

Abstract

An important problem in satellite remote sensing of aerosols is related to the need to perform an adequate cloud screening. If a cloud screening is applied that is not strict enough, the ground scene has the probability of residual cloud cover which causes large errors on the retrieved aerosol parameters. On the other hand, if the cloud screening procedure is too strict, too many clear sky cases, especially near-cloud scenes, will falsely be flagged cloudy. The detrimental effects of cloud contamination as well as the importance of aerosol cloud interactions that can be studied in these near-cloud scenes call for new approaches to cloud screening. Multi-angle, multi-wavelength photo-polarimetric measurements have a unique capability to distinguish between scattering by (liquid) cloud droplets and aerosol particles. In this paper the sensitivity of aerosol retrievals from multi-angle, photo-polarimetric measurements to cloud contamination is investigated and the ability to intrinsically filter the cloud contaminated scenes based on a goodness-of-fit criteria is evaluated. Hereto, an aerosol retrieval algorithm is applied to a partially clouded, synthetic data-set including partial cloud cover as well as non-cloud screened POLDER-3/PARASOL observations. It is found that a goodness-of-fit filter, together with a filter on the coarse mode refractive index ($m_r^{\text{coarse}} > 1.335$) and a cirrus screening adequately reject the cloud contaminated scenes. No bias nor larger SD are found in the retrieved parameters for this intrinsic cloud filter compared to the parameters retrieved in a priori cloud screened data-set (using MODIS/AQUA cloud masks) of PARASOL observations. Moreover, less high aerosol load scenes are misinterpreted as cloud contaminated. The retrieved aerosol optical thickness, single scattering albedo and Ångström exponent show good agreement with AERONET observations. Furthermore, the synthetic retrievals give confidence in the ability of the algorithm to correctly retrieve the micro-physical aerosol parameters.

Interactive Discussion

1 Introduction

Aerosol plays a complex role in our atmosphere that results in a net, negative radiative forcing. The uncertainty on the strength of this aerosol forcing is the largest contribution to the uncertainty on total radiative forcing estimates (Intergovernmental Panel on Climate Change, 2014) and complicates future climate predictions (Hansen et al., 2011). To reduce the large uncertainty of the aerosol effects on cloud formation and climate, accurate satellite measurements of aerosol optical properties (optical thickness, single scattering albedo, phase function) and micro-physical properties (size distribution, refractive index, shape) are essential. Optical properties are needed to estimate the forcing due to the direct effect and semi-direct effects (the latter depends on the absorption by aerosols). From the micro-physical properties, the refractive index is a proxy for aerosol chemical composition, which is, together with aerosol size distribution, an important characteristic to distinguish man-made aerosols from natural aerosols. Furthermore, the capability of aerosols to act as Cloud Condensation Nuclei (CCN) depends on the number of aerosol particles that in “dry” form (i.e. without water uptake) have a radius that is larger than about $0.05\ \mu\text{m}$ (Rosenfeld, 2006). At high relative humidity however, aerosols often grow by absorbing water. The aerosol refractive index strongly depends on the water uptake by the aerosols and therefore this quantity can be used to translate the measured size distribution of hydrated particles to the corresponding size distribution of dry particles (Schuster et al., 2009), which is needed to determine the number of potential CCN.

Satellite instruments that perform multi-angle photo-polarimetric measurements have the capability to provide the aerosol properties mentioned above. This has been demonstrated by theoretical studies (Mishchenko and Travis, 1997; Hasekamp and Landgraf, 2007; Kokhanovsky et al., 2010; Knobelspiesse et al., 2012; Ottaviani et al., 2013) as well as by case studies using airborne measurements (Chowdhary et al., 2005; Waquet et al., 2009a). The only satellite instruments that performed multi-angle photo-polarimetric measurements were the POLDER (Polarization and Directionality

taken from the MODIS-AQUA satellite instrument are co-located with PARASOL observations. The performance of the aerosol retrieval algorithm is evaluated for different cloud screening algorithms. In particular the case where, instead of a priori cloud screening, an a posteriori screening based on the goodness-of-fit is applied.

In Sect. 2 the PARASOL and MODIS observations and data-sets are described. In Sect. 3 a summary of the inversion method is given. Then, in Sect. 4, a data-set of synthetic partially clouded scenes is presented and the performance of the algorithm on this data-set is analysed. In Sect. 5 the algorithm is applied to real, partially clouded observations. The performance is evaluated by comparison to ground-based observations of several AERONET stations (Holben et al., 2001). In Sect. 6, the results are summarized and conclusions are drawn.

