than 4 % for stratospheric column ozone, with standard deviations of 1–3 %, while OMI retrievals show similar agreements with MLS except for 1 % smaller biases at mid and high latitudes.

Based on the comparisons, we conclude that GEMS will measure tropospheric ozone and stratospheric ozone columns with accuracy comparable to that of OMI and ozone profiles with slightly worse performance than that of OMI below  $\sim 3$  hPa.  
5

## 1 Introduction

Atmospheric ozone is a key air pollutant that must be monitored routinely over the globe due to its huge impact in determining UV-dose, air quality, radiation budget, and climate  
10 change (e.g. Crutzen, 1996; Hauglustaine and Brasseur, 2001; Liu and Trainer, 1987).

The main goal of early space-based remote sensing was to observe daily total column ozone and stratospheric ozone profiles globally (e.g. McPeters et al., 1998). Total column ozone observations were accomplished with the successive launch of the Total Ozone Monitoring Spectrometer (TOMS), onboard Nimbus-7 (November 1978–May  
15 1993), Meteor-3 (August 1991–November 1994), ADEOS (July 1996–June 1997), and Earth Probe (July 1996–December 2005) polar-orbiting satellites (Bhartia and Welle-meyer, 2002). The vertical distribution of stratospheric ozone has been observed from the Solar Backscatter UltraViolet (SBUV) on Nimbus 7 and National Oceanic and Atmo-spheric Administration (NOAA) weather satellites (1984 to now) (Bhartia et al., 1996).

20 The TOMS and SBUV record has played an essential role in warning of the problem of ozone depletion over Antarctica and in assessing the recovery of the ozone layer since the Montreal Protocol came into effect (Salby et al., 2011; Kuttippurath et al., 2012). Since the middle 1990 s, several UV/visible (and near infrared) spectrometers have been launched to continue the TOMS total ozone record, including the Global Ozone  
25 Monitoring Experiment (GOME), the SCanning Imaging Absorption spectroMeter for Atmospheric CHartographY (SCIAMACHY), the Ozone Monitoring Instrument (OMI), GOME-2, and the Ozone Mapper Profiler Suite (OMPS). These low Earth orbit (LEO)

analyze the retrieval characteristics of OMI and GEMS to evaluate how different spectral coverage affects the performance. Comparison of GEMS and OMI stratospheric ozone retrievals to MLS measurements is presented in Sect. 5. Section 6 presents conclusions on the accuracy of stratospheric ozone columns and profiles and of tropospheric ozone columns and profiles when measured with the planned GEMS spectral coverage.

## 2 GEMS program

GEMS is planned for launch in 2018 onboard GeoKOMPSAT, together with ABI (Advanced Baseline Imager) typed sensor and GOFCI-2 (Geostationary Ocean Color

- 10 Imager-2). The spatial domain of GEMS covers  $5000\text{ km} \times 5000\text{ km}$  ranging from  $5^\circ\text{ S}$  (Indonesia) to  $45^\circ\text{ N}$  (south of the Russian border) and from  $75^\circ\text{ E}$  to  $145^\circ\text{ E}$ . The nominal spatial resolution is  $7\text{ km N/S} \times 8\text{ km E/W}$  at Seoul. The N/S spatial resolution ranges from  $4.9\text{ km}$  near the Equator to  $9\text{ km}$  at the northern boundary of the domain while E/W resolution changes to keep the aspect ratio the same as that in Seoul. The 15 spatial resolution at Seoul is 5.5 times better than the  $13\text{ km} \times 24\text{ km}$  resolution of the state-of-the-art OMI LEO instrument at direct nadir. The planned GeoKOMPSAT longitude is  $128.2^\circ\text{ E}$ . The temporal resolution is 1 h during day time. The spectral coverage of  $300\text{--}500\text{ nm}$  in one channel is selected to focus on measurable tropospheric trace gases. A simple one-channel design helps to ensure the 7–10 yr lifetime requirements.
- 20 Based on sensitivity studies of spectral resolution and signal to noise ratios to retrieve concentrations of  $\text{NO}_2$ ,  $\text{SO}_2$ ,  $\text{H}_2\text{CO}$  and  $\text{O}_3$ , the spectral resolution is selected to be  $0.6\text{ nm}$ .  $\text{SO}_2$  was the main driver in optimizing the resolution and signal-to-noise ratio requirements.

