A single particle instrument has been developed for real-time analysis of organic aerosols. This instrument, named Single Particle Laser Ablation Mass Spectrometry (SPLAM), samples particles using an aerodynamic lens system for which the theoretical performances were calculated. At the outlet of this system, particle detection and sizing are realized using two continuous diode lasers operating at  $\lambda = 403 \,\mathrm{nm}$ . Polystyrene Latex (PSL), sodium chloride (NaCl) and dioctylphtalate (DOP) particles were used to characterize and calibrate optical detection of SPLAM. The optical detection limit (DL) and detection efficiency (DE) were determined using size-selected DOP particles. The DE is ranging from 0.1 to 90 % for 100 and 350 nm DOP particles respectively and the SPLAM instrument is able to detect and size-resolve particles as small as 110-120 nm. Scattered light is detected by two photomultipliers and the detected signals are used to trigger a UV excimer laser ( $\lambda = 248 \, \text{nm}$ ) used for laser desorption ionization (LDI) of individual aerosol particles. The formed ions are analyzed by a 1 m linear time-of-flight mass spectrometer in order to access to the chemical composition of individual particles. The TOF-MS detection limit for gaseous aromatic compounds was determined to be 0.85 attograms. DOP particles were also used to test the overall functioning of the instrument. The analysis of a secondary organic aerosol, formed in a smog chamber by the ozonolysis of indene, is presented as a first scientific application of the instrument. Single particle mass spectra are obtained with a global hit rate of 10%. They are found to be very different from one particle to another, reflecting chemical differences of the analyzed particles, and most of the detected mass peaks are attributed to oxidized products of indene.

## 1 Introduction

Atmospheric aerosols are known to impact on human health (Vedal et al., 2006), atmospheric chemistry and climate (IPCC, 2007). These effects, which depend strongly

Interactive Discussion

on the aerosol's chemical composition, are still poorly understood. This is partly due to the incomplete characterization of the aerosol's chemical composition, in particular its organic fraction (Kanakidou et al., 2005).

Organic aerosols (OA) can be separated into primary organic aerosols (POA), di-5 rectly emitted in the atmosphere, and secondary organic aerosols (SOA), formed by gas-to-particle conversion after atmospheric oxidation of anthropogenic and biogenic volatile organic compounds (VOC). Due to the large number of implicated molecules and to the diversity of their chemical functionalities and physico-chemical properties, the chemical composition of the organic fraction is complex. Moreover, complex processes such as SOA formation, cloud-aerosol interactions and atmospheric ageing remain poorly understood, partly because of the difficulty to describe the organic aerosol composition.

In this context, two main types of methods were adapted or developed to analyze OA and improve our knowledge of its composition and evolution. On the one hand, offline analytical techniques are used to elucidate these processes down to the molecular level. However, due to the complexity of the aerosol chemical composition, only a reduced fraction (up to 30 %) of the collected and extracted mass is identified on a molecular level (Cocker et al., 2001). Furthermore, these techniques are limited by a low temporal resolution because of the time needed to collect a sufficient amount of sample for analysis. On the other hand, real-time techniques (temporal resolution < 1 min), such as aerosol mass spectrometers (Sullivan and Prather, 2005), are also used to get a better understanding of the chemical processes, such as, for example SOA formation (Bahreini et al., 2005; Alfarra et al., 2006).

The ideal instrument as proposed by Jimenez et al. (2004) would meet all these requirements and allow for both a high temporal resolution and an access to the chemical speciation at the molecular level for each individual sampled particle. Due to their operating principle, aerosol mass spectrometers seem well suited to access to such analysis. They are generally composed by three operating parts: (1) a particle sampling interface, (2) an optical detection/sizing region, and (3) a mass spectrometer.

Interactive Discussion

A large number of techniques have been implemented in the development of aerosol mass spectrometers capable of determining the size, the morphology, the optical properties, or the elemental and molecular composition of particle in real time. Davis (1973) was the first to develop a thermal desorption aerosol mass spectrometer. In this instrument, aerosols are sampled through a steel capillary, impact on a heated surface (up to 1700°C) and are flash-evaporated as an ionized gas that is then analyzed by a magnetic sector analyzer. Other surface ionization instruments were developed using quadrupole mass spectrometers (Lassiter and Moen, 1974; Myers and Fite, 1975) which are only capable of studying one m/z at a time. During the 1980's, this one-step vaporization/ionization technique has evolved to become a two-step technique by coupling a flash vaporization, at lower temperatures, to electron impact ionization of the vaporized species (Allen and Gould, 1981; Sinha et al., 1982). Nowadays, the commercially available Aerodyne Aerosol Mass Spectrometer (AMS) still uses this scheme (Jayne et al., 2000; Drewnick et al., 2005; Canagaratna et al., 2007). In the same way. Tobias and Ziemann (1999) used a Temperature-Programmed Thermal Desorption Particle Beam Mass Spectrometry (TDPBMS) to achieve successive vaporization of components according to their vapor pressures such as for SOA formed in a smog chamber (Tobias et al., 2000). Thereafter, Atmospheric Pressure Chemical Ionization Mass Spectrometry (APCI-MS) (Hoffmann et al., 2002) has been used as a soft ionization technique, compared to electron impact, and several m/z could be scanned at a time using an ion trap mass spectrometer.

Knowing that thermal desorption allows analyzing many particles simultaneously, the development of laser aerosol mass spectrometry techniques was an opportunity to obtain single particle information in real time (Prather et al., 1994; Weiss et al., 1997). Aerosols, focused into the mass spectrometer for example by an aerodynamic lens system (ALS), are detected by one or two continuous wave (cw) lasers. They are perpendicularly crossed to the particle beam and are mostly operated in the visible spectral range. In the case of two detection lasers, particles can be aerodynamically sized by measuring their travel time between both laser beams. The measured particle

Interactive Discussion

velocity can then be used easily to calculate the necessary time delay to trigger a pulsed laser (IR or UV) for individual particle desorption and ionization. The formed ions are then detected by mass spectrometry. This kind of technique is able to give physical and chemical properties of individual particles in real time. It was firstly introduced by Sinha (1984), who used Nd:YAG laser pulses at 266 nm for the particle desorption/ionization step and a quadrupole mass spectrometer for the chemical analysis. Other laser-based single particle mass spectrometers were developed later by the Prather group (Prather et al., 1994; Nordmeyer and Prather, 1994; Noble et al., 1994).

