CH<sub>4</sub>). However, <sup>14</sup>C measurements in atmospheric methane are still rare, mainly because of the technical challenge of collecting enough carbon for <sup>14</sup>C analysis from ambient air samples. In this study, we address this challenge by advancing the system in Zazzeri et al. (2021) into a much more compact and portable sampler and by coupling the sampler with the MICADAS (Mini CARbon DAting System) accelerator mass spectrometry (AMS) system at ETH Zurich, using a gas interface.

Here, we present the new sampler setup, the assessment of the system contamination and a first inter-laboratory comparison with LARA (Laboratory for the Analysis of Radiocarbon with AMS) at the University of Bern.

With our sampling line, we achieved a very low blank, 0.7 µgC compared to 5.5 µgC in Zazzeri et al. (2021), and a sample precision of 0.9%, comparable with other measurement techniques for <sup>14</sup>CH<sub>4</sub>, while reducing the sample size to 60 L of air. We show that this technique, with further improvements, will enable routine <sup>14</sup>CH<sub>4</sub> measurements in the field for an improved understanding of CH<sub>4</sub> sources.

## 1 Introduction

Understanding the methane (CH<sub>4</sub>) budget and identifying methane sources have become a priority to tackle global warming, as methane is the second-most-important anthropogenic greenhouse gas after carbon dioxide (CO<sub>2</sub>) and because the dynamics that led to the CH<sub>4</sub> increase in the last decade have not been fully unravelled. Tracing CH<sub>4</sub> sources and monitoring mitigation strategies are urgently needed.

<sup>14</sup>C measurements of atmospheric methane can advance our knowledge of methane production processes by differentiating fossil vs. biogenic sources. This is because fossil CH<sub>4</sub> is depleted in <sup>14</sup>C and, when emitted into the atmosphere, exerts a dilution effect on the <sup>14</sup>C in the atmosphere that can be quantified. However, this research field is still underexplored, as <sup>14</sup>C measurements of atmospheric methane are challenging.

One of the main challenges is sampling enough air for <sup>14</sup>C analysis via accelerator mass spectrometry (AMS), as the atmospheric methane concentration is low (~2 ppm). Here, we build on recent advances that have been made in the analysis of <sup>14</sup>C in atmospheric methane. Traditionally, air was collected in pressurized cylinders using high-pressure pumps, followed by an extraction procedure in the laboratory (Eisma et al., 1995; Townsend-Small et al., 2012). Zazzeri et al. (2021) developed a new technique that separates methane carbon from ambient air while sampling, simplifying the transportation of collected samples in a small

trap and minimizing the laboratory processing needed. The <sup>14</sup>C measurement precision achieved is between 0.5 % and 1.2 %, comparable to the best precisions of alternative but more lab-intensive techniques. The laboratory-based system developed by Zazzeri et al. (2021) was applied in the quantification of fossil and biogenic proportions of CH<sub>4</sub> in London (Zazzeri et al., 2023). A portable system using a similar technique was demonstrated by Palonen et al. (2017), but in that study they only used samples with enriched methane concentrations of > 100 ppm, e.g. for CH<sub>4</sub> emissions from wetlands. Another promising recently developed technique applies chromatographic separation of CH<sub>4</sub> from air as it requires only 60 L of atmospheric air to be sampled in a bag (Espic et al., 2019), still achieving precisions of 1.2 %.

In this study, we advance the sensitive though simple methane sampling system in Zazzeri et al. (2021) with the portability of the system by Palonen et al. (2017), requiring as little air as demonstrated by Espic et al. (2019). The result is a compact and portable system that can be deployed in field campaigns. We present the technology advancement and the assessment of the system efficiency by quantifying the amount of extraneous carbon introduced during sample preparation and ultimately the measurement precision to be achieved. We demonstrate the method by comparing <sup>14</sup>C measurements made by the new portable system at the Laboratory of Ion beam Physics (LIP) at ETH Zurich and by the system using bag sampling and chromatographic separation at the Laboratory for the Analysis of Radiocarbon with AMS (LARA) at the University of Bern.

