Interactive Discussion

Abstract

The simultaneous presence of SO₂ and ash in a volcanic plume can lead to a significant error in the SO₂ columnar abundance retrieval when multispectral Thermal InfraRed (TIR) data are used. The ash particles within the plume with effective radii (from 1 to 10 μm) reduce the Top Of Atmosphere (TOA) radiance in the entire TIR spectral range, including the channels used for SO₂ retrieval. The net effect is a significant SO₂ overestimation.

In this work the interference of ash is discussed and two correction procedures for satellite SO₂ volcanic plume retrieval in the TIR spectral range are developed to achieve an higher computation speed and a better accuracy.

The ash correction can be applied when the sensor spectral range includes the 7.3 and/or 8.7 μm SO₂ absorption bands, and the split window bands centered around 11 and 12 μm required for ash retrieval. This allows the possibility of a simultaneous estimation of both volcanic SO₂ and ash in the same data set. The proposed ash correction procedures have been applied to the Moderate Resolution Imaging Spectroradiometer (MODIS) and the Spin Enhanced Visible and Infrared Imager (SEVIRI) measurements. Data collected during the 24 November 2006 Mt. Etna eruption have been used to illustrate the technique. The SO₂ and ash estimations are carried out by using a least squares fit method and the Brightness Temperature Difference (BTD) procedures, respectively. The simulated TOA radiance Look-Up Table (LUT) needed for the SO₂ columnar abundance and the ash retrievals have been computed using the MODTRAN 4 Radiative Transfer Model.

The results show the importance of the ash correction on SO₂ retrieval at 8.7 μm – the SO₂ columnar abundance corrected by the ash influence is less than one half of the values retrieved without the correction. The ash correction on SO₂ retrieval at 7.3 μm is much less important and only significant for low SO₂ columnar abundances. Results also show that the simplified and faster correction procedure underestimates the ash correction compared with the more time consuming but more accurate correc-

tion procedure. Such underestimation is greater for instruments having better ground pixel resolution, i.e. greater for MODIS than for SEVIRI.

1 Introduction

Volcanic eruptions are by their nature unpredictable and can send large amounts (Tg) of gas and particles high into the troposphere and sometimes into the stratosphere. Volcanic clouds contain a mix of silicate-bearing ash particles in the size range 0.1 μm to mm size or larger and gases, principally H_2O , CO_2 , SO_2 and HCl. Interest in determining the abundances of these gases and also determining the microphysics of ash particles is high because of their effects on the environment (Thordarsson and Self, 2003), including the effects on climate (Robock, 2000), on public health (Horwell and Baxter, 2006) and because of the dangers of these substances to aviation (Casadevall, 1994). Satellites are useful for measuring volcanic clouds because of the large vertical range of these emissions and their likely large horizontal spread. Also, since volcanoes are globally distributed and inherently dangerous, satellite measurements offer a practical and safe platform from which to make observations.

Over recent years methods for deriving microphysical properties of volcanic clouds using satellite data have demonstrated that quantitative information of both ash and gas (SO_2) can be retrieved (Wen and Rose, 1996; Prata and Grant, 2001). These methods generally rely on using data in the infrared window region between 7–14 μm to determine column abundance of SO_2 and infrared optical depth, particle radius and mass concentration for ash particles.

The first types of satellite measurements of volcanic clouds used visible imagery to infer the spatial extent and movement of clouds. Infrared window (7–14 μm) measurements were used to derive cloud top temperatures and then cloud top height by assuming the clouds to be opaque and by using a nearby radiosonde measurement of the change of atmospheric temperature with height. With improvements in satellite instruments (more spectral channels, greater accuracy, better spatial resolution) it

Interactive Discussion

was demonstrated that two infrared channels centered near 11 and 12 μm could be used to uniquely identify silicate-bearing ash (Prata, 1989a,b). Further work (Wen and Rose, 1994; Prata and Grant, 2001) showed that by utilizing microphysical and radiative transfer models it was possible to retrieve fine-ash (1–10 μm , radius) particle size, optical depth and subsequently mass concentrations.