To ensure the accurate retrieval of trace gases, the accuracies on the wavelength and radiometric calibrations are required to be better than  $0.01\text{ nm}$  and 4 %. Utilizing the solar Fraunhofer lines, the actual accuracy may be determined to much higher accuracy ( $0.001\text{ nm}$  or better) (Caspar and Chance, 1997; Chance, 1998). The current

requirement for polarization sensitivity is < 2 %. The impact of stray light on the UV/VIS measurements shall be less than 2 % of the true signal. The performance of the system is comparable to or expected to be better than the existing LEO instruments. GEMS will provide the first hourly measurements of trace gases from space.

- 5 Accurate cloud pressure is an input for both ozone and trace gas retrieval algorithms. OMI has used the O<sub>2</sub>-O<sub>2</sub> absorption near 477 nm and rotational Raman scattering in the range 346–352 nm to determine cloud top heights (e.g. Acarreta et al., 2004; Joiner and Vasilkov, 2006; Vasilkov et al., 2008). GEMS includes both these spectral ranges. In addition, cloud information at much higher spatial resolution will be available from an  
10 ABI typed sensor within typically 7 min from GEMS data acquisition.

### 3 Ozone profile retrieval algorithm

We use the OMI ozone profile algorithm of Liu et al. (2010a) to retrieve ozone profiles from BUV measurements. This algorithm retrieves partial ozone columns at 24 layers from the surface to ~ 60 km (0.22 hPa) using optimal estimation (OE) (Rodgers, 2000), optimally combining information from measurements with a priori information, depending on the sensitivity of the measurements. The principle of OE is to find the optimal solution by simultaneously and iteratively minimizing differences between measured and simulated radiances, and between the state and the a priori vector (e.g. an ozone profile), constrained by measurement and a priori error covariance matrixes, respectively  
15 (Rodgers, 2000). We perform retrievals from OMI radiances with OMI (270–330 nm) and GEMS (300–330 nm) spectral ranges respectively, after correcting some systematic biases derived from zonal mean MLS V2.2 data in the tropics, (Liu et al., 2010b). GEMS is designed to have spectral resolution of 0.6 nm, while the spectral resolution of OMI is approximately 0.63 nm below 310 nm and 0.42 from 310–365 nm (Leveld et al.,  
20)  
25 2006). The change in the sensitivity due to the different spectral resolution of OMI and GEMS should be insignificant (Natraj et al., 2011). For simplicity of comparison, the effects of spectral resolution are ignored. The performance of the GEMS system is at

least comparable to the existing similar LEO instruments, as pointed out in Sect. 2 and thus we use the OMI random-noise errors to construct measurement covariance error matrices for the retrieval performance of both OMI and GEMS. The inverse algorithm of Liu et al. (2010a) uses a monthly and zonal mean ozone profile climatology (McPeters et al., 2007) to define the a priori vector and the a priori error covariance matrix. We limit the study to solar zenith angles less than 85° and the average fitting residuals less than 3 %, consistent with OMI experience.

