Atmospheric Measurement Techniques Discussions

Airborne emission measurements of SO_2, NO_x and particles from individual ships using sniffer technique

Abstract

A dedicated system for airborne ship emission measurements of SO_2, NO_x and particles has been developed and used from several small aircrafts. The system has been adapted for fast response measurements at 1 Hz and the use of several of the instruments is unique. The uncertainty of the given data is about 20.3 % for SO_2 and 23.8 % for NO_x emission factors. Multiple measurements of 158 ships measured from the air on the Baltic and North Sea during 2011 and 2012 show emission factors of $18.8 \pm 6.5\,g\,kg_{fuel}^{-1}$, $66.6 \pm 23.4\,g\,kg_{fuel}^{-1}$, and $1.8 \pm 1.3 \times 10^{16}$ particles kg_{fuel}^{-1} for SO_2, NO_x and particle number respectively. The particle size distributions were measured for particle diameters between 15 and 560 nm. The mean sizes of the particles are between 50 and 62 nm dependent on the distance to the source and the number size distribution is mono-modal. Concerning the sulfur fuel content 85 % of the ships comply with the IMO limits. The sulfur emission has decreased compared to earlier measurements from 2007 to 2009. The presented method can be implemented for regular ship compliance monitoring.

1 Introduction

Ships emit large quantities of air pollutants and it is necessary to reduce these to improve air quality (Corbett et al., 2007; European Commission, 2009). Most countries have ratified the International Maritime Organization (IMO) Marpol Annex VI protocol and EU has adopted directive 2012/33/EU which sets limits on nitrogen oxides (NO_x) and sulfur dioxide (SO_2) emissions from ship exhausts. The regulation includes a global cap of sulfur fuel content (SFC) and contains provisions allowing for establishment of special SO_2 and NO_x Emission Control Areas, i.e. SECA and NECA. The Baltic Sea, the North Sea, English Channel and the coastal waters around US and Canada are designated as SECA while the North American area also is a NECA. Following the IMO regulation there will be a global cap of 0.5 % SFC used by vessels from 2020.

AMTD
6, 10617–10651, 2013

In the SECAs the used SFC must not exceed 0.1 % from 2015. The IMO regulation regarding NO_x is more complicated than for SO_2, since NO_x production is dependent on the nature of the combustion process rather than being related to fuel composition. IMO has therefore chosen emission limits (resolution MEPC.177(58)) that correspond to the total NO_x emission in gram per axial shaft energy produced from the engine in kWh. These limits depend on the engine type and they are therefore given vs. the rated rotational speed of the specific engines. Ships built between 2000 and 2010 should emit less than a certain limit (tier 1) while ships built after 2011 should emit 20 % less (tier 2). In NECA the emissions should be 80 % lower than tier 1 by 2016 (tier 3), although this time limit is presently being renegotiated within IMO.

There are several ways available for the shipping companies to adapt to the new regulations. It is possible to use alternative fuel i.e. liquefied natural gas (LNG) or methanol. Abatement techniques to reduce both NO_x and SO_2 emissions are available. However these possibilities are limited due to high costs for investments in often technologies which are under ongoing development. Therefore it is believed that there will be a higher demand and higher prices on low sulfur fuels in the future.

In the SECA the cost for ship transport will increase by 50–70 % due to increased fuel costs (Kalli et al., 2009). There will hence be considerable economic incentive not to comply with SECA regulation. Today the fuel of the ships is controlled by Port State Control authorities conducting random checks of bunker delivery notes, fuel logs and occasional fuel sample analyses in harbors. This is time consuming and few ships are being controlled. There is no available technique able to control what fuel is used in the open sea and in general it is considered easy to tamper with the usage of fuel, especially since ships are using several tanks, often with different fuel.

Here we present airborne emission measurements of emission factors in mass of emitted pollutant per amount of consumed fuel for individual ships. One valuable use of such data is as input data for modeling of the environmental impact of shipping. A new type of ship emission model that has emerged recently calculates instantaneous emissions of ships based on ship movement from Automatic Identification System (AIS),

AMTD
6, 10617–10651, 2013

ship propulsion (Alföldy et al., 2012) calculations and emission factors (Jalkanen et al., 2009, 2012). The latter are taken from laboratory tests and occasional on board measurements (Moldanova et al., 2009; Petzold et al., 2004, 2008). The emission factors depend on engine type, fuel type, use of abatement equipment and load. In general there are large uncertainties in the emission factors for some species, such as particles, and within the SECAs there is additional uncertainty in how well the IMO legislation will be respected regarding fuel use and abatement technologies. There is hence substantial need for efficient techniques for remote measurements of real ship emissions.

The airborne sniffer system described here has been developed as part of a Swedish national project named Identification of gross polluting ships (IGPS) (Mellqvist and Berg, 2010, 2013; Mellqvist et al., 2008) aimed at developing a remote surveillance system to control whether individual ships obeys the IMO legislation of reduced sulphur fuel content (SFC) and NO_x emissions, as discussed above (Alföldy et al., 2012). The sniffer system is usually combined with an optical system (Mellqvist and Berg, 2013) that can be used as a first alert system and also to quantify the emission in $g\,s^{-1}$, but this will not be discussed further here.

The principle of the sniffer method is to obtain emission factors in g pollutant per kg fuel by measuring the ratio of the concentration of the pollutant vs. the concentration of CO_2, inside the emission plume of the ships. This principle has been employed in several other studies both from the air, ships and harbors (Alföldy et al., 2012; Balzani Lööv et al., 2013; Chen et al., 2005; Mellqvist and Berg, 2013; Mellqvist et al., 2008; Sinha et al., 2003) but for a relatively small number of vessels. Here we demonstrate a dedicated system meant for routine surveillance of ship emissions from small airplanes and other platforms. The system includes a fast electrical mobility system to measure particle number size distribution, used here in flight for the first time and a custom made cavity ring down system for fast airborne plume measurements of CO_2 and CH_4. In addition we show unique measurements of 158 individual ships carried out on several occasions per ship in the North and Baltic Seas from a helicopter and two different

AMTD
6, 10617–10651, 2013

airplanes during 2011 and 2012. This data is compared to data from 2007/2008 (Mellqvist and Berg, 2010, 2013). The emission data for the individual ships has been interpreted against IMO limits and ship and engine type. This paper gives recommendations for how future compliance monitoring of ship emissions could be carried out.