SO_2 is an important volcanic gas because of its effects on the environment (e.g. acid rain, effects on plants and public health) and also because once it is high in the atmosphere (>6 km) it can be transported over long distances, has a greater residence time and can be oxidized to form sulphates. The sulphates are capable of reflecting solar radiation and causing surface cooling (Robock, 2000). While it is well known that volcanic ash particles can have a deleterious effect on aircraft engines, the effects of SO_2 and sulphates on aircraft are not well understood. However, as SO_2 and ash are often emitted by an erupting volcano simultaneously, and as the winds can transport these substances together, a measurement of SO_2 can be used, in some circumstances, as a proxy for ash. This is particularly important for aviation, when the volcanic debris has been transported over long distances and the satellite-based ash detection signal is weak.

Progress on measuring volcanic gases from satellite measurements has been restricted mostly to SO_2 using ultra-violet and infrared measurements (e.g. Krotkov et al., 2006) and HCl using microwave measurements (Waters et al., 2006). Methods for determining SO_2 from satellite instruments are now quite mature and these measurements can be made with greater precisions and accuracies than those for volcanic ash. In this work we concentrate only on the infrared retrieval methods for SO_2 with the aim of improving the algorithms and an eventual goal of achieving accuracies comparable to those from using ultra-violet sensors (e.g. OMI and GOME-2).

There are three regions of the IR spectrum where SO_2 has strong absorption: 4.0, 7.3 and 8.7 μm . The absorption in the 4.0 μm region is weak and the retrieval is complicated by reflected solar radiation during the day. The 7.3 μm feature is the strongest SO_2 absorption, but retrieval in this regions is complicated by absorption and emis-

Interactive Discussion

sion from water vapour (Prata et al., 2003). The feature at $8.7\ \mu\text{m}$ is potentially the most useful because it lies within the atmospheric window where absorption by other gases, principally water vapour, is least. However, volcanic ash also absorbs radiation throughout the window region and there is likely to be interference between the absorption by ash and absorption by SO_2 . Realmuto et al. (1994), Watson et al. (2004) and Pugnaghi et al. (2005) have shown that this region can be used to infer SO_2 from volcanoes emitting low-level plumes, as well as SO_2 in violent eruptions which may also contain copious amounts of ash.

This paper addresses the issue of accurately determining the column abundance of SO_2 within a volcanic cloud by utilizing thermal infrared satellite measurements. In particular the focus of this work is to investigate the effect of ash on the retrieval of SO_2 in the 7.3 and $8.7\ \mu\text{m}$ wavelength region.

The paper is organized as follows: in Sect. 2 the motivation of the work is discussed. In Sect. 3 an overview of the SO_2 and ash retrieval schemes is presented and in Sect. 4 the ash correction procedures are described. Section 5 provides a description of the MODIS and SEVIRI satellite instruments used to make the measurements, illustrated in the test cases. We summarize our findings in Sects. 6 and 7.

2 Motivation of the work

During volcanic eruptions ash and SO_2 can be emitted simultaneously. The plume ash particles (from 1 to $10\ \mu\text{m}$) tend to reduce the Top Of Atmosphere (TOA) radiance in the entire TIR spectral range (7 – $14\ \mu\text{m}$), including within the channels used for the SO_2 retrieval. The result is a significant SO_2 columnar abundance overestimation. Figure 1 shows the comparison between the TOA background radiance (blue line), the TOA radiance computed considering a volcanic SO_2 plume with $5\ \text{g m}^{-2}$ (green line) and the TOA radiance considering a plume containing both SO_2 ($5\ \text{g m}^{-2}$) and ash (aerosol optical thickness $\tau=1$ and effective radius $r_e=2.34\ \mu\text{m}$) (red line). All the simulations have been performed using the MODTRAN 4 Radiative Transfer Model (RTM) (Berk et

Interactive Discussion

al., 1989; Anderson et al., 1995) considering a surface temperature and emissivity of 292 K and 0.99, respectively, a plume-top altitude of 5000 m and a plume thickness of 1000 m. The other curves plotted are the MODIS-Aqua TIR slit functions; the yellow and purple lines represent the bands used for the SO₂ and ash retrieval respectively.

As Fig. 1 shows, the presence of ash produces a significant radiance decrease not only in 10–13 μm spectral range, but over all the TIR spectral range and in particular on the 8.7 μm channel. The same observations can be made by analyzing the Fig. 2 that shows the radiance percentage differences convolved with the MODIS-Aqua slit functions – the percentage radiance is computed considering the TOA background radiance and the TOA radiance of a volcanic SO₂ plume for different values of SO₂ columnar abundance (top plate), and the TOA radiance of a volcanic ash plume for different values of τ (assuming r_e=2.34 μm) (bottom plate). Comparing the top and bottom plates it can be seen that the radiance percentage difference variation on the 8.7 μm channel with τ=0.5 is comparable to the percentage difference for an SO₂ columnar abundance variation of 5 g m⁻². At 8.7 μm an ash plume with r_e=2.34 μm and τ=0.5 produces the same TOA radiance variation as an SO₂ plume with 5 g m⁻². The effect of ash at 7.3 μm is much less important and the radiance percentage difference results are always less than 3% for all the simulations considered. Therefore the ash correction can produce effects only for low SO₂ columnar abundance values.