## 2 Method

### 2.1 The sampling setup

The sampling system is based on four main steps as in Zazzeri et al. (2021): (1) H<sub>2</sub>O removal with a Nafion dryer, (2) CO and CO<sub>2</sub> removal, (3) combustion of CH<sub>4</sub> to CO<sub>2</sub>, and (4) adsorption of the combustion-derived CO<sub>2</sub> onto a molecular sieve sample trap. Figure 1 shows the system schematic. Ambient air is sampled through a Nafion dryer (Perma Pure gas dryer, PD-50-24) at up to 500 cm<sup>3</sup> min<sup>-1</sup> with a KNF membrane pump (“Pump 2” in Fig. 1), controlled by a mass flow controller. The Nafion filter enables reduction of the water content to levels of 0.01 % (Zazzeri et al., 2021). Downstream of the pump, CO is oxidized to CO<sub>2</sub> using the Sofnocat<sup>®</sup> catalyst before all CO<sub>2</sub> (from ambient air and from oxidation of CO) is removed by a trap containing 14 g of 13X molecular sieve in 1 mm pellets. This amount of molecular sieve has been found to be sufficient to trap atmospheric CO<sub>2</sub> in ~ 300 L of air (see Fig. A1). After collection of the three samples, this trap is disconnected from the system via two Swagelok ball valves and then removed and regenerated by heating at 500 °C with a high-purity ni-

trogen back-flush step for at least 3 h, in a similar manner as in Zazzeri et al. (2021).

After the sample air passes through the CO<sub>2</sub> trap, CH<sub>4</sub> is combusted at 800 °C in a small furnace comprising a 22 cm long quartz tube with 1 g of platinumized quartz wool (Sigma-Aldrich) acting as catalyst (Petrenko et al., 2008). The H<sub>2</sub>O derived from the CH<sub>4</sub> oxidation is trapped onto a magnesium perchlorate trap (“H<sub>2</sub>O trap” in Fig. 1), while the CO<sub>2</sub> derived from combustion of CH<sub>4</sub> is collected on the sample trap (13X, 45–60 mesh) for subsequent <sup>14</sup>C measurement. A non-dispersive infrared CO<sub>2</sub> sensor (NDIR FLOW<sup>EVO</sup> from SmartGas) monitors both the completeness of CO<sub>2</sub> removal from air prior to methane combustion and the completeness of CO<sub>2</sub> collection on the sample trap. If regularly calibrated and run at constant temperature and pressure, the sensor can measure CO<sub>2</sub> concentrations in a range of 0 to 100 ppm with a precision of ±1 ppm. The sample trap, minimized in size for low cross contamination, can be cooled with Peltier coolers to maximize trapping efficiency and avoid sample loss.