2 Observations

2.1 PARASOL

The recently decommissioned PARASOL satellite was launched in 2004 and flew as part of the NASA A-train for a little less than 5 years where it collected aerosol and cloud observations in synthesis with MODIS/AQUA (multi-spectral imager), CALIPSO (lidar) and CLOUDSAT. It measured the intensity in 9 spectral bands ranging from 443 to 1020 nm at up to 16 viewing angles. Additionally, the linear polarization was measured in the 490, 670, 865 nm bands. The level 1 (non-cloud screened) observations are available on a sinusoidally projected grid of $\sim 6.2\text{ km} \times 6.2\text{ km}$ pixels, named the Full Resolution (FR) grid. This data-set is processed into a non-cloud screened, Medium Resolution (MR) data-set of $\sim 19\text{ km} \times 19\text{ km}$ pixels for our analysis.

The selection of PARASOL observations that are used in the analysis are comprised of scenes, above ocean surfaces, that are obtained during the year 2006 and are in the vicinity of one of the AERONET stations listed in Table 1. The latter criterion allows for

the validation of the retrieved optical and micro-physical aerosol properties, whenever AERONET observations are available.

2.2 MODIS cloud product

Information on cloud cover and cloud properties, at a resolution higher than PARASOL, is obtained by the co-location of both the MODIS/AQUA cloud mask (MYD35, collection 005) (Ackerman et al., 1998) and cloud product (MYD06_L2, collection 005) on the sinusoidally projected, PARASOL coordinate grid. The nadir pixel size of the cloud mask and cirrus flag is $\sim 1 \text{ km} \times 1 \text{ km}$. The MODIS geo-locations in the MYD06_L2 are provided on $5 \text{ km} \times 5 \text{ km}$ pixel resolution, but have been interpolated to the $1 \text{ km} \times 1 \text{ km}$ grid. This provides 32 ± 5 and 291 ± 40 pixels of roughly $1 \text{ km} \times 1 \text{ km}$ resolution cloud information for, respectively, the FR and MR PARASOL ground pixels. For consistent treatment of the cloud fractions the MODIS observations in this study are restricted to sensor zenith angles lower than 40° . Note that this last criteria excludes the use of the full width of the PARASOL swath.

The MODIS cloud mask has four different flags; confidently clear, probably clear, probably cloudy and confidently cloudy. From this mask two different cloud fractions are derived per PARASOL ground pixel; (i) a conservative (“strict”) cloud fraction that counts all pixels that are not “confidently clear” as cloud pixels, and (ii) a “loose” cloud fraction which counts both the “probably cloudy” and “confidently cloudy” flags as cloudy pixels (but not the “probably clear”). Furthermore, a cirrus fraction was derived from the fraction of pixels for which cirrus was detected as conveyed via the cirrus reflectance flag (Gao et al., 2002).

3 Inversion method

This study uses the retrieval algorithm described in detail by Hasekamp et al. (2011). The retrieval approach is based on iterative fitting of a linearised vector radiative

Interactive Discussion

of the inversion problem, there is a chance that the retrieval does not converge to the global minimum if the first guess state vector is too far from the true state vector. Therefore, a second type of retrieval is performed which avoids this problem by already starting with the true state vector as the first guess. This retrieval is referred to as the “perfect first guess” retrieval

Figure 2 shows, for both retrieval types, the fraction of retrievals that fulfil one or more of three different goodness-of-fit criteria at different cloud fractions. While the perfect first guess retrievals obtain a fit with $\chi^2 \leq 1.2$ in 99% of the clear sky scenes, only 42% of the normal retrievals meet this criteria. The reason for a relatively large fraction of these retrievals not to converge to this value of χ^2 is that they end up in a local minimum. This happens when the first guess state vector is too far from the true state vector. In principle this can be solved by employing multiple retrievals with a different first guess but this would obviously increase the computational effort significantly.

It can be seen in Fig. 2 that virtually all cloudy cases are filtered by a strict enough goodness-of-fit criterion ($\chi^2 \leq 1.2$ in this case). The reason for the decrease in the goodness-of-fit is that the characteristic angular scattering features in DoLP for cloud droplets, such as the cloud bow, which cannot be fitted by the aerosol parameters. With less strict χ^2 -filters, such as the $\chi^2 \leq 2.0$ and $\chi^2 \leq 5.0$ -filter, a number of scenes with a small amount of thin cloud cover contribute to the results, which lead to overestimates in the AOT.