In this work two different procedures for SO₂ volcanic plume retrieval in the TIR spectral range have been developed in order to correct for the effect of ash. The two procedures address the requirements of high speed of computation (*meanval-procedure*) and of accuracy (*pixval-procedure*). The ash corrections have been applied to MODIS and SEVIRI measurements collected during the November 2006 Mt. Etna volcanic eruption.

3 Retrieval schemes

3.1 SO₂ retrieval

In the TIR spectral range, SO₂ has two wide absorption bands centered around 7.3 and 8.7 μm (see left plate of Fig. 3). Due to the strong presence of atmospheric water vapour (see right plates of Fig. 3) the 7.3 μm band is generally used when the volcanic plumes rise over 3–4 km, i.e. above the most of the water vapour. The 8.7 μm channel lies in a relatively transparent region and can be used to retrieve SO₂ in the lower troposphere. The 8.7 μm SO₂ retrieval scheme has been described by Realmuto et al. (1994), Watson et al. (2004) and Pugnaghi et al. (2005) respectively for TOMS, MODIS and ASTER, while the 7.3 μm retrieval procedure was described by Prata et al. (2003) for the TOVS/HIRS sensors, and by Prata and Bernardo (2007) for the high spectral resolution AIRS sounder.

In this work the SO₂ columnar abundance, on both the 7.3 and 8.7 μm channels is retrieved from a pixel-by-pixel least squares fit procedure using satellite sensor measurements and simulated radiances. The function being minimized may be written,

$$\chi_{c_s}^2(n, m) = \sum_{j=1}^k \left[\frac{R_{m,j}^{(n,m)} - R_{s,j}(c_s)}{R_{m,j}^{(n,m)}} \right]^2 w_j \quad (1)$$

where:

k is the number of channels (j) used for the minimization,

$R_{m,j}^{(n,m)}$ is the j -th channel measured radiance for the pixel (n, m) ,

$R_{s,j}(c_s)$ is the j -th channel simulated radiance varying the SO₂ columnar abundance c_s , and

w_j is the j -th channel weight.

The simulated radiances are computed by using MODTRAN 4 Radiative Transfer Model (RTM) (see Sect. 3.3).

Interactive Discussion

3.2 Ash detection and retrieval

Ash detection is carried out by using the Brightness Temperature Difference (BTD) procedure (Prata, 1989a, b) applied to channels centered around 11 and 12 μm while effective radius and aerosol optical thickness at 0.55 μm have been retrieved from the “inverted arches” of the BTD vs. brightness temperature at 11 μm curves by varying τ and r_e (Wen and Rose, 1994; Prata and Grant, 2001; Yu et al., 2002; Ellrod et al., 2003). To take into account the atmospheric water vapour absorption in the 11–12 μm spectral range, a water vapor correction procedure has also been applied (Corradini et al., 2007). Using the τ and r_e retrievals, the pixel-by-pixel mass is computed by using the simplified formula suggested by Wen and Rose (1994),

$$M(n, m) = \frac{4 S \rho r_e^{(n,m)} \tau^{(n,m)}}{3 Q_{\text{ext}}(r_e^{(n,m)})} \quad (2)$$

where:

S is the pixel surface,

ρ is the particle density,

$r_e^{(n,m)}$ is the effective radius of pixel (n, m) ,

$\tau^{(n,m)}$ is the aerosol optical thickness of pixel (n, m) , and

$Q_{\text{ext}}(r_e^{(n,m)})$ is the extinction efficiency factor at effective radius $r_e^{(n,m)}$.

Also in this case, the simulated radiances needed for the ash retrievals have been computed using the MODTRAN RTM (see the next section).