The real power of this technique came up by combining the laser desorption/ionization (LDI) step with Time-of-Flight mass spectrometry (TOF-MS) for ion analvsis (McKeown et al., 1991). Because of its pulsed mode of operation, TOF-MS is ideally suited to be linked to a pulsed desorption/ionization method. Note that only the power density (in W m<sup>-2</sup>) of a nanosecond laser pulse is high enough to provide substantial and rapid desorption of molecules from solid material. Other advantages of TOF-MS are its ability to obtain an entire mass spectrum on the order of microseconds, the theoretical unlimited mass range and its ion transmission efficiency close to 100%, independent of mass. Several groups designed such single particle instruments and they have been used to address a large variety of scientific cases (Hinz et al., 1994; Murphy and Thomson, 1995; Carson et al., 1995; Reents et al., 1995; Noble and Prather, 1996; Weiss et al., 1997; Gard et al., 1997; Murphy et al., 1998; Woods et al., 2001; Hunt and Petrucci, 2002). Besides the simultaneous sizing and chemical composition analysis, real time single particle techniques are able to provide information for each sampled particle.

One short-coming of the LDI technique is the fragmentation of organic molecules since the number of photons absorbed by a specific molecule during the LDI process cannot be efficiently controlled and thus dissociative ionization is not avoidable. Molecular speciation is difficult to achieve in these conditions. However, we note that interesting results relevant for the investigation of OA chemistry, as for example the

Interactive Discussion

identification of oligomeric species or the chemical characterization of different types of SOA, can nevertheless be obtained with an LDI instrument (Gross et al., 2006; Huang et al., 2007).

One way to overcome the fragmentation problem is to use Two-Step Laser Desorp-5 tion/lonization (L2DI) where vaporization and ionization are separated in time by a few microseconds. The first vaporization step can be achieved without ionizing the parent molecules which permits to reduce the UV laser power density for the second step in order to ionize molecular species near their ionization thresholds by, for example, Resonant-Two Photon Ionization (R2PI) or Single Photon Ionization (SPI) with VUV laser radiation or synchrotron radiation. Single particle L2DI was investigated by the T. Baer and K. Prather groups in the early 2000's who successfully studied micrometer sized droplets consisting of pure substances (Morrical et al., 1998; Cabalo et al., 2000; Woods et al., 2001; Smith et al., 2002). Single-particle L2DI was also used successfully to identify molecular tracers of different type of real-world traffic-related and wood combustion aerosols such as polycyclic aromatic hydrocarbons (Bente et al., 2008, 2009). These results have shown that single particle L2DI can be achieved yielding fragmentfree mass spectra. However, it is still a real analytical challenge to adapt and apply this technique for an exhaustive investigation of the chemical analysis of OA particles containing a complex mixture of species that easily undergo dissociative ionization.

In this paper, we present a newly built real-time single-particle aerosol mass spectrometer, named "SPLAM" for Single-Particle Laser Ablation Mass Spectrometry. This LDI-based instrument has been developed in our laboratory to sample, detect, determine the size and analyze organic single particle in real time. The development and characterization of the ALS, the optical detection system, the TOF-MS, and the triggering process are outlined. As a first application, we present results obtained for the analysis of a SOA produced in the laboratory from ozonolysis of indene in CESAM simulation chamber in LISA (Wang et al., 2011).

# System design

The SPLAM instrument is composed of three main parts (Fig. 1): (1) an aerodynamic focusing lens system to sample and introduce the particles into the vacuum system by forming a beam of very low divergence, and two differentially pumping stages; (2) the optical detection/aerodynamic particle sizing region which permits the determination of the aerodynamic diameter of the detected particles and the synchronization with the third part of the instrument and; (3) the chemical characterization region which consists of a vaporization/ionization region and a linear time-of-flight mass spectrometer with 1 m field free drift region. The TOF-MS with its aerosol inlet is very compact and mounted on a scientific table with rolls. It can thus be moved easily. This table is mechanically separated from the laser sources of SPLAM which are all placed on an additional 1.2 × 2.2 m optical table (Newport). Each part of the instrument is presented in the next sections.

# The aerodynamic lens system

Aerosol mass spectrometry relies on the capability to bring particles into a high vacuum system and to focus them spatially into the ion source of a mass spectrometer. For this purpose, the aerodynamic lens system developed initially in Peter McMurry's group (Liu et al., 1995a,b) has been widely used by many groups and for many different applications. Concerning the SPLAM instrument, a new ALS was designed using the theoretical model and operational software described by Wang et al. (2005a,b, 2006). The following criteria have been considered: (1) transmission of a broad diameter range (100 to 2000 nm) corresponding to the size range of atmospheric aerosol containing the highest organic fraction (Zhang et al., 2007), (2) good transmission efficiency with low beam divergence, and (3) acceleration of particles to a specific speed in function of their diameters (100 to  $150 \,\mathrm{m \, s}^{-1}$ ).

Our lens system has been exactly machined according to the dimensions calculated by Wang's design tool (1/10 mm precision for orifices, 1/100 mm precision for

Interactive Discussion

the alignment). A technical drawing in real scale is presented in Fig. 2. Our ALS is composed of five orifices mounted in a precision stainless steel tube and starting from 6.93 mm at the inlet and gradually decreasing to 3.11 mm at the exit, all separated by 90 mm spacers. Note that these orifices can be exchanged if different lens prop-5 erti µm critical orifice (Microcontrole) into the aerodynamic lens. The volume flowrate has been measured to be  $0.083\,\mathrm{I\,min}^{-1}$ , in good agreement with the model calculations. Downstream this orifice, a relaxation chamber limits the perturbations caused by the sampling process. The first four lenses focus the particles onto a centre line and the final exit aperture - the accelerating nozzle - controls gas expansion and particle acceleration into the vacuum system. This 7 mm diameter final nozzle plays an important role for the particle beam diameter determination (Liu et al., 1995a,b). The outlet of the lens system is located in the first vacuum chamber where a 250 l s<sup>-1</sup> turbomolecular pump (Varian, model V301) is used to maintain a pressure of 10<sup>-3</sup> mbar when the lens inlet is open (10<sup>-7</sup> mbar with closed ALS).

Wang's design tool (Wang et al., 2006) also allows to model the theoretical performances for an ALS of given dimensions. For our system, a theoretical transmission efficiency of 100% was calculated for particle diameters ranging from 200 nm up to 4 µm and more than 90% for particles diameter larger than 30 nm. Downstream the accelerating nozzle, the theoretical particle beam diameter is calculated to be smaller than 1 mm up to the ion source of the TOF-MS (20 cm downstream the accelerating nozzle).

The ALS is fixed and can only be moved in the direction of particle traveling. The focused particles continue to travel along a straight-line path towards the detection/sizing chamber by passing successively through two pinholes. These pinholes have respectively inner diameters of 1.5 and 1 mm and a length of 5 and 23 mm. When the lens inlet is open, the small vacuum chamber between the two pinholes - its extension is 2 cm – is maintained at 10<sup>-4</sup> mbar using a 68 Is<sup>-1</sup> turbomolecular pump (Varian, model V70).

Interactive Discussion

# The optical detection/aerodynamic particle sizing region

The real-time sizing of a particle and the synchronization between its detection and its ionization and mass analysis remains a major challenge in aerosol mass spectrometry. One way to provide improved size information is achieved by incorporating a two-laser particle velocity measurement as implemented in the SPLAM instrument.