2 Methods

In this section the instrumentation, calibration methods and uncertainties are presented. A description of the measurement campaigns and the plume sampling procedure is given here.

2.1 Instrumentation

With the setup presented herein concentrations of CO_2, SO_2, NO_x and sub micrometer aerosol particles are measured.

2.1.1 CO_2 instrumentation

A flight modified Picarro G-2301 is used to monitor the concentration of CO_2 in the air. This instrument is a greenhouse gas monitor based on cavity ring-down spectroscopy (CRDS) (O'Keefe and Deacon, 1988). The instrument is capable of measuring CO_2, CH_4 and relative humidity (RH), the latter for correction issues. The measurements are conducted sequentially with a time response t_{90}, i.e. the time to reach from 10 % to 90 % of the sample value of less than 1 s. The measurement mode was modified in order to obtain as many measurements as possible during the short time in which the aircraft traverses a plume. Depending on the needs, a low or high flow mode can be selected, with either one or two CO_2 measurements per second for each flow setting. In the latter case, the time slot for the measurement of CH_4 is replaced by a second CO_2 sample within the same sequence. During the conducted measurement flights the high flow, 2 Hz CO_2 mode was used.

AMTD
6, 10617–10651, 2013

2.1.2 SO_2 instrumentation

A modified Thermo 43i-TLE trace gas monitor was applied. This instrument analyzes the volume mixing ratio of SO_2, VMR(SO_2), in air by stimulating fluorescence by UV light (Luke, 1997). The detected intensity of fluorescence light is proportional to the volume mixing ratio of SO_2 molecules in the sample gas. In order to gain a higher flow for faster sampling, a hydrocarbon stripper and the flow meter were removed from the monitor which resulted in a flow rate of 6 LPM. The t_{90} is about 2 s and the sample rate was set to 1 Hz. The Thermo 43i-TLE shows some cross response to NO and polycyclic aromatic hydrocarbons (PAH). The VMR (SO_2) reading increases by 1.5 % of the actual VMR(NO). In this study, this error was reduced by simultaneous measurements of NO_x assuming that the fraction of NO is 80 % (Alföldy et al., 2012). The cross-response of PAH is not important since these species are only present at small levels in ship plumes (Williams et al., 2009).

2.1.3 NO_x instrumentation

The NO_x measurements were performed with a Thermo 42i-TL trace gas monitor. This instrument measures the VMR(NO) by chemiluminescence caused by the reaction of NO with ozone (Kley and McFarland, 1980). The intensity of the detected chemiluminescent light is proportional to the VMR(NO) molecules. In order to measure the volume mixing ratio of NO_x, the instrument was run in a mode in which NO_2 is first converted to NO. The sample flow was 1 LPM, which results in t_{90} of less than 1 s and the sample rate 1 Hz.

2.1.4 Particle instrumentation

The particle number size distributions ranging from 5.6 to 560 nm of the emitted plumes were also measured in flight. This was done using the TSI 3090 engine exhaust particle sizer (EEPS). The EEPS is developed for the monitoring of size distributions of aerosol

AMTD
6, 10617–10651, 2013

particles in exhaust gases from combustion engines. It features 10 Hz simultaneous sampling of 32 measurement channels between 5.6 nm and 560 nm and has a sample flow of 10 LPM with a t_{90} of 0.5 s. The data was integrated for 1 s intervals. Particles in the sample air are charged and size selected according to the size dependent mobility in an electrical field (Johnson et al., 2004). The charged particles impact on electrometer plates and the number concentrations in the different size bins are achieved as the generated current. The EEPS has been used for onboard monitoring of ship emissions (Hallquist et al., 2013) and stationary ship plume measurements (Jonsson et al., 2011) in earlier studies. The EEPS was found to be suitable for this kind of airborne plume measurements and was to our knowledge used for the first time on an aircraft. When the EEPS was operated onboard an airplane, it was connected to an isokinetic inlet for which the flow was optimized for the airspeed during plume measurement. There was no isokinetic inlet used for the helicopter based measurements, because the airspeed of the helicopter during measurement was much lower.

2.2 Calculation of emission factors

Emission factors in weight $g\,kg_{fuel}^{-1}$ or particles kg_{fuel}^{-1} are obtained as the ratio of the pollutant x vs. the volume mixing ratio of CO_2. In practice the volume mixing ratios of all measured species are first summed along the plume transect ($\sum[x]$) and then these values are normalized against the corresponding sum for CO_2. In Fig. 1 the volume mixing ratios for CO_2, SO_2 and NO_x and the total concentration of particle number are shown for one transect through the emission plume.