Comparisons of the retrieved optical properties and complex refractive indices are shown in Figs. 3 and 4 for those fits with a $\chi^2 \leq 1.2$. The statistics on the comparison of these and other retrieved parameters are given in Table 3 for three datasets; one where the goodness-of-fit criteria ($\chi^2 \leq 1.2$) has filtered nearly all cloud contaminated scenes (set 1), one with the slightly less strict goodness-of-fit criteria ($\chi^2 \leq 2.0$) which does not filter all cloud contaminated scenes (set 2) and last, only the cloud contaminated scenes that meet the $\chi^2 \leq 2.0$ criteria (set 3). The SSA, used in Fig. 3 and Table 3, is additionally filtered on the element of the averaging kernel corresponding to the fine mode imaginary refractive index ($A_{m_1}^{\text{fine}} \geq 0.1$) to ensure adequate sensitivity to aerosol

Interactive Discussion

absorption. The micro-physical parameters, used in Fig. 4 and Table 3 also are additionally filtered on the size of their uncertainty ($\sigma_{R_{\text{eff}}^{\text{fine}}} \leq 0.05$, $\sigma_{R_{\text{eff}}^{\text{coarse}}} \leq 0.1$, $\sigma_{V_{\text{eff}}} \leq 0.1$, $\sigma_{m_r} \leq 0.04$) or the corresponding element in the averaging kernel ($A_{m_i} \geq 0.1$) to ensure that the measurement is sensitive to that particular parameter and thus is constrained. It seems from Fig. 3 that the error bar on the SSA is somewhat overestimated. This is likely due to the fact that the prior error term is chosen too conservative on one or more parameters.

Figures 3 shows a very good agreement of the true and retrieved optical properties. This is confirmed by the high correlation coefficients and small SDs found in Table 3. The cloud contaminated scenes (set 3) consist almost completely of scenes with 10%, thin (COT = 1.0) cloud cover. Looking only at the scenes with cloud contamination a small bias of 0.08 is observed in the retrieved AOT. This is not reflected in the statistics of set 2, since there are 4 times more clear sky than cloud contaminated scenes in this data-set. For the retrieved SSA, no bias is observed in any of the data-sets. There is no increase in the retrieval uncertainty of the AOT nor SSA due to cloud contamination.

A good agreement is also found for the effective radii of both modes. The effective variance, however, is somewhat harder to retrieve, as can be inferred from the lower correlation coefficients. These retrieved parameters are virtually unaffected by cloud contamination; for example, the increase in the SD of the effective radii, from set 1 to set 2, is only 0.02 for the fine mode and 0.14 for the coarse mode. Note that this increase is largely, if not completely, due to the less strict χ^2 -filter not the cloud contamination. For the effective variance, this increase in the SD is small; 0.02 for the fine mode and 0.04 for the coarse mode.

High correlation coefficients are also found for the Real Refractive Index (RRI) of both modes. The mean and median differences in the comparison are small compared to the (mean) retrieval uncertainties. Unexpectedly, a small bias towards underestimation (~ 0.04) is observed for the m_r^{fine} in the cloud contaminated scenes.

by characteristic scattering features of cloud droplets, this stereo effect introduces an extra sensitivity to cloud contamination in the FR PARASOL observations.

The extent to which a comparison can be made with the fraction of good fits of the synthetic retrievals is limited, since the COT is not known for most of the partially clouded PARASOL pixels for the different cloud fraction bins that are used for Fig. 2. Furthermore, the retrieved χ^2 values in PARASOL scenes are expected to be higher on average than those found in the synthetic retrievals. This is in part due to the higher measurement precision that is used for calculating the χ^2 , which gives differences between the model and measurement more weight. Secondly, larger differences between the model and measurement are expected because of inhomogeneities in space and time, and, to a lesser extent, due to deviations from the assumed vertical distribution and/or size distribution of the aerosol.