3.3 Look-up table generation

The simulated TOA radiances Look-Up Table (LUT) used for both SO_2 and ash retrievals derives from the MODTRAN 4 RTM. The simulations have been performed using as input the atmospheric profiles (pressure, temperature and humidity), the surface characteristics (temperature and emissivity), the plume geometry (plume altitude and

Interactive Discussion

thickness) and the volcanic ash optical properties. The ash optical properties (single scattering albedo, extinction coefficient and asymmetry parameter) have been computed using the Mie code developed by the Earth Observation Data Group (EODG) of the Atmospheric Oceanic and Planetary Physics Department (Oxford University) considering the andesite refractive index (Pollack et al., 1973) and a log-normal distribution. The TOA radiance LUT are computed for 21 values of SO_2 columnar abundance (from 0 to 10 g m^{-2} , step 0.5 g m^{-2}), 21 values of aerosol optical thickness (from 0 to 10 in steps of 0.5) and 8 values of effective radii (from 0.4 to $10 \mu\text{m}$, with a constant step in a logarithmic scale). This gives a total of 3528 simulations ($R_{s,i}(c_s, \tau, r_e)$).

4 Ash correction procedures

The ash correction procedures for the SO_2 columnar abundance retrieval consist of three different steps:

1. SO_2 columnar abundance and ash are retrieved simultaneously and independently. The SO_2 columnar abundance maps at 7.3 and $8.7 \mu\text{m}$, the aerosol mass, τ and r_e maps, and also the mean values of τ and r_e of the plume are retrieved. In this step, the SO_2 retrievals are obtained while not considering the influence of ash on these channels, i.e. using the terms $R_{s,i}(c_s, 0, 0)$ for the simulated TOA radiances.
2. The plume pixels containing both SO_2 and ash are identified by the intersection between the SO_2 and ash retrieval pixel ensembles.
3. The SO_2 retrieval on both 7.3 and $8.7 \mu\text{m}$ channels is carried out again only for the SO_2 and ash intersection ensemble of pixels. The *meanval-procedure* uses the radiances computed by interpolation of the mean aerosol optical thickness ($\bar{\tau}$) and mean effective radius (\bar{r}_e) as simulated radiances, i.e. using the terms $R_{s,i}(c_s, \bar{\tau}, \bar{r}_e)$ as simulated TOA radiances.

Interactive Discussion

**Ash correction
procedure for the TIR
SO₂ retrieval**

S. Corradini et al.

The *pixval-procedure* uses as simulated radiances the radiances computed by interpolation of the aerosol optical thickness ($\tau^{(n,m)}$) and effective radius ($r_e^{(n,m)}$) for each identified pixel (n, m), i.e. using as simulated TOA radiances the terms $R_{s,i}(C_s, \tau^{(n,m)}, r_e^{(n,m)})$.

The *meanval-procedure* is faster because the interpolation is computed once for all pixels, while using the *pixval-procedure* the interpolation is computed for each pixel; for this reason the latter procedure results are more accurate.

5 Satellite instruments and data set

The satellite sensors for which the ash correction procedure can be applied are those having the 7.3 and/or 8.7 μm SO₂ absorption channels, and the channels centered around 11 and 12 μm used for the ash retrievals. In this work the ash correction procedures have been applied to the TIR images of the MODIS and SEVIRI instruments collected over Mt. Etna volcano during the November 2006 eruption.

5.1 MODIS

MODIS is a multispectral instrument with 36 spectral bands in the wavelength range from visible to thermal infrared. MODIS is aboard the NASA Terra and Aqua polar satellites, launched in 1999 and 2002 respectively, as part of the Earth Observing System (EOS) mission (Barnes et al., 1998; <http://modis.gsfc.nasa.gov/>). Terra's descending node (from north to south) crosses the equator in the morning at about 10:30 a.m. (local time), while the Aqua ascending node (south to north) crosses the equator at about 1:30 p.m. (local time). MODIS has a spatial resolution of 1000 m for the TIR bands used in our study. Bands 28 and 29 centered around 7.3 and 8.7 μm are used for the SO₂ columnar abundance retrieval while bands 31 and 32, centered around 11 and 12 μm , are used for the ash detection and retrievals. The Noise Equivalent Temperature Difference (NE Δ T) is 0.05 K for all SO₂ and ash bands except for the channel 28 (7.3 μm)

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

band), which is 0.25 K (<http://modis.gsfc.nasa.gov/>). The sensor scans $\pm 55^\circ$ across-track about the nadir from the EOS orbit altitude of 705 km, resulting in a 2330 km swath and full global coverage every one to two days.