#### 2.2.1 Description of the optical detection

After exiting the first two differential pumping stages, the particles enter into the optical detection/sizing region ( $P = 10^{-5}$  mbar when ALS inlet is open) where they pass through two continuous wave (cw) diode laser beams emitting light at  $\lambda = 403 \, \text{nm}$  (Coherent Radius,  $P \approx 40 \,\text{mW}$ ). This wavelength has been chosen in order to enhance the detection efficiency for particles of d < 500 nm. At the same time, being at the edge of the visible spectral range, the violet light still permits a relatively easy alignment of the two lasers.

These cw laser beams are spaced by 41 ± 0.5 mm and respectively called L1 and L2 (Figs. 1 and 3). Outside the vacuum system, an optical spatial filter and a beam collimation system are used for both laser beams to respectively limit the stray light and optimize the intersection of the particle and the laser beam (not shown). The Gaussian shaped cross sections of the laser beams have been determined experimentally at the intersection zone using a CCD camera (Gentec, "Beam'R"). They are 315.5 and 334.8  $\mu$ m at  $1/e^2$  and 760.9 and 755.4  $\mu$ m at 1.5 % for L1 and L2 respectively with experimental powers of  $P_{1,1} = 41.3 \,\text{mW}$  and  $P_{1,2} = 31.2 \,\text{mW}$ .

Figure 3 is a technical drawing with the real scale. When a particle passes through each laser beam, its scattered light is detected by two photomultipliers (PMT, Photonis, XP2930). These PMTs, separated by glass windows from the vacuum system, have circular active areas of 23 mm diameter and are placed at an angle of 34° with respect to the forward direction of the laser beams. The PMT active areas are placed at a 37 mm distance from the intersection between particle and laser beams, which defines

Interactive Discussion

a detection angle of 34 ± 13°. According to Mie theory, the maximum of scattered light is in the forward direction, independent of wavelength. However, as can be seen in Fig. 3, mechanical constraints do not permit to set the PMT closer to the laser beam in our configuration.

To limit the stray light inside the detection chamber and thus the noise on the PMT, the internal walls were completely blackened and two sets of four diaphragms were inserted inside of both laser inlets (Fig. 3) which efficiently avoid penetration of reflected light from the entrance windows. Finally, two light horns are used to trap the photons at both laser exits (not shown in Fig. 3).

# 2.2.2 Aerodynamic particle sizing: description and calibration

When particles pass through the first laser beam, the scattered light generates a signal to the first PMT which triggers an external timing circuit which has been programmed on a field programmable gate array (FPGA, see Sect. 2.4.). The passage in the second laser beam allows for particle velocity determination by measuring the transit time  $(t_{opt})$  of the particle between two laser beams for the given beam separation  $(41 \pm 0.5 \,\mathrm{mm})$ . Vacuum aerodynamic diameters  $(d_{\mathrm{aev}})$ , defined as the diameter of a sphere with standard density which has the same terminal velocity as the particle of interest (DeCarlo et al., 2004), are then derived for three types of size selected aerosols, as shown in Fig. 4. This figure shows experimental calibration curves for aerodynamic particle sizing measurements performed with four certified sizes of PolyStyrene Latex (PSL, Duke Scientific Corp.), and selected DioctylPhthalate (DOP) and sodium chloride (NaCl) particle diameters using a differential mobility analyzer (DMA, model 3080L, TSI inc.). These particles were produced using an atomizer (model 3076, TSI inc.) and a diffusion dryer (model 3062, TSI inc.) to remove water in the case of PSL and NaCl particle generation. Each point represents the average of hundred detected particles and the horizontal error bars correspond to an error propagation of 95% confidence intervals. In order to avoid the detection of two or more particles at the same time during these experiments, the number concentration of the aerosol to

Printer-friendly Version

be characterized is limited on purpose. The upper limit of particle concentration can be estimated by taking into account a typical particle velocity of 100 m s<sup>-1</sup> whose transit time  $t_{\rm opt}$  between the two lasers would be about 400  $\mu$ s. Given the experimental volumetric flowrate of 0.083 I min<sup>-1</sup>, this yields a maximum number concentration of about  $1.7 \times 10^3$  particles cm<sup>-3</sup> that should not be exceeded for  $d_{aev}$  measurements with the SPLAM optical detection. Therefore, in order to avoid coincidences during optical detection process, one or two dilution systems were used (1/100 diluters, model DIL-550, Topas GmbH) especially in the case of the production of particles using the atomizer.

Using counting of DOP particles, the calibration measurements provided a detection limit of  $d_{aev} = 100-110$  nm (see Sect. 2.2.3) which is probably optical and not caused by the transmission efficiency of the aerodynamic lens system, according to the previous theoretical characterization (Sect. 2.1). The particle velocity variability observed for the smaller aerodynamic diameters can be explained by the fact that small particles have more divergent flight paths inside the particle beam. This leads to more spread positions of smaller particles inside the cw laser beams, and consequently to a broader scattered light intensity range.

### 2.2.3 Optical detection efficiency and aerodynamic particle sizing performances comparison

Figure 5a compares the optical detection efficiency (DE) of SPLAM (black circles) to the above cited single particle instruments as a function of vacuum aerodynamic diameter (see Sect. 1.). The SPLAM DE was calculated as the ratio between the count rate of DOP particles measured with PMT2 (L2 scattered light, Fig. 3) and the one obtained with a condensation particle counter (CPC, model 3010, TSI inc.) connected in parallel to the ALS. Note that the PMT1 count rate (L1 scattered light, Fig. 3) is higher, however we plot L2 DE since only two-fold detection permits velocity determination and triggering of the pulsed LDI laser. Differences in L1 and L2 individual DEs can have many reasons (for example different laser power) and will not be discussed here. Our DE

) Diocus

is given for DOP particles whereas the SPLAT (Zelenyuk et al., 2005) (open squares) and ATOFMS (Su et al., 2004) (open diamonds) DEs are given for PSL particles.

A close-up of panel a from 50 to 250 nm is shown in panel b. From panel b, the optical detection limit of SPLAM can be estimated to be at about 100 nm particle aerodynamic diameter (DE = 0.4%). As expected, close to the detection limit, the DE is relatively poor (below 5%). However, it increases rapidly towards bigger particles reaching a maximum of 74% at 350 nm.

The SPLAT and ATOFMS DEs are very similar to those obtained for SPLAM, although in these two instruments elliptical mirrors for the collection of scattered photons are implemented in order to enhance their DEs. One way to understand the similar DEs obtained for fine particles despite fairly different optical setups is to consider the differences in the cw laser wavelengths used. In fact, the ATOFMS and SPLAT both operate with green cw lasers ( $\lambda = 532\,\text{nm}$ ) whereas the violet laser implemented inside SPLAM favors the detection of fine and ultrafine particles according to Mie theory. However, the decrease towards the 1  $\mu$ m is somewhat more pronounced in our instrument as compared to SPLAT which could also be a difference due to different wavelengths used.