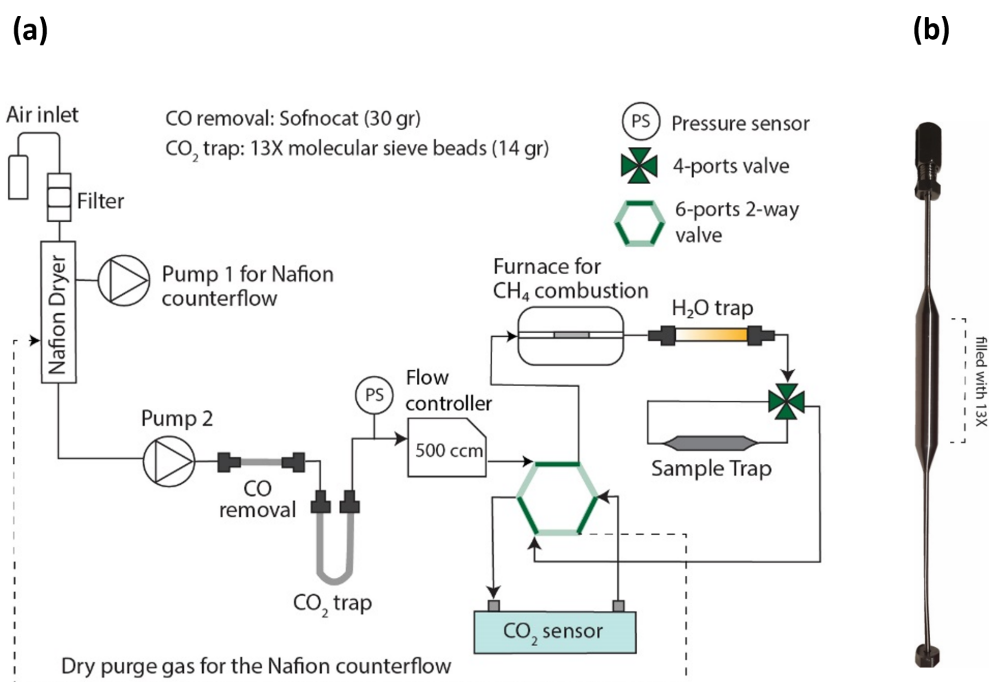

The whole system runs either on 115/230 V AC or 48 V DC provided by a battery pack. Two 72 V 30 Ah (2160 Wh) lithium batteries are sufficient to run the sampling system for 10 h.

### 2.2 Sample trap and cooling system

The sample trap consists of 0.250 g of 13X 45–60 mesh molecular sieve packed in a 4 cm long 1/4 in. o.d. stainless-steel tube. The trap tube is welded to stainless-steel capillary tubing and attached to a VICI 4-port valve which can be disconnected from the sampling system (Fig. 1b) in order to release the sample for <sup>14</sup>C analysis in the AMS. Before its first use, the sample trap is heated gradually to 650 °C in a customized oven while flushing with high-purity nitrogen. The NDIR FLOW<sup>EVO</sup> CO<sub>2</sub> sensor is used to check when the trap is not releasing CO<sub>2</sub> anymore and does not contain any residual carbon, typically after 1 h. During sampling, the sample trap is cooled down to –10 °C using two Peltier elements (part (6) in Fig. 2). This maximizes the trapping efficiency such that 0.250 g of 13X can adsorb ~ 60 µgC (methane carbon from ~ 60 L of ambient air at 2 ppm), before the CO<sub>2</sub> breakthrough happens. The adsorption capacity can be enhanced by lowering the temperature even further.

After sampling, the sample trap is disconnected from the system and heated at 450 °C for 10 min for sample desorption using the TSE (Tube Sealing Equipment) system (<https://www.ionplus.ch/tse>, last access: 8 January 2025), which enables us to measure the pressure of the desorbed gases and to quantify the amount of the CO<sub>2</sub> released. The desorbed CO<sub>2</sub> is cryogenically sealed into a glass ampule to be used in the gas interface system of the MIni CARbon DAting System (MICADAS) (Wacker et al., 2013).

Before the next sample is collected, the sample trap is cleaned of remaining CO<sub>2</sub> by flushing with high-purity nitrogen while heating at 550 °C for 30 min. Such a long pro-

**Figure 1.** (a) Schematic of the sampling system. First, the filtered air is dried with a Nafion dryer; then, any CO<sub>2</sub> from ambient air and from oxidation of CO is removed by a trap. The CO<sub>2</sub> derived from the combustion of CH<sub>4</sub> is collected onto a final sample trap. Dark green lines in the 6-port valve indicate the active flow direction. In the indicated configuration, the CO<sub>2</sub> sensor measures the CO<sub>2</sub> level after the sample trap, enabling us to check for the trap breakthrough. In the alternative configuration, complete CO<sub>2</sub> removal prior to CH<sub>4</sub> oxidation can be checked. (b) Sample trap filled with 0.250 g of 13X.

cedure compared to other cleaning processes for other applications is only precautionary; a shorter procedure might be sufficient to remove any residual carbon from previous sampling.