5.2 SEVIRI

5 SEVIRI is the main sensor of the Meteosat Second Generation (MSG) satellite. The MSG platform is a geosynchronous satellite launched on 28 August 2002 (<http://www.eumetsat.int>). The orbit altitude is 42 000 km (measured from the center of the Earth) with a period of 24 hours and a nadir point of approximately 3° W over the equator. SEVIRI is a 50 cm diameter aperture, line-by line scanning radiometer which
10 provides images data in four Visible and Near InfraRed (VNIR) channels and eight infrared (IR) channels. The VNIR channels include the High Resolution Visible (HRV) channel which contains 9 broadband detection elements to scan the Earth with 1 km of spatial resolution. All the other channels (including the IR channels) are designed with
15 3 narrow band detection elements per channel, to scan the Earth with a 3 km spatial resolution. Its main advantage is the repeat cycle of 15 min, which includes on board calibration time, the retrace and the overall satellite stabilization process. Bands 6 and 7 (centered around 7.3 and 8.7 μm) and bands 9 and 10 (centered around 10.8 and 12 μm) are used for the SO_2 and ash retrievals, respectively. The Noise Equivalent Temperature Difference (NE Δ T) varies from 0.11 K (bands 7 and 9) to 0.16 K (bands 6 and 10). SEVIRI's characteristics allow high temporal resolution retrievals, which are
20 very useful in the study of the evolution of volcanic plumes.

5.3 Test case measurements

25 Mt. Etna is located in the eastern part of Sicily (Italy) (see Fig. 4) and is one the major degassing volcanoes in the world (Allard et al., 1991). Etna's general quiescent state is periodically interrupted by eruptive crises, during which significant SO_2 and ash emissions can reach the area surrounding the volcano, causing problems to the population

Interactive Discussion

of the region (Andronico et al., 2005) and to air traffic (Catania and Reggio Calabria airports are nearby). During 2006 Mt. Etna exhibited episodic explosive activity producing SO₂ and ash plumes that rose up into the atmosphere and drifted several km away from the vent. These episodes occurred frequently from September to December (Spinetti et al., 2006; De Beni et al., 2006) showing weak intensity and short duration compared to previous 2001 and 2002 eruptions (Andronico et al., 2005; Behncke et al., 2003). The 24 November 2006 SO₂ and ash emission started at about 04:00 and 09:00 UTC respectively and ended simultaneously at about 15:00 UTC. The eruption took place both at the summit and the south east crater of Mt. Etna and produced the largest volume of ash in the entire September–December eruptive period. On this day the wind was blowing from the NNW direction causing the ash plume to move towards the city of Catania. The ash fallout created major problems for the Fontanarossa International Airport of Catania which was subsequently closed to air traffic. In this work the SEVIRI and MODIS images collected the 24 November at 12:15 and 12:20 UTC respectively are considered as a test case. Figure 5 shows the RGB and channel 11 μm images (left and right plates) for MODIS and SEVIRI (top and bottom plates) instruments.

6 Results and discussion

In this section the characteristics of the MODTRAN simulations and the details of the ash correction procedures applied to the MODIS and SEVIRI measurements are presented.

6.1 Characteristics of MODTRAN simulations

As described in Sect. 3.3 the simulated TOA radiances have been performed using as input the atmospheric profiles, the plume geometry, the surface characteristics, and the ash optical properties. The 24 November 2006 atmospheric vertical profiles derived from Trapani WMO Meteo station (the nearest WMO station to the Etnean area)

procedure for the TIR
SO₂ retrieval**S. Corradini et al.

were measured at 12:00 UTC. The plume-top altitude is estimated by comparing the ash plume top temperature, computed as the mean brightness temperature of channels centered around 11 and 12 μm of the most opaque plume region (near the vent), and the Trapani radiosounding temperature profile. The procedure gives a plume-top height of about 5000 m which is consistent with independent observations (Spinetti et al., 2006). The plume thickness has been assumed to be 1000 m. For both of the images, the processing has been applied only over the sea. The sea surface emissivity was estimated from a convolution between the ASTER spectral emissivity library database (<http://speclib.jpl.nasa.gov/>) and the MODIS and SEVIRI slit functions. The convolution gives the same emissivity values for both instruments (see Table 1). The sea surface temperature has been retrieved by inversion of the radiative transfer equation in the TIR spectral range, using the channels centered around 11 and 12 μm . The volcanic plume is not transparent in these channels, therefore the surface temperature estimation under the plume is not possible. The sea surface temperature below the plume has been assumed as the mean temperature of two wide regions selected just outside the plume area (see Corradini et al., 2007). The mean sea surface temperature retrieved for both MODIS and SEVIRI is $291.5 \text{ K} \pm 1 \text{ K}$.