The carbon fuel content is required for the calculation of the emission factors. Studies show it is 87 ± 1.5 %; for marine gas oil, marine diesel oil and residual oil (Cooper, 2003; Tuttle, 1995). For the calculations it is assumed that this fraction remains unchanged after fuel burning and that all burnt carbon is emitted as CO_2. Hence the SO_2 emission factor, EF(SO_2), in $g\,kg_{fuel}^{-1}$ using the atomic respectively molar masses for C and SO_2

AMTD
6, 10617–10651, 2013

can be calculated by

$$\mathrm{EF}(\mathrm{SO_2})\left[\mathrm{g\,kg_{fuel}^{-1}}\right] = \frac{m(\mathrm{SO_2})}{m(\mathrm{fuel})} = \frac{M(\mathrm{SO_2})\cdot\sum\left[\mathrm{SO_{2,ppb}}\right]}{M(\mathrm{C})/0.87\cdot\sum\left[\mathrm{CO_{2,ppm}}\right]} = 4.64\frac{\sum\left[\mathrm{SO_{2,ppb}}\right]}{\sum\left[\mathrm{CO_{2,ppm}}\right]}. \quad (1)$$

The values of SO_2 were corrected for the interference of NO. The cross-sensitivity of the modified instrument was experimentally found to be 1.5 %. A NO to NO_x ratio of around 80 % is assumed (Alföldy et al., 2012). Hence, for samples where NO_x was measured, $\sum[SO_2]$ was subtracted by 1.2 % of $\sum[NO_x]$ over the same plume sample. For samples without measured NO_x data, modeled data from the STEAM database (Jalkanen et al., 2009, 2012) for the NO_x to CO_2 ratios multiplied with measured CO_2 data was used for the correction instead. Where neither measured nor modeled NO_x data was available, the $EF(NO_x)$ was assumed to be 65 $\mathrm{g\,kg_{fuel}^{-1}}$ which was the median value of the measured $EF(NO_x)$ of other ships. The missing NO_x data for correction of the SO_2 data was then retrieved with Eq. (3) in combination with the measured CO_2 data. For the calculation of the sulfur fuel content (SFC), it is assumed that all sulfur is emitted as SO_2. Hence the SFC is calculated by

$$\mathrm{SFC}[\%] = \frac{m(\mathrm{S})}{m(\mathrm{fuel})} = \frac{M(\mathrm{S})\cdot\sum\left[\mathrm{SO_{2,ppb}}\right]}{M(\mathrm{C})/0.87\cdot\sum\left[\mathrm{CO_{2,ppm}}\right]} = 0.232\frac{\sum\left[\mathrm{SO_{2,ppb}}\right]}{\sum\left[\mathrm{CO_{2,ppm}}\right]}. \quad (2)$$

The NO_x emission factor in $\mathrm{g\,kg_{fuel}^{-1}}$ is calculated accordingly in Eq. (3) Most of the NO_x emission is in form of NO (Alföldy et al., 2012). Nonetheless, for these calculations the molecular mass of NO_x is assumed to be the molecular mass of NO_2 following IMO guidelines (MEPC, 2008).

$$\mathrm{EF(NO_x)}\left[\mathrm{g\,kg_{fuel}^{-1}}\right] = \frac{m(\mathrm{NO_2})}{m(\mathrm{fuel})} = \frac{M(\mathrm{NO_2})\cdot\sum\left[\mathrm{NO_{2,ppb}}\right]}{M(\mathrm{C})/0.87\cdot\sum\left[\mathrm{CO_{2,ppm}}\right]} = 3.33\frac{\sum\left[\mathrm{NO_{2,ppb}}\right]}{\sum\left[\mathrm{CO_{2,ppm}}\right]} \quad (3)$$

The specific fuel oil consumption (SFOC) in terms of mass of consumed fuel per axial shaft power is retrieved from the STEAM model (Jalkanen et al., 2009, 2012). It

AMTD
6, 10617–10651, 2013

corresponds to SFOC data supplied by the engine manufacturer through the IHS Fairplay World Shipping Encyclopedia (IHS, 2009), corrected for the estimated load from the ship speed using correction curves supplied by engine manufacturers. The current SFOC value for the measured ship was taken from the STEAM database as a function of the ship's speed at the time of the measurement. The SFOC data is used for the calculation of the NO_x emission per produced energy $EF_{kWh}(NO_x)$ in

$$EF_{kWh}(NO_x)[g\,kWh^{-1}] = EF(NO_x) \cdot SFOC(load). \quad (4)$$

The emission factor for particle number EF(PN) is calculated in Eq. (5) as the sum of the total concentration of the particle number, $\sum[PN]$, with an assumed emission factor of CO_2 of $3.2\,kg\,kg_{fuel}^{-1}$ (Hobbs et al., 2000).

$$EF(PN)[particles\,kg_{fuel}^{-1}] = \frac{\sum[PN]}{\sum[CO_2]} \cdot EF(CO_2) \quad (5)$$

For the calculation of the particle mass distribution, the particle density is assumed to be $1\,g\,cm^{-3}$. The emission factor for particle mass, EF(PM), was then calculated correspondingly to Eq. (5) by substituting $\sum[PN]$ with $\sum[PM]$.

The Geometric Mean Diameter (GMD) and the corresponding Geometric Standard Deviation (GSD) were calculated for the size-resolved particle number concentrations by

$$GMD\,[nm] = \frac{\sum\left[n \cdot \ln\left(D_p\right)\right]}{N} \quad \text{and} \quad (6)$$

$$GSD\,[nm] = \left[\frac{\sum\left[n \cdot \left[\ln\left(D_p\right) - \ln(GMD)\right]^2\right]}{N}\right]^{1/2}. \quad (7)$$

In Eqs. (6) and (7) n is the number concentration in the Channel, N the integrated number concentration and D_p the particle diameter, i.e. the midpoint of the channel.

AMTD
6, 10617–10651, 2013

2.3 Calibrations

The measurements of volume mixing ratios taken inside the ship plumes are analyzed relative to the background and therefore offset errors can be neglected. The accuracy over the dynamic range of interest was assured by frequent calibrations with standard gases, obtained from AGA and Air Liquide with mixing accuracies for CO_2 of 1 % and for SO_2 and NO_x around 5 %.