## 4 Comparison of retrieval characteristics between OMI and GEMS

This section shows the validity of the proposed GEMS spectral coverage for providing the adequate tropospheric ozone information as well as investigating the loss of the stratospheric ozone information from excluding shorter UV wavelengths. We perform ozone retrievals from one orbit of OMI UV measurements on 30 April 2006 with four spectral ranges (windows). The upper limit of these windows is fixed to be 330 nm while the lower limit varies from 270 nm to 310 nm. We investigate the effect of different windows on ozone retrievals using their retrieval sensitivities and errors. We use the Averaging Kernel (AK), which characterizes how well the measurements probe the vertical distribution of atmospheric ozone information (Rodgers, 2000; Liu et al., 2005, 2010a) to represent the retrieval sensitivity. Each row of the AK matrix indicates the sensitivity of the retrieved ozone at each layer to the perturbation of ozone at all layers. When the diagonal value of the AK matrix for a layer is unity, the measurements have perfect information for ozone at that layer. The AKs can be used to estimate the Vertical Resolution (VR) of retrievals often specified as the Full Width at Half Maximum (FWHM). Each diagonal element of the AK gives the DFS for that layer, the number of independent pieces of information available at that layer from measurements. The DFS is a standard measure of the capability of atmospheric profile retrievals from satellite measurements (e.g. Liu et al., 2005, 2010a; Worden et al., 2007; Natraj et al., 2011; Bak et al., 2012). The error budget in OE-based retrievals is estimated in terms of

to  $\sim 3$  for GEMS although the change in corresponding stratospheric ozone column retrieval errors is negligible.

We further examine altitude regions where excluding measurements below 300 nm causes much loss of stratospheric information. In Fig. 2, the performances for retrieving ozone profiles from OMI (blue lines) and GEMS (red lines) are compared with respect to the mean AKs and mean relative retrieval errors in low and mid latitude regions, respectively. In the atmosphere below  $\sim 20$  km, AKs for each instrument show similar distributions. This illustrates that GEMS contains not only most of the tropospheric ozone information compared to OMI, but also most of the capability to separate tropospheric from stratospheric ozone columns. OMI AKs have well-defined peaks from  $\sim 25$  km to 45 km, with the highest DFS values. GEMS AK plots have very broad peaks above 30 km, with rapid reduction of their DFS values. The GEMS profile retrieval errors increase by 1–2 % for most of the stratosphere and by 3–4 % above  $\sim 40$  km, compared to OMI. In addition, Fig. 2 shows the comparison of the retrieval errors with a priori errors (black line). The magnitude of GEMS retrieval errors is very close to a priori error above  $\sim 40$  km, indicating the weak retrieval sensitivity and the strong influence of a priori on the retrievals. The reduction of the spectral range thus has some impact on the quality of the stratospheric ozone profile retrievals from GEMS.

## 5 Evaluation of ozone retrievals against MLS

In this section, we assess whether information available from GEMS measurements is enough to resolve the true variability of the stratospheric ozone profiles. The MLS V3.3 standard O<sub>3</sub> products for April 2006 are used as reference values. We collocate MLS and OMI pixels within  $\pm 0.5^\circ$  in both latitude and longitude and 500 s in time, giving  $\sim 30\,000$  collocated pixels. We apply data screening to exclude bad retrievals from both profile algorithms using criteria described in Sect. 3 for OMI and in Sect. 5.1 for MLS. V3.3 MLS O<sub>3</sub> profiles are recommended for use from 261–0.02 hPa (Livesey et al., 2011). They are provided at 12 pressure levels per pressure decade from 1 hPa and

**Evaluation of ozone profile and tropospheric ozone retrievals**

J. Bak et al.

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

higher pressures ( $\sim 1.3$  km resolution), 6 per decade from 0.1–1 hPa ( $\sim 2.5$  km resolution), and 3 per decade at lower pressures. For comparisons, the MLS profiles of volume mixing ratio are converted into partial ozone columns in Dobson Units (DU, 1 DU =  $2.69 \times 10^{16}$  cm $^{-2}$ ). V3.3 MLS and OMI/GEMS partial columns are interpolated into the MLS V2.2 retrieval grids. The vertical spacing of the V2.2 pressure grid is similar to OMI,  $\sim 2.5$  km below 0.1 hPa, and hence the interpolation error on the difference between OMI and MLS retrieved profiles is expected to be smaller when comparing them on this grid.

In Figs. 3–7 we compare the OMI and GEMS profiles and column ozone to MLS from 215 hPa to 0.2 hPa, the vertical range recommended by Liu et al. (2010b) for comparing OMI and MLS v2.2 ozone profiles. The comparison approach largely follows Liu et al. (2010b).