6.2 MODIS image elaboration

6.2.1 First step: Ash and SO₂ retrievals

In the first step the simultaneous retrieval of SO₂ and ash is carried out. The SO₂ retrieval is obtained without considering the influence of ash on MODIS channels 28 and 29. Figure 6 shows the ash (top plates) and SO₂ (bottom plates) retrievals using MODIS data. The top left and top right plates show the ash aerosol optical thickness at 0.55 μm and the effective radius maps, while the bottom left and bottom right plates show the SO₂ retrievals at 7.3 and 8.7 μm respectively. The top left plate shows that larger τ occur in the area close to the vent, while the smaller values occur at the cloud edges. There are also other regions of high τ probably due to volcanic puffs. The parti-

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

**Ash correction
procedure for the TIR
SO₂ retrieval**S. Corradini et al.

cle effective radii (top right plate) are distributed non-uniformly along the plume: larger particles (up to 5 μm) thicken around the western part of the plume. The total mass, mean τ and mean effective radius are: 3145 tons, 0.31 and 3.06 μm respectively. Figure 7 shows the τ and r_e histograms and mean values. The SO₂ columnar abundance maps indicate a meaningful underestimation of the 7.3 μm retrieval compared to the 8.7 μm retrieval, the total masses computed are: 841 and 18 728 tons respectively. The main reasons for these differences are that the ash influence is stronger on the 8.7 μm channel compared with the 7.3 μm channel (see Sect. 2). The ash absorption that leads to the SO₂ retrieval overestimation is stronger at 8.7 μm than at 7.3 μm . A second reason for the differences is that atmospheric water vapour absorption is not negligible in the altitude range where the plume has been modeled (between 4000 and 5000 m). The 7.3 μm MODIS SO₂ estimation has been compared with the Atmospheric Infrared Sounder (AIRS) retrieval. AIRS is a grating spectrometer operating at IR wavelengths between 3.7 and 15.4 μm (2378 channels) with a scanning of $\pm 49^\circ$ from nadir and an instantaneous field of view of 1.1° providing nadir pixels with dimensions $15 \times 15 \text{ km}^2$ (Chahine et al., 2006). The instrument is aboard the EOS-Aqua polar orbiting satellite. Figure 8 shows the AIRS SO₂ retrieval, using the 7.3 μm absorption band (Prata and Bernardo, 2007), for an image collected over Etna volcano on 24 November 2006 at 12:17 UTC. The SO₂ total mass retrieved by AIRS is 800 tons; this is a good match to the 7.3 μm SO₂ retrieval obtained from MODIS data.

6.2.2 Second step: Ensemble intersection

In the second step, the intersection between the SO₂ and ash maps is evaluated to obtain the ensemble of pixels containing both SO₂ and ash. The blue pixels of Fig. 9 represent pixels with ash and SO₂, while the green and red pixels are the pixels containing only ash and only SO₂, respectively.

6.2.3 Third step: Ash corrections

Figure 10 shows the SO₂ retrievals (7.3 and 8.7 μm) after the ash correction using both the *meanval* and *pixval* procedures. The top and bottom plates are the 7.3 and 8.7 μm SO₂ corrected images while the left and right plates are the images corrected by using the *meanval-procedure* and the *pixval-procedure* respectively. The left plates show that the *meanval-procedure* tends to overestimate the correction for the pixels having τ and r_e less than the mean values and underestimate the correction for all the other pixels. The *pixval-procedure* (right plate of Fig. 10) produces a more uniform SO₂ map. As Table 2 shows, and as expected, the correction procedure is greater at 8.7 μm than at 7.3 μm. The total mass of SO₂ retrieved at 8.7 μm is less than one half of the total mass retrieved without correction. The variation of the total mass retrieved at 7.3 μm (see Table 2) is much less important even if the ash correction is not negligible because the SO₂ columnar abundance retrieved values are low (see Sect. 2). Table 2 also shows that the SO₂ total mass computed using the *pixval-procedure* is significantly lower than the total mass computed using the *meanval-procedure*. The ash correction procedures allow also to define a criteria for the identification of opaque pixels (white pixels in Fig. 10). For these pixels the following inequality is true,