5.2 Additional filters

In Fig. 7 the Aerosol Optical Thickness (AOT) retrieved from the MR PARASOL data is compared to the level 2.0 AERONET observations that are coincident in space (distance ≤ 40 km) and time ($\Delta t \leq 1$ h). The AERONET AOT is measured in direct sun observations and can be obtained with higher measurement precision than the AOT retrieved from PARASOL observations. It is therefore considered as the “truth” in this comparison. The left panels show the mean AOT bias cumulatively for increasing cloud fraction. This bias is calculated like: $\tau^{\text{par}} - \tau^{\text{aer}}$, where τ^{par} is retrieved from an individual PARASOL observation and τ^{aer} is the mean of all AERONET observations that are within the 1 h time-range. In the panels on the right the SD of the AOT are shown cumulatively for increasing cloud fraction. Since cloud screening has been applied to the AERONET observations, the retrieved AOTs shown in Fig. 7 are subject to some artificial cloud screening. However, there are still numerous occasions where there is a partially clouded PARASOL scene within the 40 km range, as confirmed by MODIS, while an unobstructed view of the sun is available for the AERONET station within the 1 h time-range.

Interactive Discussion

of Fig. 7. By applying these two additional filter criteria, the AOT bias for the $\chi^2 \leq 10.0$ and $\chi^2 \leq 5.0$ criteria remain constant with increasing cloud fraction. This indicates that there is no significant cloud contamination in these data-sets.

The fractions of good fits found at higher cloud fractions are still non-zero after applying these two additional filter criteria. The AOTs retrieved in these scenes do not strongly affect the mean AOT shown in the bottom panels of Fig. 7. The explanation for this is two-fold; the fraction of successfully retrieved clear sky scenes outweigh the fraction of successfully retrieved cloudy scenes and no strong overestimate in AOT is retrieved in these latter scenes. This suggests that the successful retrievals in scenes with a high MODIS cloud fraction, are falsely identified as cloudy.

Based on the agreement found for the retrieved AOTs, it is concluded that the $\chi^2 \leq 10.0$ -criteria, together with the two additional filters, successfully screens for cloud contamination. Even better agreement, but far less data-points (75 and 58 % for, respectively, the FR and MR retrievals) can be obtained by using the stricter $\chi^2 \leq 5.0$ criteria. In the remainder of the paper the goodness-of-fit criteria $\chi^2 \leq 10.0$ is applied. For the sake of brevity, the goodness-of-fit filter together with the coarse mode refractive index filter and cirrus filter will be referred to as the “goodness-of-fit+” filter.

5.3 Validation of the AOT & Ångström exponent

In this section the retrieved AOT and ÅE are compared to those observed with AERONET for 3 datasets with different cloud screenings: (i) goodness-of-fit plus, (ii) MODIS loose cloud mask, and (iii) MODIS strict cloud mask. The results of the latter two cloud screenings are simulated by applying the MODIS loose or strict cloud mask to the PARASOL retrievals. The additional filter criteria on the cirrus fraction is also applied to the two MODIS cloud screenings. The coarse mode refractive index filter is only applied on the goodness-of-fit+ filter.

Figures 9 and 10 show the AOT comparisons of the three cloud screenings for, respectively, the FR and MR retrievals. Every data-point shows the daily mean AOT

(at 670 nm) retrieved from PARASOL observations within a range of 40 km of an AERONET station, vs. the mean of the AOTs retrieved from AERONET observations (at 675 nm) within ~ 1 h of the PARASOL overpass. The grey bars show the range in AOT measurements for AERONET, and $1\text{-}\sigma$ uncertainty in the retrieval for PARASOL.

Some scatter is to be expected due to spatial and temporal inhomogeneity of the atmosphere. Comparisons in the other bands yield almost identical results.

While the MODIS strict cloud mask produces the smallest differences with the AERONET values, it does discard 16% of the FR, and 35% of the MR results obtained with the goodness-of-fit+ filter. Scenes with higher aerosol loading are often flagged cloudy by both MODIS cloud masks, especially at lower resolution, while most of these filtered data-points are in good agreement with the optical thicknesses observed by AERONET. The larger absolute errors that can be expected in scenes with higher aerosol loading are one of the causes for the somewhat poorer statistics found in the MR, goodness-of-fit+ filtered results. When the data-points with $\tau^{\text{par}} \geq 0.4$ are excluded (7 data-points), the mean and median differences as well as the SD are nearly identical to those found with the loose cloud mask.

The comparison of the \AA E s derived from the AOTs retrieved by PARASOL (using the 490 and 670 nm bands) and AERONET (using the 500 and 675 nm bands) is shown in Fig. 11. For this comparison only data with $\tau_{670\text{nm}}^{\text{par}} > 0.1$ are included as the information on aerosol size becomes limited for low aerosol loadings. There is a small bias (-0.11 – -0.13) in the \AA E retrieved by PARASOL and AERONET. Note that since this offset is present and of roughly equal strength in all three data-sets, it can most likely not be explained in terms of cloud contamination.