# 2.3 Chemical characterization region: the photoionization time-of-flight mass spectrometer

After being detected and sized, the particles enter the ionization source of the mass spectrometer where short-lived burst of ions are produced. Time-of-flight mass analyzers are ideally suited for characterizing simultaneously all the ions formed during the LDI process for each detected particle.

An home-made TOF mass spectrometer was implemented in the SPLAM instrument.

After passing through a 1 mm orifice with a length of 5 mm, the particles reach the TOFMS ionization region where a pressure of 10<sup>-8</sup> mbar is maintained by two 2501s<sup>-1</sup>
turbomolecular pumps (Varian V301). The pressure in this region does not change at all when the ALS inlet is opened. This is particularly important since it means that our

differential pumping system is very efficient and that our TOF-MS will exclusively detect compounds from the aerosol phase. This has been further evidenced by introducing gaseous toluene via the ALS inlet. R2PI ( $\lambda$  = 248 nm) coupled to TOF-MS is extremely sensitive to aromatic hydrocarbons (see also below). No toluene could be detected 5 under these conditions.

A 17 mJ excimer laser (KrF, Optex, LambdaPhysik) emitting at  $\lambda = 248$  nm was used as a desorption/ionization laser at a maximum repetition rate of 10 Hz and a pulse width of 10 ns. The laser is focused into the ion source by an  $f = 30 \,\mathrm{cm}$  fused silica lens. The ion extraction region of the TOF-MS is slightly off-focus yielding a 7.5 × 1 mm rectangular shaped spot size in this region which is horizontally oriented in order to optimize the mass resolution and to maximize the hit efficiency since particles will travel through the longer axis of this rectangle. Here, the laser power density reaches about  $1.4 \times 10^7$  W cm<sup>-2</sup> (at 12 mJ pulse energy).

The TOF-MS itself is of linear configuration and is operating according to the Wiley-McLaren ion space focusing conditions (Wiley, McLaren, 1955). It has a two-stage accelerating electric field consisting of a three copper plate grids, spaced by 1 cm. The length of the field free drift region is 1 m. A Behlke high voltage switch (HTS 21-06-GSM) is used to extract the ions orthogonally to the particle beam. The Behlke switch has a very steep edge (<3 ns) and thus favors good mass resolution. Moreover, in order to further improve the mass resolution, a delay time  $\tau$  is applied for the ion extraction (see Sect. 2.4) (Wiley and McLaren, 1955). The acceleration potentials used are +145 and -1460 V respectively for the extraction and acceleration region. Positive ions are detected by two 40 mm microchannel plate detectors in series (MCP, Hamamatsu). The signals are preamplified (Ortec fast preamplifier) and sent to an acquisition card (National Instruments, PXI-5621, 64 MHz, 14 bit vertical resolution) interfaced to a personal computer. In its latest version, the TOF-MS achieves a mass resolution of  $m/\Delta m \approx 500$  (for LDI desorbed DOP molecules).

The sensibility of the TOF-MS has been characterized using an effusive inlet for gaseous molecules, coupled directly to the ion source chamber. Using the KrF excimer

Interactive Discussion

laser, most of aromatic compounds which have intensive  $S_0 \to S_n$  electronic transitions at  $\lambda = 248$  nm, can be ionized near their ionization threshold with R2PI thus avoiding dissociative ionization. For such compounds, fragment free mass spectra can be obtained. Moreover, under these conditions, molecular oxygen, molecular nitrogen, carbon dioxide, alkanes, alkenes, and aliphatic aldehydes are almost not ionized and thus background noise is significantly reduced (Zimmermann et al., 1997). This allows very low detection limits (DL) for aromatic compounds. A series of semi-volatile polycyclic aromatic hydrocarbons (HC) was studied in gas phase in order to determine SPLAM's molecular DL. Typically, when about 100 mass spectra are averaged, a few hundred molecules are needed inside the ionization volume to give an appreciable mass signal. For single shot mass spectra, a few thousand molecules are needed (Gaie-Levrel, 2009). These numbers can be used to estimate the capabilities of SPLAM in the case of aerosol particles. For gaseous 2-methylnaphthalene, for example, the TOF-MS is able to detect  $1.6 \times 10^5$  molecules in its ionization volume yielding a weight DL of 0.85 attogram (excimer laser power density  $\approx 2 \times 10^6 \,\mathrm{W \, cm^{-2}}$ ) by taking into account that a signal is detectable when the signal to noise ratio is higher than 3. Supposing a homogeneous  $d = 200 \,\mathrm{nm}$  particle composed of a  $\mathrm{M} = 150 \,\mathrm{g} \,\mathrm{mol}^{-1}$  compound and a 1 g cm<sup>-3</sup> density, a particle weight of 4 fg can be calculated (~2.10<sup>7</sup> molecules). In principle, our TOF-MS has thus the ability to detect 2-methylnaphthalene with a 0.02 % weight fraction inside this particle. However, since the DL is estimated from gas phase R2PI, the estimation for the particle case holds only for complete particle vaporization and for an optimal spatial overlap between the ionization volume and the gas plume of the vaporized particle. Furthermore, a higher power density is needed for the LDI process and R2PI conditions are difficult to realize under these conditions.

During these gas phase experiments, a series of non-aromatic compounds with relevance for SOA chemistry (terpenes and related atmospheric oxidation products) were also studied. Although the electronic transition moments of this class of compounds are generally not zero at 248 nm, only poor DL were obtained and dissociative ionization was predominant in the mass spectra. We can thus conclude, that SPLAM using  $\lambda$  = 248 nm for Resonance-Enhanced Multiphoton-Ionization (REMPI) will be a method well suited for the detection of particle-bound aromatic molecules, such as for example those found in anthropogenic or biomass burning aerosols. This conclusion will be emphasized in Sect. 3.2 by the study of the chemical composition of SOA formed by the ozonolysis of indene as first scientific application of SPLAM.

# 2.4 Synchronization of optical detection and LDI mass spectrometry

The synchronization between the optical detection and the desorption/ionization laser is achieved using a Field Programmable Gate Array card (FPGA, Avnet, ADSADS-XLX-V4FX-EVL12-G). Figure 6 shows the chronogram of this process. The trigger time  $t_{\rm trig}$  is calculated from the residence time  $t_{\rm opt}$  of the particles between both continuous lasers. Since the trigger delay (i.e. the temporal separation between an external pulse and emission of photons) of the excimer laser is  $450 \pm 5$  ns, this additional time delay has to be taken into account to exactly synchronize the impact of the UV photons to an arriving particle. Considering their measured particle velocities and the associate uncertainties, particles are expected to arrive in a  $1.86 \times 1$  mm area, homogeneous in energy, in the middle of the  $7.5 \times 1$  mm laser spot (see Sect. 2.3). Moreover, as already mentioned in the Sect. 2.3, a delay time of  $2.55 \,\mu s$  is applied before extracting the produced ions in order to enhance mass resolution.