Usually the gases were measured from gas cylinders containing about 204 ppb NO_x, 401 and 407 ppb SO_2 as well as 370.5 and 410.6 ppm CO_2, respectively. During the last campaign, a standard Thermo 146i Dynamic Gas Calibrator was used instead together with a Thermo 1160 Zero Air Supply, mixing highly concentrated SO_2 and NO_x, both at 60 ppm, with filtered zero air. Mixing ratios of 400 ppb for SO_2 and 300 ppb for NO_x were used for calibration with the dynamic gas calibrator. The results were used to calculate a time series of respective calibration factors and offsets which in turn were used to post calibrate the plume measurements.

The calibrations were usually carried out on the ground before and after the measurement flights. The average precision of the measurements of the calibration gases was found to be negligible small for CO_2, 1.6 % for SO_2 and 0.5 % for NO_x.

The calibration factors that were applied to the measured values are linear interpolated values from the nearest calibrations. The estimated interpolation error is the average of the standard deviations between adjacent calibration factors. This yields 0.1 % for CO_2, 5.4 % for SO_2 and 6.3 % for NO_x.

2.4 Uncertainties

The plumes of 158 different ships have been analyzed. Some ships were repeatedly measured on different occasions so in total 174 plumes were analyzed. The plumes were usually traversed several times for each occasion to improve the statistical validity of the measurements. An average of the precision for all measurements was calculated as the median value of the individual 1-σ uncertainties of the respective

AMTD
6, 10617–10651, 2013

emission factors for plumes that were traversed at least three times. For the calculated emission factors of SO_2 and NO_x in $g\,kg_{fuel}^{-1}$ this yields measurement precisions of 18.8 and 22.4 % respectively.

The overall uncertainties of the emission factors are calculated as the square root of the sum of all squared uncertainties due to calibrations and measurements for the respective gas species and CO_2. Hence, adding the square root of the quadratic sums for the SO_2 emission factor this yields a total uncertainty of 20.3 % and correspondingly 23.8 % for the NO_x emission factor in $g\,kg_{fuel}^{-1}$. These uncertainties are comparable the uncertainties of land-based measurements by Alföldy et al. (2012) who found values of 23 % and 26 % for the emission factors of SO_2 and NO_x respectively. This could be explained with repeated measurements of the specific plumes by repeated traverses with the aircrafts, though the sampling period is shorter as compared to land-based measurements.

In a recent study by Balzani et al. (2013) it is reported that about 14 % of the fuel sulfur content was not emitted as SO_2 for measurements using sniffer technique. Hence, the overall error is 20.3 % for SO_2 with a possible systematic negative bias of 14 %.

An additional uncertainty for NO_x with regard to the IMO regulation, is the fact that the emission factors are usually reported in $g\,kWh^{-1}$, which requires a multiplication with the SFOC. Here, the uncertainty was estimated to be 11 %, assuming the real operation deviates from the test bed measurements of the SFOC. This estimation bases on the average deviation over the range of the SFOC values in the used model database. Thus the total uncertainty for the NO_x emission factor in $g\,kWh^{-1}$ is added to 26.2 %.

A quantification of the uncertainties for the particle measurements has not been performed at this stage.

2.5 Measurement campaigns

The results of four airborne measurements campaigns which were conducted in the years 2011 and 2012 are discussed in this paper. The flights were conducted from

AMTD
6, 10617–10651, 2013

airports in Roskilde (Denmark), Kiel (Germany) and Ostend (Belgium). A summary of the presented measurement campaigns is given in Table 1. The measurements were made on 25 days within these periods. The campaigns covered different European sea areas amongst those the English Channel and the German Bight, but in particular the western Baltic Sea. A map of the monitored regions is shown in Fig. 2.

The measurements were conducted from airplanes, Piper PA31 and Partenavia P68B, and a helicopter of type Eurocopter AS365 Dauphin. The choice of instrumentation depended on the loading possibilities of the respective airborne vehicle. Inlet probes for gas measurements were sited beneath (Piper PA31) or on the side of the fuselage (Partenavia P68B and Dauphin helicopter) of the aircraft. The Partenavia was already equipped with an isokinetic inlet which was used for particulate matter measurements. The particle inlet on the Dauphin was mounted beside the gas inlet, with some distance from the fuselage to minimize effects due to the downwash of the main rotor. The minimum instrumental setup used during all campaigns consisted of a flight modified Picarro G-2301 and a Thermo 43i-TLE for CO_2 and SO_2 measurements, respectively. NO_x was measured with the Thermo 42i-TL during all except the first campaign. The particle size distributions were measured with the EEPS onboard the Partenavia airplane and the Dauphin helicopter. A brief overview of the instrumental setup on each campaign is presented in Table 2. The Partenavia is shown together with the rack mounted instrumental setup in Fig. 3.

2.6 Flight procedure during measurements

The aim of the IGPS project is to relate the measured emission plumes to individual ships. Therefore it is necessary to identify and locate the ships in the area surrounding the measurement. Ships from a certain size and upward are obliged to frequently broadcast their status by the Automatic Identification System (AIS) which was received and logged during the measurement flights. This signal contains the ship identification number and name, its position, course and speed and further information. Together with information about the position of the aircraft and meteorological information, the

AMTD
6, 10617–10651, 2013

source of an emission plume can be identified and connected to the determined emission parameters.

The flights took place above open waters with dense ship traffic. The AIS data was used for the selection and localization of the ships to be observed. Additionally, the AIS data contains information about the course and speed of the ship. Together with meteorological information about current wind speeds and directions the plume position with respect to the ship can be calculated according to Berg et al. (2012). The AIS data is presented on the operators screen like the example in Fig. 4 so ships can be selected before plume measurement and plumes can literally be related to them on the fly.

The plume height is usually between 50 and 70 m. The aircraft traverses the plume in these heights in a zigzag shaped manner. So the emission of several transects through the plume of a ship can be measured. The distance from the ship for these manoeuvers is between 25 to 10 km. Ideally, the procedure begins at further distance from the ship and the ship is approached with each new transect.