$$R_{m,j}^{(n,m)} < \min[R_{s,j}^*(c_s)] \quad (3)$$

where the $R_{s,j}^*(c_s)$ represents the simulated radiances considering the two procedures. When the radiance measured is less than the minimum corrected simulated radiance (correspondent to the maximum values of SO₂ columnar abundance considered), the SO₂ retrieval is not possible. This doesn't mean that the pixel doesn't contain any SO₂, but only that the SO₂ retrieval is not well-posed. The gas/ash flux can be calculated by multiplying the integral of the column abundance, performed along each transect perpendicular to the plume axis (see small panel to the bottom right corner of Fig. 11), by the wind speed. The wind speed (6 ms⁻¹) was extracted from the Trapani atmospheric profile at the mean plume altitude (4500 m a.s.l.). Note in particular the big difference

between the $8.7\ \mu\text{m}$ SO_2 flux before and after the correction. Figure 11 shows the fluxes along the plume axis computed for the SO_2 retrievals at 7.3 and $8.7\ \mu\text{m}$ before (pale red and pale blue lines respectively) and after the pixel ash correction (red and blue lines respectively). The green line represents the ash flux.

5 6.3 SEVIRI image elaboration

6.3.1 First step: Ash and SO_2 retrievals

The simultaneous retrieval of SO_2 and ash is carried out and the SO_2 retrieval is obtained without considering the ash influence on SEVIRI channels 6 and 7. Figure 12 shows the ash (top plates) and SO_2 (bottom plates) retrievals using SEVIRI data: the top left and top right plates show the aerosol optical thickness at $0.55\ \mu\text{m}$ and the effective radius maps, while the bottom left and bottom right plates show the SO_2 retrievals at 7.3 and $8.7\ \mu\text{m}$ respectively. Taking into account the different ground spatial resolution, the MODIS and SEVIRI ash retrievals maps (compare Fig. 12 and Fig. 6) present a good match because the same structures are identifiable (τ and non uniform particle, r_e distribution). Even though the mean τ (0.27) and the mean r_e ($3.31\ \mu\text{m}$) retrieved (see Fig. 13) are in good agreement with the same quantities retrieved by MODIS, the total mass is significantly lower (1815 tons) than the total mass retrieved by MODIS (3145 tons). This can be explained considering that SEVIRI has a higher NE Δ T (i.e. lower sensitivity), and smaller ground pixel resolution than the MODIS instrument. Figure 12 shows that in this case SEVIRI fails in the SO_2 retrieval at $7.3\ \mu\text{m}$ – the SO_2 columnar abundance retrievable on this channel yields a radiance variation that is less than the instrument sensitivity. The $8.7\ \mu\text{m}$ SO_2 retrieval is significantly lower (13275 tons) than the MODIS SO_2 retrieval because of the lower NE Δ T.

Interactive Discussion

6.3.2 Second step: Ensemble intersection

The intersection between the SO₂ and ash maps is displayed in Fig. 14 . Here again the yellow pixels represent the intersection between the sets of pixels where SO₂ and ash have been retrieved separately in step one, while the green and red pixels are the pixels containing only ash or only SO₂, respectively.

6.3.3 Third step: Ash correction procedures

For all the pixels of the intersection ensemble, the SO₂ retrieval is carried out again using the *meanval-procedure* and the *pixval-procedure*. Figure 15 shows the SO₂ retrievals at 8.7 μm after the ash correction. The left and right plates are the images corrected by using the *meanval-procedure* and the *pixval-procedure* respectively. Also in this case the SO₂ total mass at 8.7 μm is less than half of the total mass retrieved without correction (see Table 3). Table 3 highlights the fact that the SO₂ total mass computed using the *pixval-procedure* is significantly lower than the total mass computed using the *meanval-procedure*, even though the percentage difference variation due to the ash correction is lower than that computed in the MODIS data. The reason for this is that SEVIRI has a lower ground pixel resolution than MODIS. In the limit of an instrument having only one big pixel, the results of the two different procedures must be the same. Also in this case the white pixels of the Fig. 15 are the opaque pixels, identified by means of Eq. (3). The gas/ash fluxes computed along the SO₂ and ash retrieved plumes are plotted in Fig. 16. The fluxes were obtained using the same wind speed (6 ms⁻¹) as for MODIS. Note in particular the significant difference between the 8.7 μm SO₂ flux before and after the correction when ash is present.