An interesting feature in Fig. 11 are the outliers with largely underestimated \AA E , indicative of cloud contamination, that are only present in the MODIS loose and strict cloud screened results. In the goodness-of-fit+ filter these scenes are discarded because $m_r^{\text{coarse}} \leq 1.335$. These are instances where the goodness-of-fit+ filter outperforms the MODIS cloud masks in detecting cloud contamination.

5.4 Validation of the SSA & RRI

A direct comparison of the micro-physical properties is complicated because of differences in the retrieval methods of AERONET inversion algorithm and the aerosol retrieval algorithm discussed in this paper. The former retrieves a continuous size distribution, wavelength dependent, complex refractive index and derives, among other properties, the single scattering albedo from diffuse sky measurements (almucantar scans) (Dubovik and King, 2000; Dubovik et al., 2002). Whereas the aerosol retrieval algorithm discussed in this paper retrieves a bi-modal, log-normal size distribution with two separate, spectrally neutral, complex refractive indices (one for each aerosol mode). However, the agreement found in the ÅE (see Fig. 11) gives confidence in the retrieved size parameters. Since the SSA is dependent on the micro-physical aerosol properties, a comparison of this derived parameter gives an indication of the quality of those retrieved micro-physical properties. In order to facilitate a comparison with the RRI retrieved with the AERONET inversion code, the RRI of both the fine and coarse modes are weighted by volume and combined to form m_{comp} (following Hasekamp et al., 2011);

$$m_{\text{comp}} = \frac{V^{\text{fine}} m_r^{\text{fine}} + V^{\text{coarse}} m_r^{\text{coarse}}}{V^{\text{fine}} + V^{\text{coarse}}} \quad (2)$$

Where superscripts fine and coarse denote the mode and V stands for volume. This quantity should to some extent reflect the RRI retrieved with the AERONET inversion algorithm, even though it is only an approximation.

The AERONET diffuse sky measurements are not made as frequent as the direct sun observations from which the AOT product is obtained. Furthermore, the (level 2.0) data obtained from these measurements are subject to strict quality assurance criteria. In particular the criteria that $\tau_{440\text{nm}} > 0.4$ rejects many observations. In order to get a useful amount of coincident observations, comparisons of the SSA and RRI are made with level 1.5 AERONET observations, which have been cloud screened but not quality assured, and the time constraint of the temporal co-location is relaxed to 12 h.

Interactive Discussion

Figure 12 shows time-series with the SSAs, as retrieved from, respectively, PARASOL and AERONET observations at a number of AERONET stations. There is a reasonable agreement in the SSA from the two retrieval approaches. There are very few differences between the time-series obtained with the goodness-of-fit+ filtering and the loose cloud mask filtering. The statistics at different AERONET stations and both this filters are listed in Table 4. The mean difference between the AERONET and PARASOL SSA is generally lower than 0.04. Furthermore, the statistics for the MODIS loose mask filtered results are not significantly better than those obtained with the goodness-of-fit+ filter.

Figure 13 shows time-series of m_{comp} and the AERONET RRI at 670 nm for a number of AERONET stations. The statistics of these two values are summarized in Table 5 for those stations where more than 5 coincident observations are found. It is uncertain what can be expected from this comparison given that m_{comp} is a crude approximation of the AERONET RRI. For the values retrieved by the aerosol retrieval algorithm, the error bars show the uncertainty in the retrieved value. In general, larger error bars indicate that the retrieval depends stronger on the a priori value for the RRI and associated priori error. For the values retrieved with the AERONET inversion algorithm, the error bars indicate the range of all the measurements that satisfy the time-constraint of the temporal co-location. For many cases the error bars overlap, for others there is a significant difference. Most importantly, the loose cloud mask filtered data-set shows fewer data-points and nearly identical statistics (see Table 5). In other words, the discrepancies between m_{comp} and the AERONET RRI cannot be attributed to cloud contamination.