3 Results

Here the overall results of the measured ships are presented and discussed. Results for individual measurements can be found as Supplement to this article.

3.1 SO_2 emission factors

The distribution of the number of the observed ships over their SO_2 emission factor is shown in the histogram in Fig. 5. The maximum of the distribution is found at 20 $g\,kg_{fuel}^{-1}$ The first and the third quartile of the SO_2 emission factors in the histogram are 15.8 and 21.9 $g\,kg_{fuel}^{-1}$. This is reasonable because the IMO limit for sulfur in the fuel of ships in the observed region is 1 % which corresponds to 20 $g\,kg_{fuel}^{-1}$. Hence, this maximum was expected as measurements were taken mostly from commercially driven cargo, tanker and passenger vessels that were assumed for economic reasons to generally

AMTD
6, 10617–10651, 2013

run close to the sulfur limit. Hence, a sharp decrease in the number of ships with SO_2 emission factors higher than 20 g kg_{fuel}^{-1} can be seen.

Yet, the SO_2 emission factors of four of the analyzed 174 ship plumes are between 40 and 44 g kg_{fuel}^{-1}. Two of these plumes originated from a fast Ro-Pax ferry which was observed on two different days during the campaign in Roskilde in 2011 – 15 June and 29 June with SO_2 emission factors 42.4 and 40.7 g kg_{fuel}^{-1} respectively. The other two plumes with exceptionally high emission factors were emitted from a crude oil tanker and a cargo ship. Considering the uncertainty in the measurements of 20 % it can be found that 85 % of all monitored ships would comply with the sulfur limit of 1 %. Not considering a systematic bias of 14 % for sulfur that is emitted in other forms than SO_2, as mentioned in the uncertainty analysis. The results of flight campaigns over North and Baltic Sea conducted between 2007 and 2009 are shown in the inset in Fig. 5 (Berg, 2011; Mellqvist and Berg, 2010, 2013). The overall distribution of the SO_2 emission factor was 18 % higher as compared to the distribution found in this study. The reason is that in 2010 the IMO changed the limit for the amount of sulfur in fuel in the North and Baltic Sea from 1.5 to 1 %.

3.2 NO_x emission factors

NO_x emissions were measured for 87 different vessels on 91 different occasions. The distribution of the number of analyzed ship plumes over NO_x emission factors is shown in Fig. 6. Most ship plumes emit around 70 g kg_{fuel}^{-1} of NO_x. The first and third quartiles are 51.9 and 76.1 g kg_{fuel}^{-1}. The average NO_x emission factor related to the produced energy is 13.1 g kWh^{-1} with respective first and third quartiles of 10.4 and 15.2 g kWh^{-1} for the measured plumes. In Table 3, the NO_x emission factors are presented for different crankshaft speeds. The highest emission factors with an average of 13.6 g kWh^{-1} were measured at slower engine speeds with a significant difference to emissions at engine speeds above 500 rpm. For a ship running close to its design speed, which is typically the case in this study, a difference between the instantaneous emission factor

AMTD
6, 10617–10651, 2013

and the IMO curve is foreseen for the ships. For instance a typical slow speed, Wärtsilä engine has 15.8 g kWh^{-1} at 75 % load while the NO_x weighted IMO value here is 3 % lower (Tadeusz Borkowski, personal communication, 9 June 2013). For measurements of ships in harbors running at 25 % load this discrepancy becomes much larger. However, considering the instantaneous emissions that were evaluated for this study, the tier 1 limit would apply to 58 % and the tier 2 limit to 7 % of the observed ships. Summarized it is seen that 95 % of the analyzed ship plumes would comply with the respective NO_x limits considering their instantaneous NO_x emission figures.

3.3 Particle emission factors

Size-resolved particle number distributions were measured between 15 and 560 nm at different distances to the vessel. Concentrations of particles with diameters below 15 nm were neglected due to high noise that occurred in the lower size channels of the EEPS. The distributions in the measured size range are mono-modal.

The averaged particle diameters and emission factors at different distances to the emission source are presented in Table 4. The average geometrical mean diameter increases from 50 to 62 nm with increased distance. The half width of the distribution increases from 49 to 61 nm. In addition the emission factor for particle number (PN) decreases with longer distance from 3 to 1×10^{16} particles kg_{fuel}^{-1}. The strongest gradient of the emission factor for particle number as function of distance to the ship can be seen for distances below 1 km. However, the emission factor for particle mass (PM) does not change significantly over distance from its average of 2770 mg kg_{fuel}^{-1}.

A relation between the averages of the emission factors of PN and PM, which were binned for the corresponding SO_2 emission factors from the measurements, can be seen in Fig. 7. The correlations are good with R^2 values of 0.98 for PN and 0.81 for PM. However, standard deviations for both emission factors are in the order of their averages. For the PN emission factor, the slope of the found regression is $(1.1 \pm 0.2) \times 10^{15}$ particles g^{-1} and compares very well with the one that was presented by Alföldy (Alföldy et al., 2012) with corresponding slope $p_{1,Lit} = 1 \times 10^{15}$ particles g^{-1}.

AMTD
6, 10617–10651, 2013

As the intercept is around zero and the slope is positive it is assumed that the emitted particles in the measured size range are sulfur based.

4 Discussion

The emission factors sorted for different ship types are presented in Table 5. A comparison of the found results with other studies is given in Table 6.

The majority of the measured emissions originated from passenger ships, cargo ships and tankers. The SO_2 emission factors of these three types are around 19.0 $g\,kg_{fuel}^{-1}$. Trailing suction hopper dredger vessels show a much lower average SO_2 emission factor of 7.4 $g\,kg_{fuel}^{-1}$. Further, the presented emissions were measured from four different ships of this type. So they seem to run on low sulfur fuel in general. This is has also been reported for measurements at the harbor of Rotterdam in 2009 (Alföldy et al., 2012). Passenger and cargo ships and tankers are commercially driven, so the emission factor of SO_2 is around 19 $g\,kg_{fuel}^{-1}$ was expected for these types, because all measurements were conducted in regions with a 1 % limit for sulfur content in the fuel.