In the single particle mode of operation, the maximum analysis rate is 10 particles per second since at a higher repetition rate, the decrease of the excimer laser pulse energy is too important. Therefore, an upper limit of 10 Hz was programmed for the laser pulse repetition rate. In its current state, the synchronization of the SPLAM instrument allows the laser triggering from  $t_{\rm opt}$  determination. However, at this stage of development, the time  $t_{\rm opt}$  associated with the mass spectrum of the sampled particle is not recorded.

As explained before, the SPLAM instrument was designed to study the organic fraction of atmospheric aerosol particles. The study of SOA produced in one of the LISA simulation chamber CESAM was performed as the first scientific application of SPLAM. Prior to this study, some preliminary test experiments were performed using DOP particles in order to test the overall functioning of the instrument.

# 3.1 Preliminary tests using DOP particles

In order to test the feasibility of the synchronization procedure between the optical detection and the vaporization/ionization region of the SPLAM instrument, preliminary tests were performed using DOP (Sigma Aldrich, >99 % purity) particles generated by nebulization of the pure viscous oil using a constant output atomizer (TSI, model 3076).

#### 3.1.1 Characterization of blank level

Figure 7a shows a typical noise level on the mass spectra obtained for a single laser pulse on a filtered N<sub>2</sub> flux. The maximum and minimum thresholds of an ion signal to be considered as significant were calculated as three times the standard deviation obtained at each mass. These levels are presented as red shaded area on the panel A and a 4 mV threshold was then determined for the whole spectra by excluding the higher noise located around m/z 25.

#### Mass spectra of individual DOP particles 3.1.2

Figure 7b shows a typical mass spectrum of an individual DOP particle. For this experiment, the produced particle concentration was diluted by a factor of 1000. The laser power density was  $1 \times 10^8 \,\mathrm{W \, cm^{-2}}$  with a 1 mm<sup>3</sup> ionization volume.

We mention that every single particle mass spectrum was repeatable in terms of peak position indicating that the TOF time scale is constant. As mentioned before, in

its current state, the acquisition system does not allow us to record the PMT signals and therefore, no link can be made between the particle diameter and the mass spectrum. However, from experimental observation variation of particles travel times  $t_{ont}$ , the range of aerodynamic diameters of the sampled particles was determined independently to be comprised between  $d_{\text{agy}} = 200$  and 900 nm. The range of this sampling is consistent with the DOP size distribution measured by SMPS and knowing that SPLAM optical DE is weak under 200 nm.

Concerning the mass peak intensity repeatability, the mean intensity normalized to m/z 57 and associated standard deviation calculated from 50 single particle DOP mass spectra are indicated in red in Fig. 7. As can be seen from these statistics, the fragment intensities of m/z 261 ( $C_{16}H_{21}O_3^+$ ), 167 ( $C_8H_7O_4^+$ ), 149 ( $C_8H_5O_3^+$ ), 113 ( $C_8H_{17}^+$ ), 112  $(C_8H_{16}^+)$ , 105  $(C_7H_5O^+)$ , 104  $(C_7H_4O^+)$ , 83  $(C_6H_{11}^+)$ , 71  $(C_5H_{11}^+)$ , 57  $(C_4H_9^+)$ , 43  $(C_3H_7^+)$ , which are typical cationic fragments of DOP (NIST, 2008), vary a lot. With the photon distribution inside the rectangular cross section of the UV laser beam being homogeneous, this is probably explained by the variation of the pulse energy of the LDI laser over time which is typically ±10%. This means that each particle does not receive exactly the same power density when being illuminated by the UV laser pulse. The variability of the DOP particle sizes could also explain, in part, peak intensity variations: even if the power deposited per unit of particle surface is the same for small and large particles (at constant pulse energy), the power received per unit of particle volume might be different for particles of different size.

We think however, that these intensity variations do not obstruct chemical speciation since identical mass peaks are observed for every laser shot.

As already mentioned, the ions observed in our single particle mass spectra are also observed in the 70 eV electron impact mass spectrum (EI-MS) compiled in the NIST chemistry webbook (NIST, 2008), with similar intensity ratios. This means that dissociative ionization of DOP molecules is predominant with both ionization methods, EI and LDI, since the DOP parent cation (m/z 390) is not observed for example. The similarity of our DOP mass spectra with the EI-MS demonstrates that under LDI conditions,

Printer-friendly Version

the amount of internal energy released to the parent cation is not far from to the one transferred during the EI process. However, there is one striking difference: in the EI-MS of DOP, m/z 279 is a strong ion (25% relative to the base peak m/z 49) whereas this peak is absent in the single particle LDI mass spectra. It is known from work comparing 70 eV EI ionization to photoionization using tunable VUV synchrotron radiation (Schwell et al., 2000) that during the 70 eV EI process, approximately 20 eV of the 70 eV electron kinetic energy is transferred as internal energy to the molecule. It can thus be concluded that at least 4 photons of 248 nm (5 eV) are transferred to the DOP neutral molecules during LDI, and probably a little more since m/z 279 is apparently also fragmented during LDI.

#### 3.1.3 Particle hit rate determination of SPLAM

The hit rate, which is defined as the ratio between the numbers of particles hit by the vaporization/ionization laser that generate ions detectable by the mass spectrometer. and the number of particles sized by the optical detection during the same time period, was determined to be 15% in these preliminary experiments. This corresponds to a typical hit rate obtained by other single particle aerosol mass spectrometers (Su et al., 2004). Unfortunately, approximately half of the single particle mass spectra exhibit very intense and unidentifiable broad mass peaks, appearing between m/z 40 and m/z 65 (not shown). This is explained as an ion extraction artifact inside the ion source of the TOF-MS. In these cases, the LDI ion plume is probably formed at the edge of the extraction region which does not allow proper extraction and space focalization of the ions. Therefore, these spectra have to be discarded and the effective hit rate, corresponding to the fraction of analyzable mass spectra, is thus estimated to be about 7-8%.

We can conclude from these preliminary experiments using DOP particles that all three parts of our instrument - (1) sampling a polydisperse aerosol using the aerodynamic lens system, (2) particles sizing by a two-fold optical detection, and (3) synchronization with LDI and measurement of single particles mass spectra by TOF-MS

Interactive Discussion

 work properly. The instrument is thus adapted for single particle analysis of organic aerosols. In order to scientifically validate the SPLAM instrument, we have analyzed a SOA formed in smog chamber experiment and main results are described in the following section.