7 Conclusions

The interference of ash on the SO₂ retrieval from TIR multispectral data of volcanic plumes has been demonstrated and analyzed. To compensate for the ash effect two

Interactive Discussion

correction procedures for the SO₂ retrieval have been developed. A necessary condition for the application of the procedures is a sensor spectral range that includes a channel for the SO₂ retrievals, and also the split window bands centered around 11 and 12 μm required for the ash retrieval.

5 The two procedures satisfy the requirements of high computation speed (*meanval-procedure*) and accuracy (*pixval-procedure*) and are based on three different steps. In the first step the SO₂ columnar abundance and ash retrievals are computed simultaneously and independently (the SO₂ retrieval is obtained without considering the influence of ash). In the second step plume pixels containing both SO₂ and ash are
10 identified. In the third step, only for these pixels, is the SO₂ columnar abundance computed again with the ash correction. The two procedures differ in this final step in considering as simulated TOA radiances, the radiance interpolated using the mean aerosol optical thickness and mean effective radius retrieved over the whole image (*meanval-procedure*), and the radiance interpolated using the aerosol optical thickness
15 and effective radius of each identified pixel (*pixval-procedure*).

All the radiance simulations utilize the MODTRAN 4 RTM. Together with the ash correction, a criteria for the identification of the opaque pixels has also been described. As a test case MODIS and SEVIRI data collected on Mt. Etna volcano during the
20 November 2006 eruption are presented. The results show the importance of the ash correction on SO₂ retrieval at 8.7 μm for both MODIS and SEVIRI. The 8.7 μm SO₂ total mass corrected by the ash influence is one half and one third of the values retrieved without correction for *meanval-procedure* and *pixval-procedure*, respectively. The ash correction on the SO₂ retrieval at 7.3 μm is much less important and need only be
25 considered for low SO₂ columnar abundances. The SEVIRI SO₂ and ash total masses retrieved are significantly lower than the SO₂ retrieved by MODIS. The possible cause, apart from the different ground pixel resolutions, is the lower MODIS NEΔT for the channels used in the retrievals. The results show also that the faster and simplified *meanval-procedure* underestimates the ash correction compared to the more accurate *pixval-procedure*. Such underestimation is greater for an instrument having greater

ground pixel resolution, i.e. the difference between the SO₂ total mass retrieved by the two procedures is greater for MODIS than for SEVIRI. Both correction procedures highlight that the amount of SO₂ retrieved is significantly overestimated if the effect of volcanic ash is neglected.

**Ash correction
procedure for the TIR
SO₂ retrieval**

S. Corradini et al.

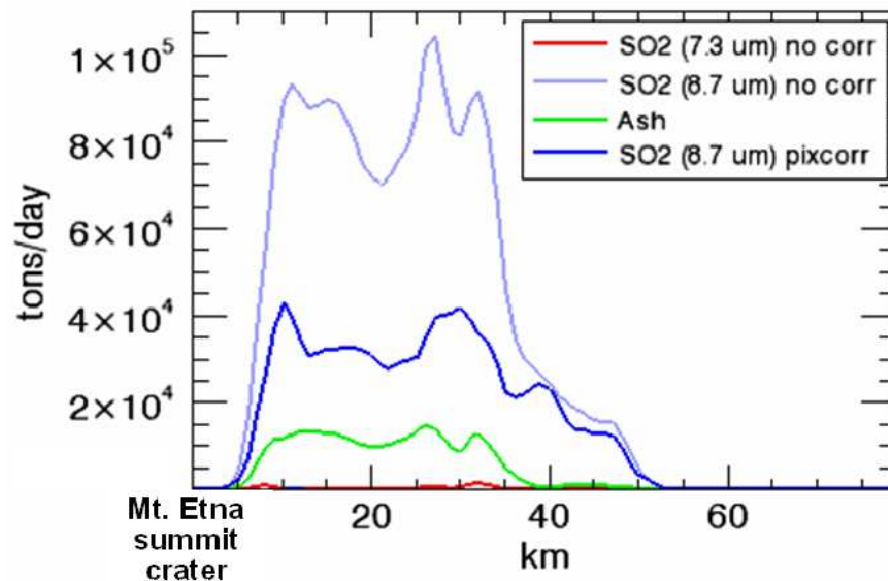

Fig. 16. SO₂ and ash flux derived from the SEVIRI image. The pale red and pale blue lines represents the SO₂ flux at 7.3 and 8.7 μm respectively before the correction, the red and blue lines represents the SO₂ flux at 7.3 and 8.7 μm after the pixval correction and the green line is the ash flux.