The NO_x emission factors are similar for the different ship types. Although it can be seen that cargo ships emit at a slightly higher amount of NO_x compared to passenger ships and tankers. This is also described by Williams et al. (2009) for measurements in the Mexican Gulf, showing that container carriers and passenger ships emit an average of 60 $g\,kg_{fuel}^{-1}$ while larger ships such as bulk freight carriers and tanker ships have average NO_x emissions of 87 and 79 $g\,kg_{fuel}^{-1}$, respectively. The averaged NO_x emission factors shown in Table 9 are in agreement with ship-borne measurements carried out by Williams et al. (2009) and Murphy et al. (2009) who describes simultaneous airborne and on-board measurements for one ship. Alföldy et al. (2012) made measurements on the shore side in the ship channel of Rotterdam measuring an average NO_x emission factor of 53.7 $g\,kg_{fuel}^{-1}$ which they claim is in agreement with the EDGARv4.2 database (European Commission, 2009). This is significantly below the

AMTD
6, 10617–10651, 2013

values found for the presented flight measurements but can be explained with typically different engine load conditions in harbors.

The overall average of the PN emission factor is $1.8 \pm 1.3 \times 10^{16}$ particles kg_{fuel}^{-1} and for PM it is 2770 ± 1626 mg kg_{fuel}^{-1}. These values match very well of other studies on ship emissions (Alföldy et al., 2012; Chen et al., 2005; Jonsson et al., 2011; Lack et al., 2009; Moldanova et al., 2009; Murphy et al., 2009; Petzold et al., 2008, 2010; Sinha et al., 2003). Closer to ships typical measured particle concentrations are in the order of 1×10^{11} particles cm^{-3} so a significant amount of particles would coagulate (Hinds, 1999; Willeke and Baron, 1993). Hence coagulation is assumed to be the dominant process for the decrease seen in the PN emission factor with distance while the PM emission factor remained stable.

The PN and PM emission factors of the observed passenger ships are at the lower limit, whereas cargo ships and tankers show significantly higher emissions. Although only five plumes of four different passenger ships were analyzed for particulate matter emission factors, it appears that passenger ships emit about half as many particles as other ship types. The plumes of the passenger ships were traversed even up to several kilometers away from the ship and the precision is comparatively high. Hence, this indicates that the PN emission factor of passenger ships generally is small compared to other types.

5 Summary and conclusions

Airborne in-situ measurements of 174 ship plumes from 158 different ships at open sea were analyzed for this study. The emission factors of SO_2, NO_x and particles with particle diameters between 15 and 560 nm are presented.

The average SO_2 emission factor is 18.8 ± 6.5 g kg_{fuel}^{-1}. This corresponds to a sulfur fuel content of around 1 %, which was found for most of the studied ship plumes. The results show that 85 % of the monitored ships comply with the limits that were defined by the IMO for sulfur content in the observed sea regions. By comparison with earlier

AMTD
6, 10617–10651, 2013

studies (Berg, 2011; Mellqvist and Berg, 2010, 2013) a reduction of the SO_2 emission factors after the reduction of the sulfur limit in 2010 was observed.

The average of the engine dependent emission of NO_x is $66.6 \pm 23.4\,g\,kg_{fuel}^{-1}$. This compares very well to earlier studies conducted from measurement platforms on land, water and in the air.

The particle emission factors were presented relative to consumed fuel and engine power. The PN emission factors decrease with the distance to the plume while the particle diameters increase which was assumed to be due to coagulation. A strong gradient was found for distances up to 1 km. A correlation between average sulfur and particle emissions was found, although the standard deviation for individual measurements is very high.

The uncertainty for the SO_2 and NO_x emissions in $g\,kg_{fuel}^{-1}$ is respectively 20 % and 24 % and is comparable to the results of a land-based study (Alföldy et al., 2012). With this level of uncertainty the developed system can be used for the identification of gross polluting ships from airborne platforms. By using aircrafts as operation platforms, the limitation of monitoring ships from stationary land-based sites becomes obsolete. Further, numerous ships can be reached and controlled within in a short time, especially when they are making way at open sea. Another benefit of a moving over a stationary platform is that a changing wind direction is less critical as the flight path can be adapted to the direction of the plume. The main drawback in using airplanes is the very short time in which a plume is traversed at each transect, because a better averaging could be achieved with longer sampling times for the plumes. On the other hand samples can be taken repeatedly with aircrafts. It is noteworthy that with measurements from aircrafts particles of the same plume can be sampled at different distances.

The system is presently installed more permanently in the mentioned Navajo Piper aircraft for compliance monitoring. New flight measurements will be carried out, using also two optical devices.

Table 3. NO_x emissions in relation to the rated engine speed of the ships. In total 91 plumes were analyzed. In this table, ships going on 2-stroke engines are found below 300 rpm. Ships with higher rated engine speeds were going with 4-stroke engines. In order to see if NO_x emissions are exceeding the IMO limits, the measurement uncertainty was considered. It should be considered that in contrast to IMO regulation the measurements only show the instantaneous emission.