## 3.2 Study of aromatic SOA produced from indene ozonolysis

# 3.2.1 SOA production and sampling in the CESAM chamber

Aromatic SOA were produced in the CESAM simulation chamber described elsewhere (Wang et al., 2011). A brief description is given here: the 4.2 m<sup>3</sup> stainless steel chamber is equipped by a pumping system to deeply clean the chamber between experiments and to limit wall memory effects. An internal fan allows for homogeneous mixing of gaseous species and aerosols. In the case of our indene ozonolysis study, the chamber was filled with 80 % N<sub>2</sub> (U quality, Air Liquide) and 20 % O<sub>2</sub> (Alphagaz 1, Air Liquide) after several pumping cycles. A 1 ppm concentration of ozone, produced by an UV lamp, was injected and controlled using an ozone analyzer (Horiba model APOA-370). The volatile precursor, indene (Sigma Aldrich, 99 % purity), was then injected to yield a 1 ppm concentration. This aromatic precursor was chosen for its known high potential to form secondary organic aerosols (Chiappini, 2006). The temporal evolution of the size distribution of produced particles during this experiment was monitored using a Scanning Mobility Particle Sizer (TSI, DMA model 3080 + CPC model 3010) and is presented in Fig. 8. Between the beginning and the end of this experiment, the mean diameter of the measured size distribution was shifted from 80 to 100 nm with maximum number concentrations of  $4 \times 10^3$  to  $1 \times 10^3$  particles cm<sup>-3</sup> respectively. As for DOP experiment, a separated aerodynamic sizing of the detected SOA particles during this experiment, using the optical detection of the SPLAM instrument, allowed to determine the sampled  $d_{agu}$  range being comprised between 170 and 900 nm which correspond to the bigger particles formed inside the chamber, i.e. the extreme right part of the distribution, which is consistent knowing the optical SPLAM DL.

The CESAM chamber was connected to SPLAM via a 4 mm inner diameter copper tube. The length of this tube was kept as short as possible (about 1.5 m). Figure 9, lowest panel, shows the typical noise level of the SPLAM mass spectrum obtained for a single laser pulse when gas was sampled (SPLAM aerosol inlet open, CESAM chamber filled with synthetic air and ozone, but without indene). The red shaded area, presented on this panel, was calculated as three times the standard deviation obtained at each mass and corresponds to the maximum and minimum thresholds of an ion signal to be considered as significant. From this calculation, the maximum level was determined to be 4 mV. This level is also indicated as red shaded area in Fig. 10a and b.

# 3.2.3 Single particle mass spectra and SOA chemical composition analysis

During this five hour aerosol formation experiment, single particle mass spectra were obtained about two hours after the ozone injection, with a global hit rate of about 10 % (see Sect. 3.1.3). The mass spectra were subdivided into two groups taking into account the type of observed mass peaks and their signal intensity.

Figure 9a–c shows representative single particle mass spectra corresponding to a first group. About 80 % of the analyzable mass spectra belong to this group which is characterized by three relatively intense fragments, at m/z 39, 57 and 63. These fragments are assigned to organic cations formed by dissociative ionization of larger hydrocarbons (HC). For example, m/z 63 ( $C_5H_3^+$ ) is a typical fragment observed in the ionic fragmentation of aromatic HC which in turn makes sense considering the chemical system under study. On the contrary, m/z 39 ( $C_3H_3^+$ ) and m/z 57 ( $C_4H_9^+$ ) are generally weak in the EI-MS fragmentation of aromatic HC. Theses two fragments are considered to be typical in the MS of aliphatic HC or molecules with aliphatic side chains. However, since LDI apparently transfers a little more internal energy to the molecules

in our conditions ( $\sim 1.4 \times 10^7 \,\mathrm{W\,cm}^{-2}$  laser power irradiating the sample, see above), m/z 39 and m/z 57 might be more intense as compared to 70 eV EI-MS. At this stage,

Figure 10a and b correspond to representative mass spectra classified in a second group which contributes to about 20% of the analyzable mass spectra. The intensity scale of the spectra shown in Fig. 10a is different with respect to those shown in Fig. 10b, in order to better distinguish weak fragments. Differences in signal intensity can be interpreted in terms of different particles sizes. The peculiarity of the second group is that, in addition to m/z 39, 57 and 63, it presents fragments with higher m/z up to 280. The m/z 280 ion (Fig. 10b,3) is the highest mass actually observed in our measurements.

we cannot go further in the analysis of group 1 mass spectra.

From Fig. 10, one can easily notice that the obtained mass spectra of the second group do not resemble to each other. This is significant since we are convinced that LDI of single chemical substances present in the aerosol phase always yield approximately the same mass spectra with our experimental set-up (see Sect. 3.1). We can thus expect that specific molecules present in the aerosol phase will always leave the same typical fingerprint which could be used, in principle, for molecular speciation. This fingerprint will of course be very different from 70 eV EI-MS found in most data bases. From the observed differences in the mass spectra of single particles we thus conclude that this reflects real chemical differences of the aerosol particles that have been detected. However, at the moment, we do not have enough statistics to identify further chemical sub-groups inside group 2 particles.

The m/z mass of the observed ions are indicated in Fig. 10 for each analyzed particle characterized by a different mass spectrum. The only common ions to all particles are m/z 12 ( $C^+$ ), 24 ( $C_2^+$ ), 27 ( $C_2H_3^+$ ), and 39 ( $C_3H_3^+$ ). At this point we have to consider what type of semi-volatile and non-volatile degradation products can be expected to be formed during the ozonolysis of indene and which kind of fragments they can produce during dissociative ionization. The  $O_3$ /indene chemical system has been studied earlier by Chiappini (2006a). In this study, the SOA particles were sampled on glass

fiber filters and subsequently analyzed by supercritical fluid extraction coupled to GC-CI-MS analysis of the derivatized compounds (Chiappini et al., 2006). Ten different degradation products have been identified using this technique.

In the literature, EI (70 eV) and PI (15 eV) reference mass spectra can be found only 5 for benzoic acid, phthaldialdehyde and phthalic acid (NIST, 2008; Gaie-Levrel et al., 2008). Under these conditions, it is very difficult to proceed to molecular speciation from our single particle mass spectra. Also, more statistics are needed in order to measure the frequency of occurrence of certain type of single particle mass spectra.

The expected ions for benzoic acid are m/z 122, 105, 77, 51 (NIST, 2008). Only m/z 51 is found in the MS no. 5 (Fig. 10b). Photoionization at 15 eV of phthaldialdeyde gives rise to principal ions m/z 134 (M<sup>+</sup>), 106 (C<sub>7</sub>H<sub>6</sub>O<sup>+</sup>), 105 (C<sub>7</sub>H<sub>5</sub>O<sup>+</sup>), 78 (C<sub>6</sub>H<sub>6</sub><sup>+</sup>), 77  $(C_6H_5^+)$ , and 51  $(C_4H_3^+)$  (Gaie-Levrel et al., 2008). The mass spectrum no. 5 (Fig. 10b) shows three of these ions (m/z 134, 78, 51). Phthalic acid gives rise to principal ions m/z 166 (M<sup>+</sup>), 148 (C<sub>8</sub>H<sub>4</sub>O<sub>3</sub><sup>+</sup>), 104 (C<sub>7</sub>H<sub>4</sub>O<sup>+</sup>), and 76 (C<sub>6</sub>H<sub>4</sub><sup>+</sup>) at 15 eV PI. Only ion m/z 104 is observed in the single particle MS no. 1 in Fig. 10a.