6 Conclusions

The effect of cloud contamination on aerosol retrievals from multi-angle photopolarimetric measurements of the POLDER-3 instrument over the ocean is investigated. For retrievals from synthetic measurements it is found that a goodness-of-fit

5 criterion filters out all cases (partially) covered by medium to thick clouds ($COT \geq 5$), and virtually all cases with partial thin cloud cover ($COT = 1$). Aerosol retrievals from PARASOL observations at two spatial resolution, $6\text{ km} \times 6\text{ km}$ (FR) and $19\text{ km} \times 19\text{ km}$ (MR), are considered. Here, MODIS is used to quantify the cloud contamination for each PARASOL ground pixel. It is found that the FR measurements are more sensitive to cloud contamination than the MR measurements because of so-called stereo effects which occur when, for example, a cloud is seen in one viewing direction but not in the other viewing directions. For MR measurements such effects play a much less important role and the effect of clouds on the measurements is mainly a result of angular scattering features characteristic for cloud droplets. In some cases, the effect of clouds can be described by a coarse aerosol mode with refractive index close to that of water (~ 1.33). Therefore, an additional criterion which ensures that the coarse mode refractive index is lower than 1.335 is needed. Furthermore, a goodness-of-fit criterion is not always sufficient to filter out ice clouds, which have less distinct angular features than liquid water clouds. To filter out such clouds the MODIS filter based on $1.38\ \mu\text{m}$ measurements is needed. A cloud mask based on a goodness-of-fit criterion, a coarse mode refractive index criterion and a cirrus filter is able to adequately reject cloudy scenes. Moreover, the cloud masks based on MODIS sometimes misinterpret scenes with high aerosol load as cloud contaminated. The aerosol retrievals that pass the goodness-of-fit, the coarse mode refractive index, and cirrus filter, do not show a bias and SD with AERONET dependent on MODIS cloud fraction. The implication of our findings for future dedicated aerosol polarimeters is that such instruments can fly stand-alone and do not require additional information from a cloud imager. A $1.38\ \mu\text{m}$ channel for cirrus detection would be advantageous, or even required. Given the large sensitivity of multi-angle photo-polarimetric measurements to cloud contamination, a necessary next step is to not only use this sensitivity to filter out cloud contaminated scenes, but instead retrieve cloud information simultaneously with aerosol information, describing clouds as an additional size mode with a prescribed refractive index corresponding to water droplets.

Table 3. The correlations, mean and median differences, SDs and retrieval uncertainties are given for the retrieved and derived parameters in three data-sets; (i) all retrievals with $\chi^2 \leq 1.2$, (ii) all retrievals with $\chi^2 \leq 2.0$ and (iii) only the retrievals in clouded scenes with $\chi^2 \leq 2.0$. The units for size parameters R_{eff} and V_{eff} are in micron.

PARASOL sensitivity to cloud contamination

F. A. Stap et al.

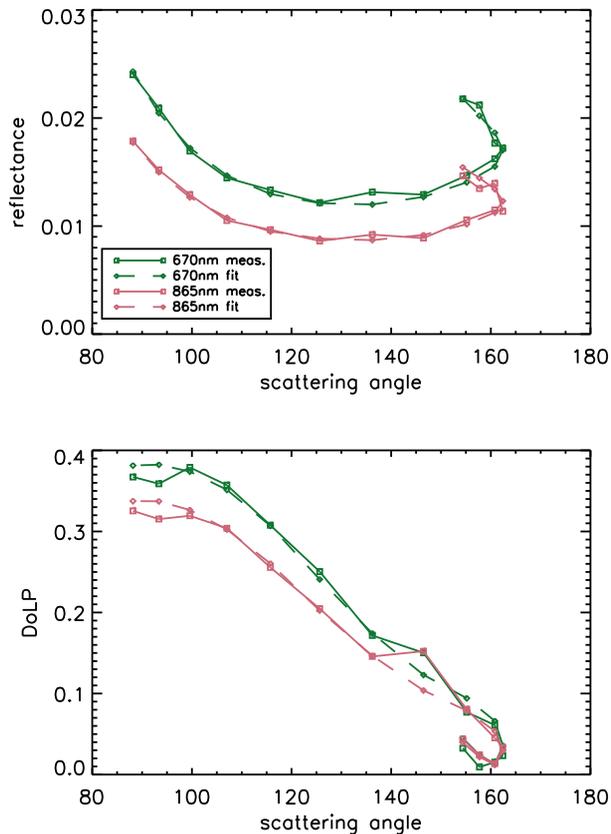

Figure 1. A POLDER-3/PARASOL observation of a scene with $\sim 20\%$ cover. The 670 and 865 nm bands are shown in, respectively, green and red. The dashed lines show the best fit to this observation (assuming clear sky conditions). The fit has a high χ^2 value (~ 13.7), mostly due to the discrepancy near the cloud-bow, which is visible in the degree of linear polarization (DoLP) at a scattering angle of $\sim 140^\circ$. The measurement errors are of the size of the symbols.