## 5.1 MLS data

MLS is on board the Aura platform with OMI, so the effect of the spatiotemporal variability on comparisons with OMI (and GEMS) is relatively small (Liu et al., 2010b). MLS measures microwave thermal emission from many molecules; ozone profiles are derived from emission near 240 GHz. MLS is limb-viewing and thus has higher vertical resolution but much sparser horizontal coverage than OMI. The V3.3 MLS O<sub>3</sub> data used here is from the NASA Goddard Space Flight Center Earth Sciences (GES) Data and Information Services Center (DISC). Although extensive validation results for the V3.3 MLS ozone product have been not released, they are not expected to differ significantly from those for the V2.2 data (Livesey et al., 2011). Based on the V2.2 MLS validation papers by Froidevaux et al. (2008), Jiang et al. (2007), and Livesey et al. (2008), the precision of the ozone profiles is  $\sim 5\%$  for much of the stratosphere, increasing to  $\sim 10\%$  at the lowest stratospheric altitudes. The precision of the stratospheric column ozone down to 215 hPa is about 2 %. To exclude bad retrievals, we reject profiles with negative ozone values less than  $-0.15$  ppmv over 45–261 hPa pressure range and consider profile having even *status* value, *quality* higher than 0.6, *convergence* lower

than 1.18, and *precision* value higher than 0, according to the V3.3 data screening recommendations by Livesey et al. (2011).

## 5.2 Comparison of profiles

We analyze the statistical differences of GEMS/OMI retrievals and a priori relative to MLS profiles for April 2006. A priori profiles are based on the monthly zonal mean ozone profile climatology of McPeters et al. (2007) (hereafter the “LLM” climatology). The absolute difference is normalized to MLS measurements to define the relative differences. Figure 3 shows the mean biases versus  $10^{\circ}$  latitudinal bins at each MLS layer from 0.22–215 hPa and the corresponding  $1\sigma$  standard deviations. OMI and GEMS retrievals have similar agreement with MLS around the mean tropopause (black line), but show some large negative biases, usually within –20 % to –40 % below 68 hPa at low/mid latitude. The standard deviations of the biases range from 20 % to 50 %. These large differences in the tropopause region likely originate from insufficient vertical resolution of OMI to capture the small-scale changes observed by MLS. A priori biases have opposite signs around tropical tropopause, mostly positive, indicating that some of the differences (where ozone values are relative small) are due to systematic biases between OMI/GEMS and MLS.

The largest impact of not using measurements below 300 nm is mainly found for pressures less than  $\sim 3$  hPa ( $\sim 40$  km) where there is no peak in the AKs for GEMS and the retrieval error is very close to a priori (Fig. 2). GEMS retrievals show the large biases of  $\sim 20$  % down to 3 hPa, especially at high latitude. The GEMS positive mean biases at these layers are consistent with those of the a priori, indicating the strong influence of the a priori on retrievals. Moreover, the GEMS retrievals have more vertical oscillation in the biases between 1–50 hPa especially in  $30^{\circ}$  S– $30^{\circ}$  N, due to reduced vertical sensitivity and stronger a priori influence relative to OMI retrievals. For example, the tropical region shows distinct negative bias of  $\sim -10$  % at  $\sim 2$  hPa and positive bias of  $\sim 10$  % at  $\sim 10$  hPa where OMI is retrieved within  $\pm 5$  % with respect to MLS.

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

Figure 4 shows globally-averaged profiles of mean biases and standard deviations for April 2006. From 60 to 100 hPa, the global mean biases of GEMS show 5 % larger negative mean biases than OMI. From 1 hPa to 0.2 hPa, the global biases range from ~ 0 % to 17 % for GEMS and from 0 % to 10 % for OMI. The global mean bias profiles remain within ± 5 % between 1 hPa and 60 hPa for both OMI and GEMS retrievals. However, the corresponding standard deviations of GEMS mean biases are found to be slightly larger than those for OMI, by up to ~ 5 %.