Rated engine speed [rpm]	Average EF(NO_x) [g kWh^{-1}]	Average EF(NO_x) [g kg$_{fuel}^{-1}$]	Number of plumes	Number of plumes exceeding IMO limits
0 . . . 300	13.6 ± 5.3	71.3 ± 28.3	44	3
300 . . . 500	13.8 ± 2.4	67.9 ± 10.4	18	–

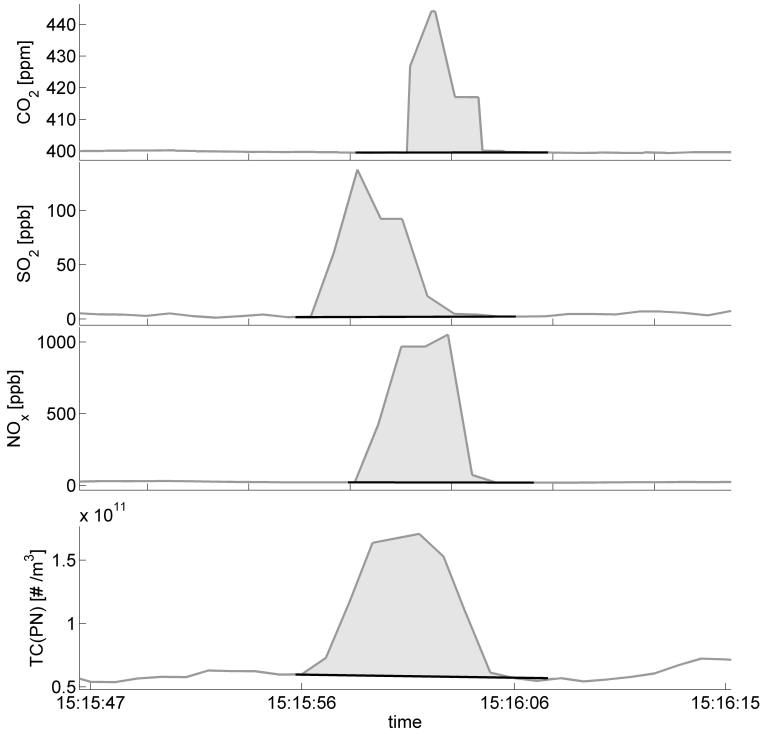

Fig. 1. Example of a plume transect measurement. The volume mixing ratios of CO_2, SO_2 and NO_x are measured. The presented total concentration, TC(PN) of particles is calculated from the measurement of the particle number over size distribution. The volume mixing ratios and particle concentration above the respective baselines (black line) are summed along the transect path. The ratio of the areas (light grey) for SO_2, NO_x and TC(PN) to CO_2 is proportional to the respective emission factor expressed in $g\,kg_{fuel}^{-1}$ and $particles\,kg_{fuel}^{-1}$, respectively.

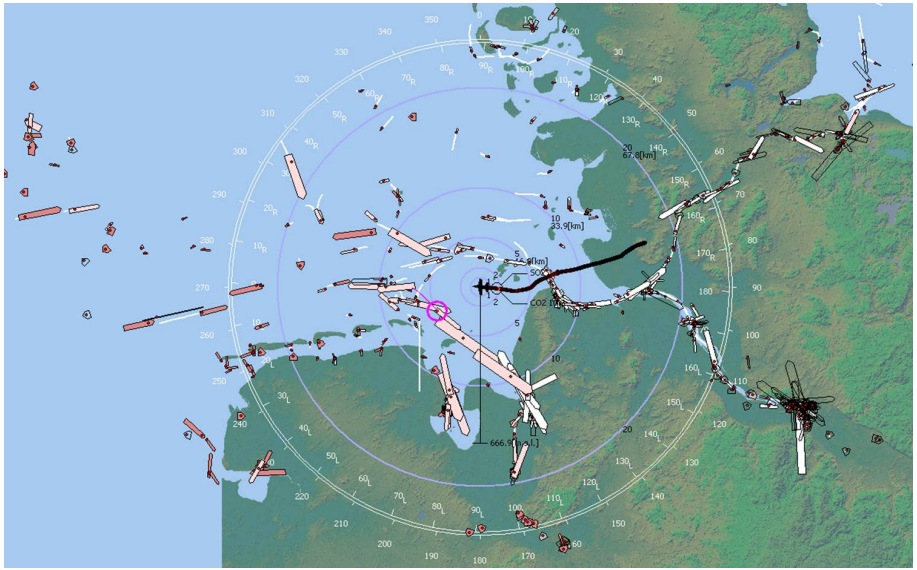

Fig. 4. Map for real-time navigation purpose that is presented to the operator by the IGPS software showing the current locations of surrounding ships and aircraft from the received Automatic Identification System (AIS) data sent by the ships. The different size of the ships corresponds to their Gross Tonnage. The blue circles around the aircraft's location indicate the distance to the ships and the time to reach these. The two white circles give information about the ships' locations relative to the aircraft with respect to north and the current course of the aircraft respectively.