PARASOL sensitivity to cloud contamination

F. A. Stap et al.

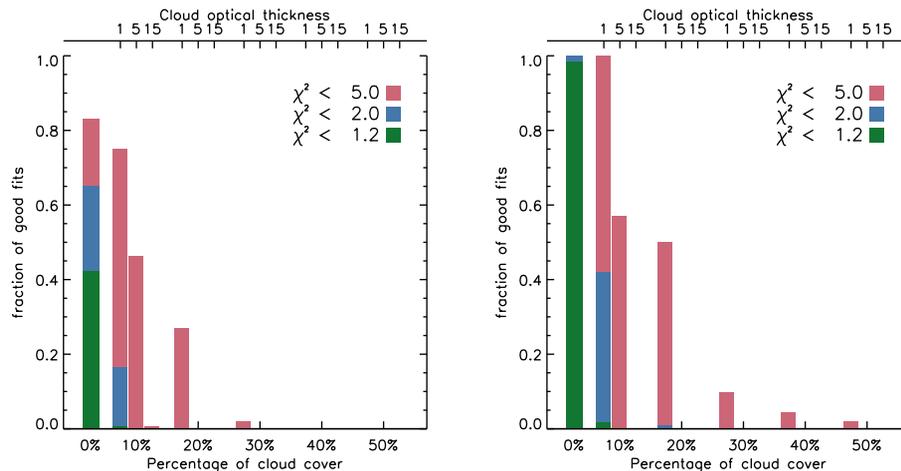

Figure 2. The fraction of good retrievals for three different χ^2 filters, per cloud fraction bin, for the normal (left) and perfect first guess retrieval (right). The cloud fraction bins have been further divided into the three optical thicknesses (top axis) that were used to simulate the cloud.

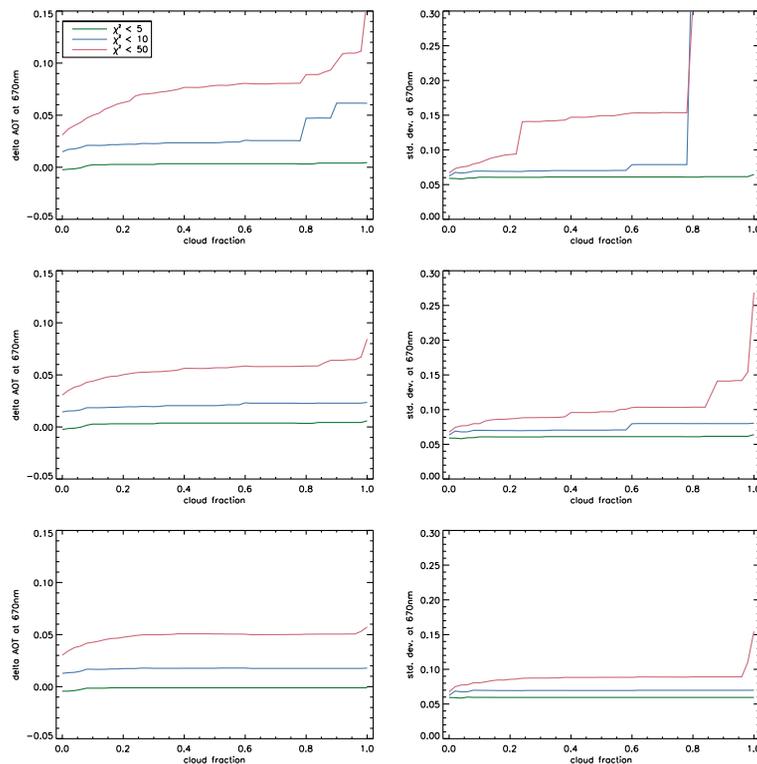

Figure 7. The mean AOT difference between PARASOL and AERONET (left panels) and the SD of the AOT differences between PARASOL and AERONET (right panels) in the 670 nm band are shown cumulatively for increasing cloud fraction from MODIS, for three different χ^2 -filters. The results of the top panels have only been filtered with the goodness-of-fit criteria, the middle panels have additionally been filtered on $m_r^{\text{coarse}} > 1.335$ and the bottom two panels are filtered on both the $m_r^{\text{coarse}} > 1.335$ and a cirrus mask.