### 5.3 Comparison of sub-column O<sub>3</sub> in the stratosphere

In order to better understand the information obtained with different spectral windows, we explore the retrieval performance for sub-layer column O<sub>3</sub>. The profiles are integrated into the three pressure layers, bounded by the 0.2, 1, 68, and 215 hPa pressure levels. Figure 5a gives scatter plots of GEMS versus MLS layer column ozone grouped into low (0°–30°), mid (30°–60°), and high (60°–90°) latitude bands for the Northern Hemisphere. Figure 5b and c give OMI and a priori with respect to MLS. The comparison statistics (mean biases, standard deviations, and correlation coefficients) are summarized in Table 1.

First, the weak sensitivity of GEMS measurements to 0.2–1 hPa layer column O<sub>3</sub> (upper column O<sub>3</sub>) is clearly found, with a correlation coefficient of ~ 0 with MLS. In this layer, the scatter of GEMS versus MLS is very similar to that of a priori and MLS, especially in the low/mid latitudes. In contrast, OMI contains more information content than GEMS due to the inclusion of spectral information below 300 nm, as seen from the positive correlation of more than 0.6 with MLS above 30° N. Second, both OMI and GEMS retrievals show considerable sensitivity to middle and lower layer column O<sub>3</sub>. They show much better agreement with MLS than with a priori. However, the GEMS retrievals have slightly weaker correlation with MLS than does OMI even below 1 hPa. The GEMS performance for the middle column O<sub>3</sub> increases the positive biases by ~ 0.4 % at low latitude and ~ 1.5 % at mid/high latitude in relation to OMI. For the lower column O<sub>3</sub>, the largest difference between OMI and GEMS with MLS is at mid

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

**Evaluation of ozone profile and tropospheric ozone retrievals**

J. Bak et al.

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

latitude: mean biases increase from  $-9.1$  DU ( $-13\%$ ) for OMI to  $-15.5$  DU ( $-20.8\%$ ) for GEMS. In this pressure range, the ozone is mostly retrieved in the UTLS region and some of large negative biases are associated with the insufficient vertical resolution of nadir BUV observation. The larger negative biases of GEMS indicate that there is some impact of the 270 to 300 nm spectral information on retrieval in the UTLS region despite the negligible difference in the retrieval sensitivity around the tropopause between OMI and GEMS as shown in Fig. 2.

#### 5.4 Comparison of stratospheric column ozone

We compare stratospheric column ozone (SCO) from 0.2 to 215 hPa as function of latitude in Fig. 6. Both OMI and GEMS SCO are generally negatively biased with respect to MLS. In Table 1, we indicate the positive biases above 68 hPa and negative biases below it for sub-layer column  $O_3$  between 215 hPa and 0.2 hPa. Therefore, the SCO negative biases might be largely contributed by the retrievals in the UTLS region. The OMI biases relative to MLS V3.3 for April 2006 investigated in this study are within 10 DU ( $-3\%$ ) that are larger compared to the biases relative to MSL V2.2 for 2006 within 5.5 DU ( $2\%$ ) (Liu et al., 2010b). The mean biases show their maximum values in mid latitudes; their standard deviations increase generally with latitude. The GEMS/OMI biases in the tropics are less than  $-2\%$ . The main difference in OMI and GEMS stratospheric column ozone is found at latitude bands above  $35^\circ$  N/S; GEMS biases are larger than OMI biases by up to 5 DU ( $\sim 1\%$ ). Standard deviations for the GEMS and MLS differences are similar to those for the OMI and MLS differences, varying from 1 % to 3 %, depending on latitude.

### 6 Conclusions

We investigate the retrieval performance for ozone profiles from OMI level 1B data using different spectral windows (OMI: 270–330 nm, GEMS: 300–330 nm), in order to

**Evaluation of ozone profile and tropospheric ozone retrievals**

J. Bak et al.

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

retrievals above  $\sim 3$  hPa. Even for below  $\sim 3$  hPa, some improvements are found outside of the UTLS region. However, the ML climatology tends to increase the differences between retrievals and MLS generally in the UTLS compared to the LLM climatology. We will further investigate the various a priori data to select the optimal one for GEMS ozone profile retrievals in a future study.