In the work of Gaie-Levrel et al. (2008), the dissociative photoionization of otolualdehyde, 2-methylphenol and o-toluic acid has also been studied. These three compounds are observed during the 2-methylstyrene oxidation with ozone but not with indene as an aerosol precursor (Chiappini, 2006a), although these two molecules have very similar chemical structure. We note, however, that most of the expected principal ions from o-tolualdehyde (m/z 120, 119, 92), 2-methylphenol (m/z 108, 107, 91, 90, 89, 80, 79) and o-toluic acid (m/z 136, 119, 118, 91, 90, 89) are observed in our single particle group 2 mass spectra. Yet, we cannot claim an identification of these three compounds in the absence of reference single particle MS in the same LDI conditions.

At this stage we cannot explain all ions observed in our spectra and a real molecular speciation is apparently not possible. However, typical ions for expected indene degradation products are observed. Furthermore, the high molecular weight ions m/z 280 (MS no. 3), 193 (MS no. 1), 190 (MS no. 6), 189 (MS no. 4), 181, 180 (MS no. 5) and 170 (MS no. 2) observed for each particles of the second group cannot be attributed for

Interactive Discussion

the moment. They might belong to cations formed by ionization of other non-identified products or even of organic oligomers which could be present in the indene SOA.

#### Discussion of the first results of SPLAM 3.2.4

Even though during the LDI process dissociative ionization of the molecules present in the aerosol phase is predominant, the SPLAM instrument has detected high molecular weight ions originating from indene degradation products in the particulate phase. This can be seen as a step forward compared to SOA analysis studies involving the AMS instrument from Aerodyne (Bahreini et al., 2005; Alfarra et al., 2006). Indeed, the main studies involving this instrument for chemical analysis of SOA give rise to a very high fragmentation level and common dominant fragments at m/z 41, 43, 44 and 55 are observed in all mass spectra. This do not permits to lead a real chemical mechanism investigation at the molecular level.

The SPLAM instrument configuration is very similar to the one developed by Huang et al. (2007) who also measured single particle LDI mass spectra. These authors investigated SOA formation initiated by OH photooxidation of five aromatic hydrocarbons: benzene, toluene, ethylbenzene, p-xylene, and 1,2,4 trimethylbenzene. To our knowledge, this is the only smog chamber study of anthropogenic type SOA, formed from aromatic HC, and using LDI single particle mass spectrometry for analysis. Huang et al. analyzed a few hundred mass spectra for each of the five types of SOA and determined an appearance frequency distribution for the eight main mass peaks (m/z 18, 29, 43, 44, 46, 57, 67, 77). For all five types of SOA, m/z 57 is by far the most abundant mass peak. On the contrary, m/z 39 and 63 which are observed in our group 1 mass spectra (80% of all MS in our study) are much less frequent in the experiments of Huang et al. It is interesting to note that these authors also observe many high molecular weight ions (up to m/z 186) despite the fragmentation induced by LDI. However, these ions seem to be less abundant since they do not appear in their appearance frequency analysis. This is qualitatively in accordance with our results since only 20 % of our single particle MS show ions with higher m/z ratios. The study of Huang et **AMTD**

**Conclusions** 

aromatic precursors.

A single particle aerosol mass spectrometer, called SPLAM (Single Particle Laser Ablation Mass Spectrometry), equipped with an aerodynamic lens system, a two-fold optical detection and a 1 m linear TOF-MS, has been developed, calibrated and characterized. The instrument was designed to detect and analyze sub-micrometer sized organic aerosol particles. The transmission of the aerodynamic lens system has been modeled and designed using the program developed by Wang et al. (2006). The lens transmits particles with diameters comprised between 200 nm and 4 µm with a theoretical efficiency of 100% into a beam of very low divergence (diameter < 1 mm at the ion source). The optical detection limit in terms of particle size was determined to be at 100 nm approximately. The two-fold optical detection efficiency DE is measured to be 0.4 % at  $d_{\text{aev}} = 10 \text{ nm}$  and 74 % at  $d_{\text{aev}} = 350 \text{ nm}$ . After aerodynamic sizing, the particles enter the TOF-MS which is equipped with an excimer laser emitting at  $\lambda = 248$  nm used for one step particle laser desorption/ionization (LDI). The mass resolution is  $m/\Delta m = 500$ . The laser is triggered by the optical particle detection upstream. The three stage differential pumping of SPLAM excludes any detection of gas phase compounds.

al. (2007) confirms that fragmentation induced by LDI seems to be less problematic

compared to a thermal desorption AMS, at least for the analysis of SOA formed by

The instrument has been fully characterized and scientifically validated by a study of SOA produced in a smog chamber from ozonolysis of indene. The obtained mass spectra were classified in two groups with a 10 % global hit rate. The first group, which represents 80 % of the total mass spectra number, is characterized by three relatively intense fragments at m/z 39, 57 and 63 while a second group additionally presents fragments with higher m/z, up to 280 and represents 20% of the total mass spectra.

Interactive Discussion

Group 2 mass spectra are very different from one to another and we think that this reflects different chemical types of particles to be present in the indene SOA. However, under LDI conditions different particle sizes could give different fragmentation patterns of the aerosol phase compounds as has been pointed out. This issue has to be investigated in more detail in the future.

Our results have been compared to those of Huang et al. (2007) who recently studied SOA formed from gaseous aromatic precursors, using LDI single particle TOF-MS. They are qualitatively consistent with our work since similar types of mass spectra are observed (see Sect. 3.2.4).

The lack of reference spectra adapted for LDI conditions has so far hindered molecular speciation. Also, more statistics are needed to measure the frequency of occurrence of ions, including those with high molecular weight. This kind of data could then help to measure more significant fragment ion intensity ratios to be compared to the adapted reference spectra. This is crucial for molecular speciation under LDI conditions.

Different experimental approaches are also possible to proceed towards molecular speciation with SPLAM, for example the use of L2DI or SPI. Both techniques permit to ionize molecules close to their ionization threshold and therefore reduce the number of dissociative ionization reactions. Molecular speciation is probably more straightforward in these conditions since fewer mass peaks will appear per molecule. As an example, SPI using synchrotron radiation, coupled to flash vaporization on a heated surface, has been used recently with success to chemically analyze ensemble of nanoparticles (Mysak et al., 2005: Wilson et al., 2006; Gloaguen et al., 2006; Gaie-Levrel et al., 2011).

More generally, it has to be noted also that signal to noise ratios in single particle mass spectrometry of nanometer sized and chemically complex particles are very low, even when very sensitive detection techniques are used. A statistic evaluation, over at least a few hundreds of particles, is necessary to understand the real chemical meaning of the mass spectra. The real-time character of this type of measurements is then somewhat reduced. For example, if a few hundred particles are needed for chemical

analysis, the maximum time resolution would be a few minutes with the current particle analysis rate.