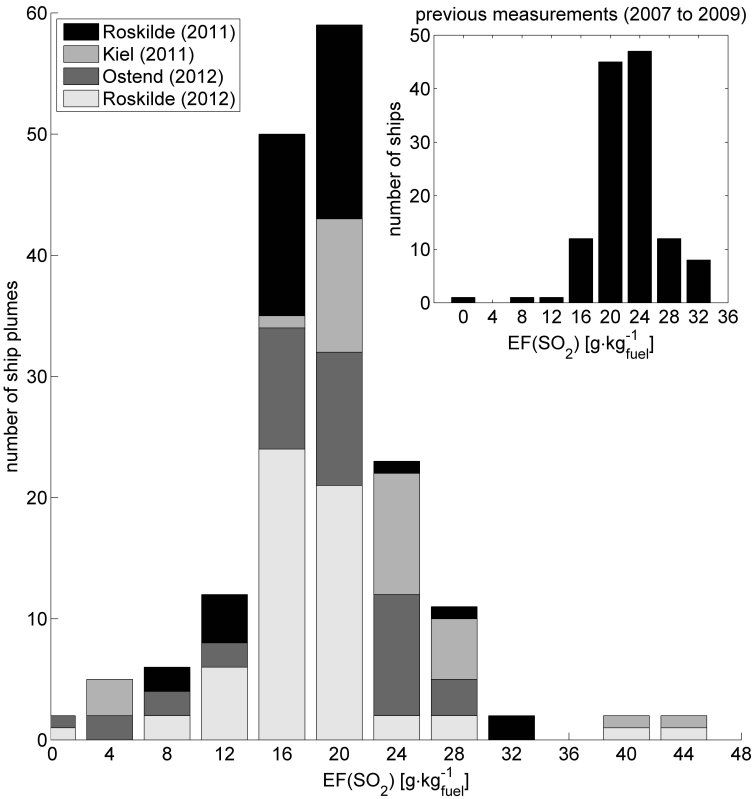

Fig. 5. Histogram of the emission factor of SO_2, $EF(SO_2)$, from airborne measurements for four campaigns in the years 2011 and 2012. The inset shows according results from earlier campaigns between 2007 and 2009. The comparison indicates a reduction of $EF(SO_2)$. This coincides with the reduction of the limit of sulfer in fuel to 1 %. The corresping values for the sulfur fuel content can be optained by dividing the $EF(SO_2)$ by 20.

AMTD
6, 10617–10651, 2013

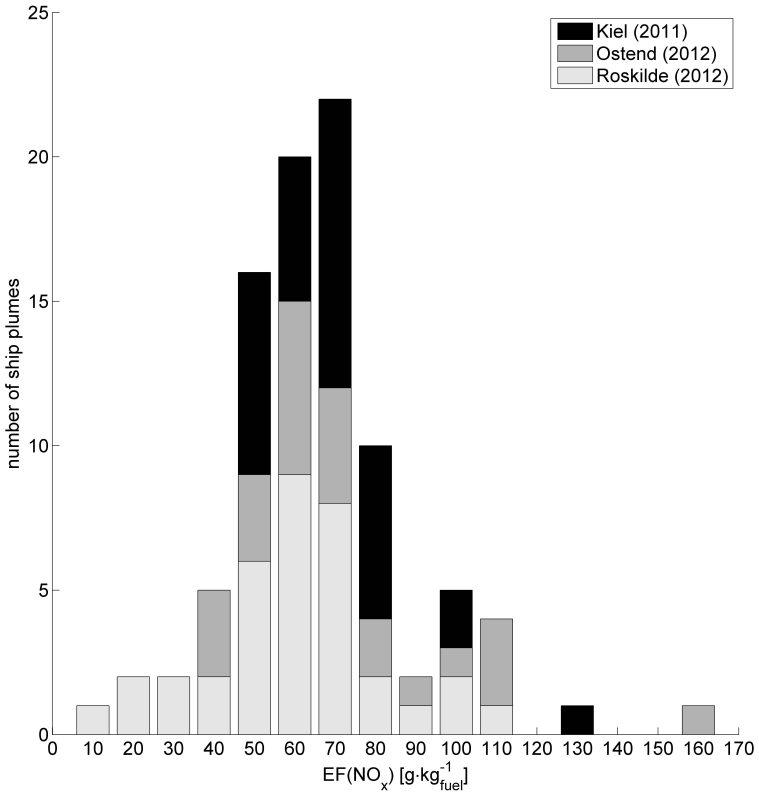

Fig. 6. Histogram of the NO_x emission factor, $EF(NO_x)$, relative to the amount of consumed fuel from airborne measurements for three campaigns in the years 2011 and 2012.

AMTD
6, 10617–10651, 2013

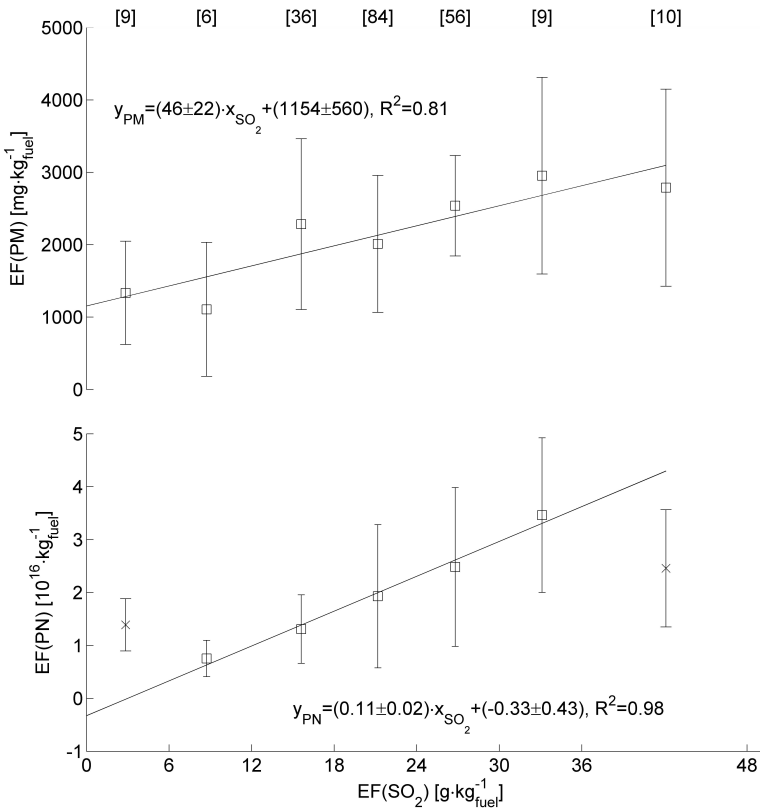

Fig. 7. Emission factors of particle number (PN) and particle mass (PM) related to the SO_2 emission factor. The results were binned for the SO_2 emission factor. The ticks on the x-axis correspond to the bin edges. The numbers in square brackets indicate the number of individual plume transects distributed for different SO_2 emission factors. The square-shaped markers indicate the values which were taken into account for the calculation of the linear regressions.