Both GEMS and OMI retrievals below 68 hPa show large mean biases with MLS and their large standard deviations, but GEMS has larger biases. The altitude region below 68 hPa is associated with the UTLS region where atmospheric dynamical processes strongly influence ozone variability. The LLM climatology only represents ozone variances as function of month and latitude and thereby is not suitable for representing the ozone variances in the UTLS region. Therefore, some standard deviations of the differences between OMI/GEMS and MLS might be related to differences between a priori and true states. Therefore, there is substantial room for improving ozone retrievals in the UTLS region by using the dynamically-oriented a priori information. The tropopause-height dependent (TB) climatology of ozone profiles for the OMI retrieval algorithm is under development by Bak et al. (2011). We will investigate the use of TB climatology for GEMS retrievals in future work. Furthermore, we indicated that the large negative biases around the tropopause are associated with the systematic biases between OMI/GEMS and MLS V3.3 retrievals.

Based on the comparison results, we determine that future GEMS measurements are suitable for deriving ozone profiles below  $\sim 3$  hPa with accuracy slightly worse than OMI. We compare the stratospheric column ozone (SCO) integrated over the 0.2–215 hPa as a function of latitude. GEMS SCO shows similar quality to OMI SCO. The GEMS SCO biases are less than  $-4\%$  and  $-3\%$  for OMI with the similar standard deviations of their biases. As the total ozone column is derived from wavelengths longer than 300 nm, the similar OMI/GEMS SCO retrieval performance indirectly demonstrates that the tropospheric ozone column retrieval performance is similar to that of OMI.

<sup>a</sup>Mean biases and 1 $\sigma$  standard deviations are in DU (values in parenthesis are in percent).

<sup>b</sup>Correlation coefficient.

## Evaluation of ozone profile and tropospheric ozone retrievals

J. Bak et al.

**Fig. 1.** Retrieval characteristics with the four spectral ranges between 270 nm and 330 nm, calculated from OMI level 1b data in orbit 9522 on 30 April 2006. In the left panels (**a,c**), the mean of Degrees of Freedom for Signal (DFS) in the troposphere and stratosphere are plotted in 1° latitude bins (80° S to 80° N) with solar zenith angles given. The right panels (**b,d**) show the corresponding retrieval errors in tropospheric and stratospheric ozone columns, normalized to the a priori.

## Evaluation of ozone profile and tropospheric ozone retrievals

J. Bak et al.

**Fig. 2.** Comparison of mean averaging kernels and relative retrieval errors (normalized to a priori profiles) at each layer from OMI (blue) and GEMS (red) retrievals, for low latitude (30° S–30° N: upper panel) and mid latitude (30° S/N–60° S/N: lower panel). The associated a priori error is also plotted with black line in right figures. In this analysis, we only consider pixels with cloud fraction of less than 0.3 and surface albedo less than 20 %. The caption includes the average conditions for low/mid latitude pixels: solar zenith angle ( $\overline{\text{SZA}}$ ), viewing zenith angle ( $\overline{\text{VZA}}$ ), cloud fraction ( $f_c$ ), and surface albedo ( $\overline{\alpha}_s$ ). The dashed line denotes the mean tropopause height. The first column of each legend gives the center altitudes of the 24 layers. The other two columns in the left figures give DFS; in the right figures they give absolute retrieval errors in Dobson units ( $1 \text{ DU} = 2.69 \times 10^{16} \text{ cm}^{-2}$ ).