### 2.3 AMS analysis

The sample is measured with the MICADAS accelerator mass spectrometry facilities for radiocarbon measurements in the Laboratory of Ion Beam Physics, ETH (Wacker et al., 2010). The <sup>14</sup>C analysis using the gas interface of the MICADAS takes about 20 min and achieves a measurement precision of less than 1 % for modern samples (Wacker et al., 2013) for a sample containing 20 μg of carbon. Precisions down to 0.5 % can be achieved when measurements are repeated on ≥ 50 μg of carbon (Fahrni et al., 2013).

The combusted NOX standard (SRM-4990C, Mann, 1983; Wacker et al., 2019) and the <sup>14</sup>C-free CO<sub>2</sub> premixed with helium in gas bottles were measured for standard normalization or blank correction. Measured data (Zazzeri, 2025) were evaluated with the BATS computer program, where the samples were fractionation-corrected, blank-subtracted and normalized with the NOX standard (Wacker et al., 2010) to obtain  $F^{14}\text{C}$  values (Reimer et al., 2004).

### 2.4 Characterization of the extraneous contaminant carbon within the sampler

Extraneous contaminant carbon in the sample trap after a sample collection might derive from intrusion of lab air into the system, from incomplete removal of atmospheric CO<sub>2</sub>, from residual carbon on the sample trap prior to sampling or from impurities within the combustion column.

To check for and quantify the contaminant carbon, we collected CH<sub>4</sub> samples of different sizes, and we followed the relationship between the measured fraction modern ( $F^{14}\text{C}$ ) vs. the sample masses given by the mass balance in Eq. (1):

$$F^{14}\text{C}_{\text{meas.}} = F^{14}\text{C}_{\text{true}} + \frac{1}{\mu\text{C}_{\text{meas.}}} \left[ \mu\text{C}_{\text{add}} \times \left( F^{14}\text{C}_{\text{add}} - F^{14}\text{C}_{\text{true}} \right) \right], \quad (1)$$

where “meas.” indicates the measured value,  $F^{14}\text{C}_{\text{true}}$  indicates the  $F^{14}\text{C}$  value of the sampled air,  $\mu\text{C}_{\text{add}}$  indicates the carbon added into the system and  $F^{14}\text{C}_{\text{add}}$  indicates its  $F^{14}\text{C}$  value. If assuming a constant contamination, the contaminant carbon added to the system is given by the  $\mu\text{C}_{\text{add}}$  value that produces the best fitting curve through the  $F^{14}\text{C}_{\text{meas.}}$  values plotted against the measured sample masses ( $\mu\text{C}_{\text{meas.}}$ ). We assess the goodness of fit using reduced chi-squared statistics (i.e. “curve\_fit” function from the “scipy.optimize” Python package).

**Figure 2.** Setup of the atmospheric methane sampling device. The whole system fits well into a box of 80 × 40 × 30 cm. It runs either on 115/230 V AC or 48 V DC provided by a battery pack. Major parts of the system are (1) the Nafion dryer (mostly hidden underneath), (2) pumps (partially hidden), (3) CO<sub>2</sub> trap, (4) flow controller, (5) furnace for CH<sub>4</sub> combustion, (6) sample trap with Peltier coolers, and (7) CO<sub>2</sub> sensor.

To quantify the modern contaminant carbon, we collected seven samples from 10 to 70 μgC from a 2 ppm mixture of fossil methane and synthetic air with no CO<sub>2</sub>, CO or hydrocarbons (Fossil Ref).

To check for any fossil contaminant, we collected seven samples, from 10 to 75 μgC, from a cylinder of pressurized ambient air (Ref 1), with a CH<sub>4</sub> mole fraction of 2040 ppb. Note that in this case, the  $F^{14}C_{\text{true}}$  of the reference gas ( $F^{14}C_{\text{true}}$ ) is unknown. The amount of fossil contaminant carbon and the  $F^{14}C$  value of the reference gas are calculated by tweaking μgC<sub>add</sub> and  $F^{14}C_{\text{true}}$  in Eq. (1) to produce the best fitting curve.