We note that a statistical evaluation – like the frequency of occurrence analysis of ions – does not obstruct the single particle information. Rather, it is way to analyze a large number of low intensity mass spectra. Different chemical sub-groups of single particle MS could still be identified in parallel.

Finally, we can conclude that the SPLAM instrument shows a high potential to study SOA from aromatic precursors using LDI, especially once a statistical evaluation over a few hundred particles will be implemented. For other types of SOA, formed from non-aromatic precursors, other experimental approaches like L2DI or SPI are necessary. Combustion aerosols could also be a scientific target of SPLAM since PAH are present for which very low detection limits have been measured. Finally, all type of aromatic pollutants present in the aerosol phase and their atmospheric dynamics could be measured with SPLAM in real time.

Acknowledgements. Financial support was provided by the French Ministry of Research (ACI Nouvelles Méthodologies et capteurs), the Ministry of Environment (PRIMEQUAL program), the Ile-De-France region (SESAME program) as well as the CNRS (INSU, PNCA). The authors want to thank CNRS-INSU for supporting CESAM as a National Instrument and Jean-François Doussin for fruitful collaboration and encouraging support. Warm thanks go to Xiaoliang Wang (now Desert Research Institute, Nevada) for very helpful discussions about his aerodynamic lens model as well as to Eric Villenave (University of Bordeaux) for accompanying the whole project with valuable advices.

The publication of this article is financed by CNRS-INSU.

**Fig. 1.** Schematic illustration of the Single Particle Laser Ablation Mass Spectrometry (SPLAM) instrument. Particles are focused by an aerodynamic lens system. The particle beam crosses two continuous diode laser beams allowing optical detection of individual particles and determination of their respective aerodynamic diameter. An external timing circuit permits to trigger a UV laser to vaporize and ionize individual particles. The formed ions are analyzed by the time-of-flight mass spectrometer.

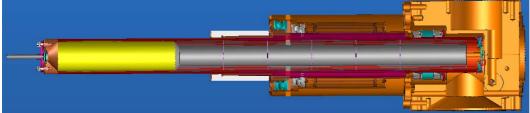

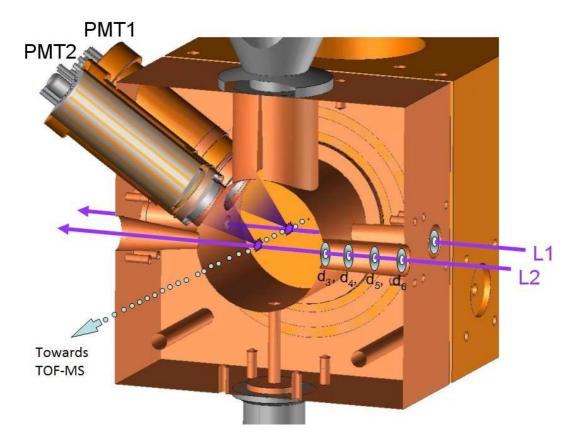

Fig. 2. Scheme of the aerodynamic lens system of SPLAM and its z-translation mechanism (vertical cuts). (a) View of the five lens orifices and the relaxation chamber. (b) View of the ALS integrated into the first two pumping stage regions (drawings: Mecaconcept).

Interactive Discussion

**Fig. 3.** Optical detection chamber of SPLAM. The particle beam crosses two diode laser beams (L1 and L2). Scattered light is detected in forward direction by two photomultiplier tubes at an angle of  $34 \pm 13^{\circ}$  (centre of active detection area, see Sect. 2.2). The four diaphragms inserted into the tunnels of the incoming laser light avoid the penetration of reflected light from the entrance windows (not shown) into the detection chamber. The laser beams are trapped by light horns (not shown).

**Fig. 7. (a)** Typical noise level on the mass spectra obtained for a single laser pulse when aerodynamic lens system has sampled a filtered  $N_2$  flux. The red shaded area, calculated as three times the standard deviation obtained at each mass, corresponds to the maximum and minimum thresholds of an ion signal to be considered as significant, **(b)** typical mass spectrum of an individual DOP particle. The mean intensity ratios of each detected mass peak normalized to m/z 57 and their associated standard deviation are indicated below the mass peaks identifications.

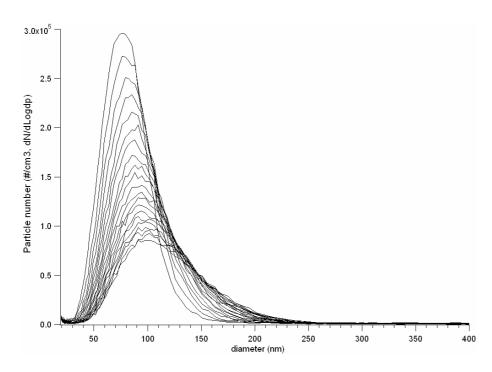

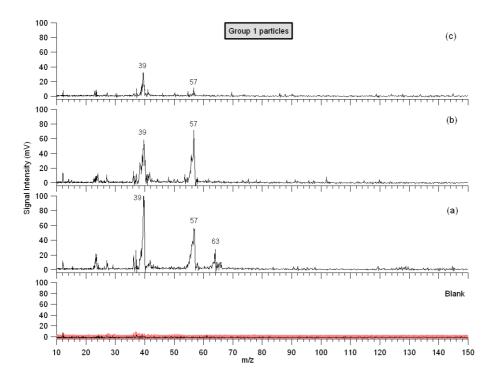

Fig. 8. Temporal evolution of the size distribution of produced SOA.

**Fig. 9.** Blank: typical noise level on the mass spectra obtained for a single laser pulse (SPLAM inlet open, CESAM chamber, filled with synthetic air and ozone, but without indene). The blank level is determined to be at 4 mV (indicated as red shaded zone). See text for further explanations; **(a)**, **(b)**, **(c)**: examples of a single particle mass spectra of SOA produced by ozonolysis of indene in the smog chamber CESAM (group 1 particles).

Interactive Discussion

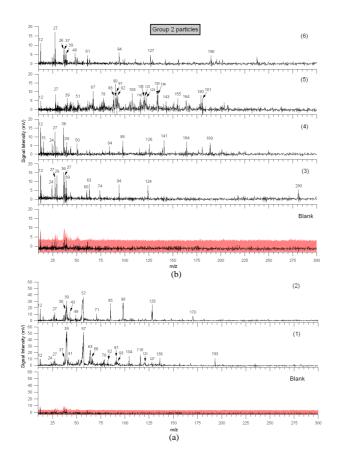

Fig. 10. Single particle mass spectra of SOA produced by ozonolysis of indene in the smog chamber CESAM (group 2 particles). (a) and (b) have different ordinate scaling. The blank level is determined to be at 4 mV (indicated as red shaded zone in the lowest panels). See text for further explanations.