## Evaluation of ozone profile and tropospheric ozone retrievals

J. Bak et al.

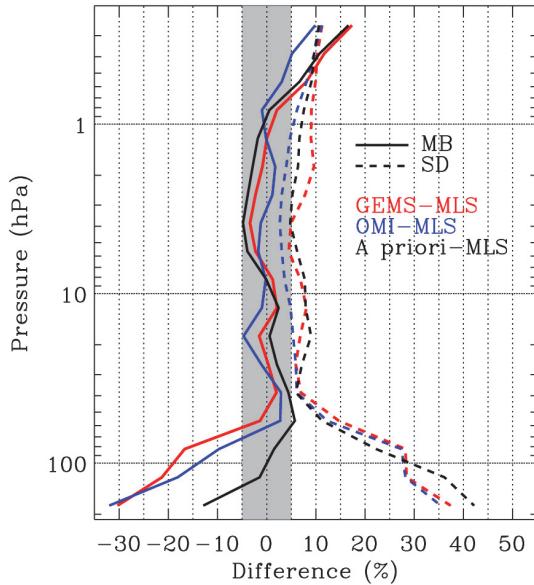

**Fig. 3.** Comparison of MLS ozone profile measurements with respect to **(a)** GEMS and **(b)** OMI retrievals for  $10^{\circ}$  latitude bins ( $-80^{\circ}$  S– $80^{\circ}$  N) for April 2006. **(c)** The a priori (based on LLM climatology) used in the GEMS/OMI retrievals is also compared with MLS. Left and right panels show the Mean Biases (MB) and the  $1\sigma$  Standard Deviations (SD) of the relative differences as functions of MLS vertical layers (0.22–215 hPa). The black line indicates the position of the mean tropopause during April 2006.

## Evaluation of ozone profile and tropospheric ozone retrievals

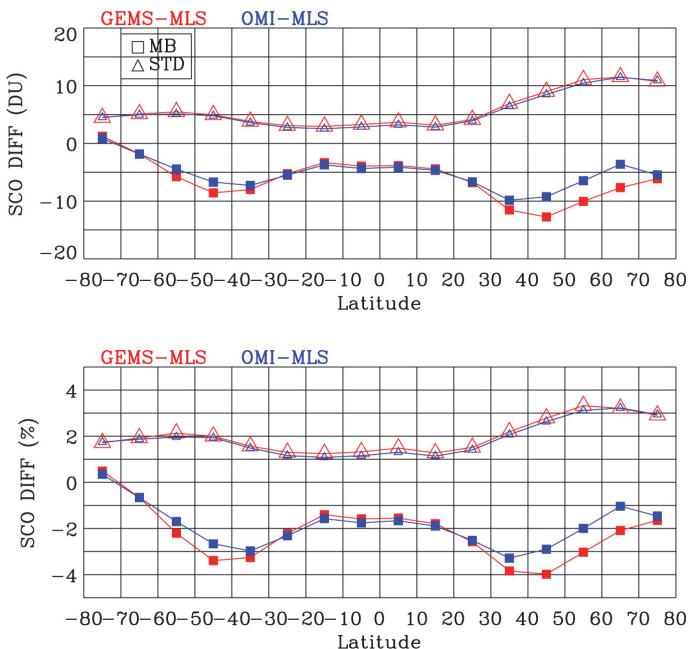

J. Bak et al.

**Fig. 5.** Scatter plots of (a) GEMS versus MLS, (b) OMI versus MLS, and (c) a priori versus MLS for partial column ozone at three vertical layers between 0°N and 90°N for April 2006. The layers are bounded by 0.2, 1, 68, and 215 hPa. Color coding for different latitude bins is indicated in the legend on the top left panel. Dashed lines are unit slope.

# Evaluation of ozone profile and tropospheric ozone retrievals

J. Bak et al.

**Fig. 6.** Comparison of Stratospheric Column Ozone (SCO) above 215 hPa in 10° latitude bins for April 2006. The upper panel and lower panel display the mean biases (square symbol) and standard deviations (triangle symbol) for absolute differences (DU) and relative differences (%), respectively. The relative difference is defined as the absolute difference  $\times 100\% / \text{MLS}$ .

**Evaluation of ozone profile and tropospheric ozone retrievals**

J. Bak et al.

**Fig. 7.** Same as Fig. 3, but for the use of ML climatology (2012) as a priori data.