In order to verify the source of the contaminant carbon, we collected five blanks. Three blanks were collected by running the system with lab air and without combustion for 3 h. This enabled verification of any contaminant carbon deriving from atmospheric CO<sub>2</sub> that was not trapped in the CO<sub>2</sub> trap and from residual carbon in the sample trap. Two samples were collected by flushing the system with nitrogen and with the combustion furnace at 800 °C to verify that additional carbon

**Table 1.** Mass,  $F^{14}C$  values and uncertainty of samples collected. Modern samples were collected from Ref 1, fossil samples were collected from Fossil Ref and “Bern” represents samples extracted following the chromatographic procedure at LARA.

ETH no.	Mass (μgC)	$F^{14}C$	± (%)

133991.3.1	66	1.3616	0.96

was not produced within the combustion process. No carbon was extracted from these five blanks.

## 2.5 Comparison with chromatographic extraction procedure

Three samples transferred in sampling bags from the cylinder of pressurized ambient air Ref 1 were extracted at LARA, University of Bern, using 60 L of air and following the chromatographic extraction procedure in Espic et al. (2019). CO<sub>2</sub> derived from the sample extraction in Bern was measured using the gas interface system of the MICADAS AMS system at ETH, in the same manner as the samples collected with our portable sampler.

## 3 Results

Table 1 shows the  $F^{14}C$  values and masses of the samples collected.

Assuming a  $F^{14}C_{\text{true}}$  value for Fossil Ref of 0.01 and a  $F^{14}C$  value of the modern contaminant ( $F^{14}C_{\text{add}}$ ) of 1, the best fitting curve through the Fossil Ref samples indicates a constant level of modern contamination (μgC<sub>add</sub>) of 0.5 ± 0.1 μgC. Larger samples (> 50 μgC) show an offset that can be explained with a size-dependent contamination, an ad-

**Figure 3.**  $F^{14}\text{C}$  values against the measured mass of the samples collected from the Fossil Ref. The grey bands represent the  $1\sigma$  uncertainty bar on the curve fit.

ditional  $0.1\ \mu\text{gC}$  every  $10\ \mu\text{gC}$  collected, which we can correct for (Fig. 3).

The data collected from Ref 1 best fit onto a curve with an  $F^{14}\text{C}$  value of  $1.38 \pm 0.01$  for the reference gas. However, by considering only the quantified modern contamination of  $0.5\ \mu\text{gC}$ , we do not achieve the best fitting curve, and we need to add approximately  $0.2 \pm 0.1\ \mu\text{g}$  of contaminant fossil carbon. Zazzeri et al. (2021) indicated that some fossil carbon might be produced within the combustion furnace; therefore, it is likely that even with our setup the combustion process led to the production of some fossil carbon.

Ref 1 samples extracted in Bern, blue markers in Fig. 4 (not included for determining the constant contamination), agree well with the  $F^{14}\text{C}$  values for Ref 1 samples with the same mass ( $60\ \mu\text{gC}$ ) extracted at ETH, indicating that the two extraction methods are comparable. Samples of  $60\ \mu\text{gC}$  are equivalent to 2 or 3 h of sampling of ambient air with our portable system at 500 sccm or 60 L of ambient air with the extraction line in Bern.

#### 4 Discussion

In order to make the sampler portable, we have reduced the size of the sampler components compared to the system in Zazzeri et al. (2021). The main changes include the following:

- a smaller CO<sub>2</sub> trap placed before the combustion furnace, with 14 g against 60 g of molecular sieve; its adsorption capacity is demonstrated by the very low modern blank, which indicates that all the ambient CO<sub>2</sub> is captured while sampling;
- a new design of the sample trap, with 0.250 g of molecular sieve against 1 g, accommodated in a 4 cm long tube and connected to a single 4-port VICI valve; collection

**Figure 4.** Measured  $F^{14}\text{C}$  values against the measured mass of the samples collected from Ref 1. Symbols in blue are the Ref 1 samples extracted in Bern and are not included for the curve fitting. The grey bands represent the  $1\sigma$  uncertainty bar on the curve fit.

of  $60\ \mu\text{gC}$  (2 or 3 h of sampling at 500 sccm) has been achieved by cooling down the sample trap using two Peltier elements;

- a smaller combustion furnace built at the Laboratory of Ion Beam Physics;
- connections and tubing of 1/8 in. size instead of 1/4 in.