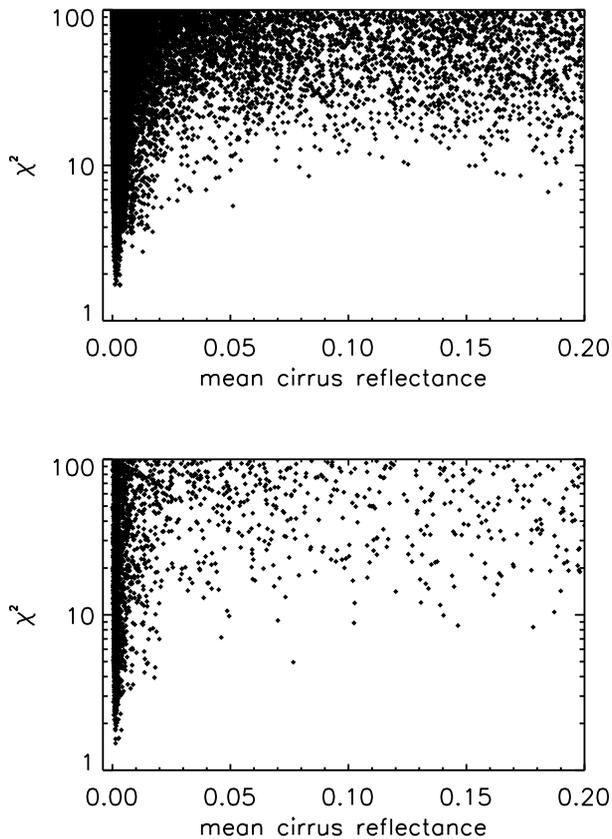

Figure 8. The χ^2 of the retrieval vs. the mean cirrus reflectance in the full resolution (top) and medium resolution (bottom) scenes. The coarse mode real refractive index filter has been applied on the data in this figure.

PARASOL sensitivity to cloud contamination

F. A. Stap et al.

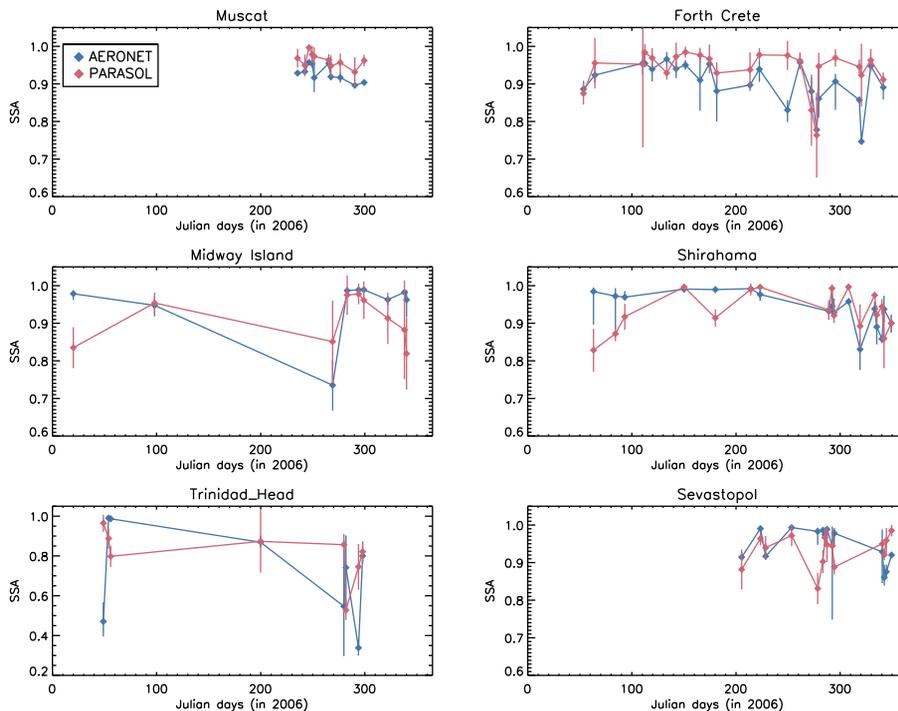

Figure 12. Time-series of SSAs (at 670 nm) retrieved from the PARASOL observations using the goodness-of-fit+ cloud screening vs. those retrieved by AERONET, for a number of AERONET stations. The error bars for AERONET show the range of all the observations within 12 h of the PARASOL overpass, those for PARASOL show the 1- σ retrieval uncertainty. The PARASOL retrievals are additionally filtered on the value of the averaging kernel of the fine mode imaginary refractive index (≥ 0.1) in order to ensure adequate sensitivity to the absorption.