All these modifications led to an important reduction in the level of constant modern contamination, from  $5.5 \pm 1.1\ \mu\text{gC}$  in Zazzeri et al. (2021) down to  $0.5 \pm 0.1\ \mu\text{gC}$ . According to the  $F^{14}\text{C}$  measurements of our modern reference cylinder (Ref 1), we have an extra  $0.2 \pm 0.1\ \mu\text{gC}$  of fossil contamination, leading to  $0.70 \pm 0.14\ \mu\text{gC}$  total amount of contaminant carbon with an averaged  $F^{14}\text{C}$  value of 0.71. We also found a size-dependent contamination of 1 %, which can be explained either with a tiny leak within the sampler or with some outgassing.

To further test the system contamination and demonstrate full separation of CH<sub>4</sub> and CO<sub>2</sub>, more gas mixtures could be used for  $F^{14}\text{C}$  measurements. For example, the system could be run using a mixture made of 2 ppm of fossil CH<sub>4</sub> and 400 ppm of CO<sub>2</sub> from combustion of OXII (oxalic acid II), diluted in N<sub>2</sub> or He.

The overall uncertainty for individual samples of  $60\ \mu\text{gC}$ , calculated by propagating the error from counting statistics and background uncertainty, is 0.9 %, comparable with other measurement techniques for <sup>14</sup>CH<sub>4</sub>, demonstrating that a larger sample, and therefore a longer sampling time, is not needed.

The main benefit of a portable system that needs only 60 L of air for one sample is the important time saving both in the field and in the laboratory. The sample processing time in the laboratory has been reduced significantly, and so has the likelihood of contamination or mistakes by the operator.

The system, given its small size, could be placed in a vehicle, enabling sampling in a source area (such as a landfill site or an urban environment) or performing a mapping of isotopic signatures in a region.

## 5 Conclusions

We have advanced the CH<sub>4</sub> sampling system from Zazzeri et al. (2021) to a portable system that can be used in field campaigns while also reducing the contamination in the system. Further improvements could be made to automate the system so that the valve and pump switching and the flow rate are computer-controlled, making the whole sampling procedure more consistent. More samples could be collected in parallel and at the same time. In addition, the CO<sub>2</sub> desorbed from the sample trap is presently cryogenically trapped in glass ampoules sealed for offline <sup>14</sup>C measurements, but a direct coupling of the zeolite trap to the gas interface (Wacker et al., 2013) connected to the MICADAS AMS system could be implemented, avoiding the additional step of using glass ampoules.

Full assessment of the fossil carbon contamination in <sup>14</sup>CH<sub>4</sub> measurements is still challenging, because there is no modern reference material available for CH<sub>4</sub>. The production of a modern CH<sub>4</sub> standard for <sup>14</sup>C analysis, followed by an inter-laboratory comparison, should be pursued.

Overall, the combination of a selective and field deployable CH<sub>4</sub> sampler and sensitive AMS analysis provides a unique technology that can expand the use of <sup>14</sup>CH<sub>4</sub> measurements.

## Appendix A

**Figure A1.** CO<sub>2</sub> concentrations (in ppm) measured with the NDIR sensor downstream the CO<sub>2</sub> trap while flushing the trap with lab air. The trap starts saturating after 4 h and 30 min of flushing at a 1 L min<sup>-1</sup> flow rate. Note that the NDIR sensor measures negative values for a gas stream with no CO<sub>2</sub>.
