## Abstract

Ammonia and amines are common trace gases in the atmosphere and have a variety of both biogenic and anthropogenic sources, with a major contribution coming from agricultural sites. In addition to their malodorous nature, both ammonia and amines have been shown to enhance particle formation from acids such as nitric, sulfuric and methanesulfonic acids, which has implications for visibility, human health and climate. A key component of quantifying the effects of these species on particle formation is accurate gas-phase measurements in both laboratory and field studies. However, these species are notoriously difficult to measure as they are readily taken up on surfaces, including onto glass surfaces from aqueous solution as established in the present studies. We describe here a novel technique for measuring gas-phase ammonia and amines that involves uptake onto a weak cation exchange resin followed by extraction and analysis using ion chromatography. Two variants, one for ppb concentrations in air and the second with lower (ppt) detection limits, are described. The latter involves the use of a custom-designed high-pressure cartridge to hold the resin for in-line extraction. These methods avoid the use of sampling lines, which can lead to significant inlet losses of these compounds. They also have the advantages of being relatively simple and inexpensive. The applicability of this technique to ambient air is demonstrated in measurements made near a cattle farm in Chino, CA.

## 1 Introduction

Atmospheric aerosol particles are known to reduce visibility and adversely affect human health. They also impact the climate as they are able to scatter and absorb solar radiation and serve as cloud and ice condensation nuclei (Finlayson-Pitts and Pitts, 2000; Seinfeld and Pandis, 2006). Ammonia and amines are routinely detected in the particle phase and have been identified as important contributors to new particle formation and growth (Angelino et al., 2001; Berndt et al., 2010; Bzdek and Johnston,

Interactive Discussion

2010; Bzdek et al., 2011; Chen et al., 2012; Creamean et al., 2011; Dawson et al., 2012; Loukonen et al., 2010; Muller et al., 2009; Ruiz-Jiménez et al., 2012; Smith et al., 2010; VandenBoer et al., 2011). Accurate measurement of gas-phase ammonia and amines both in the atmosphere and in laboratory experiments is a key component of understanding and quantifying their role in particle chemistry and physics.

Atmospheric ammonia and amines have a wide variety of sources, both biogenic and anthropogenic (Ge et al., 2011a, b). Industrial and agricultural practices involving animals, e.g., cattle feed lots or swine facilities (Anderson et al., 2003; Hiranuma et al., 2010; Kuhn et al., 2011; Mosier et al., 1973; Ni et al., 2012; Schade and Crutzen, 1995), are significant sources of these species in the atmosphere. Agricultural emissions of ammonia and short-chain aliphatic amines, in particular, account for a large fraction of the global flux of these species into the atmosphere (Ge et al., 2011a, b; Schade and Crutzen, 1995). Other sources include ocean biota (Ge et al., 2011a; Gibb et al., 1999), biomass burning (Ge et al., 2011a; Lobert et al., 1990), and release from carbon capture and storage devices that use amines to trap CO<sub>2</sub>, which could be a more important source of atmospheric amines and ammonia as the technology becomes more widely adopted (Borduas et al., 2013; Ge et al., 2011a; Nielsen et al., 2012; Rochelle, 2009; Schreiber et al., 2009).

Importantly, it has been shown that gas-phase ammonia and amines significantly enhance particle formation from common atmospheric acids, such as sulfuric, nitric and methanesulfonic acids (Almeida et al., 2013; Angelino et al., 2001; Berndt et al., 2010; Chen et al., 2012; Dawson et al., 2012; Loukonen et al., 2010; Smith et al., 2010; Yu et al., 2012), and contribute to growth of atmospheric nano-particles (Barsanti et al., 2009; Bzdek et al., 2011; Smith et al., 2010; Wang et al., 2010). Short-chain alkyl amines have been shown to displace ammonia in particles (Bzdek et al., 2010, 2011; Chan and Chan, 2012; Liu et al., 2012; Lloyd et al., 2009), which enhances their importance in particle formation and growth. Although amines are short-lived in the atmosphere due to oxidation by common atmospheric oxidants such as OH and O<sub>3</sub> (Nielsen et al., 2012; Tang et al., 2013), amines and the precursors to sulfuric and

methanesulfonic acids (Bates et al., 1992; Ge et al., 2011a; Ni et al., 2012) are in sufficiently close temporal proximity in the atmosphere that they are important contributors to particle formation.

Reliable data on the sources, sinks, and ambient concentrations of gas-phase amines, therefore, are crucial to predicting new particle formation in the atmosphere. However, gas-phase amines are notoriously difficult to measure and typical concentrations in the atmosphere are of the order of a few ppb or less (Ge et al., 2011a). Several techniques for measuring gas-phase ammonia and amines have been reported in the literature. On-line mass spectrometric (MS) techniques include ambient pressure proton transfer MS (Hanson et al., 2011), chemical ionization MS (Yu and Lee, 2012), and proton transfer reaction MS (PTR-MS) (Borduas et al., 2013; Feilberg et al., 2010; Kuhn et al., 2011; Liu et al., 2011; Tanimoto et al., 2007). Off-line techniques typically involve collection of a gas-phase sample onto a substrate (e.g., activated charcoal or an acid-impregnated glass fiber filter) (Fournier et al., 2008; Fuselli et al., 1982), into an acidic solution (Akyüz, 2008; Gronberg et al., 1992; Schade and Crutzen, 1995), or onto a whetted glass frit (Huang et al., 2009). Samples are then extracted and analyzed using gas or liquid chromatography, sometimes with a derivatization step included (Akyüz, 2008; Fuselli et al., 1982; Gronberg et al., 1992; Hiranuma et al., 2010; Huang et al., 2009; Nishikawa and Kuwata, 1984; Santagati et al., 2002; Schade and Crutzen, 1995). Ion chromatography (IC) has also proven to be useful for both gas- and particle-phase ammonia and amines (Gibb et al., 1999; Orsini et al., 2003; Praplan et al., 2012; VandenBoer et al., 2011). Formation of an indophenol complex which is measured spectrometrically has been developed for NH<sub>3</sub> (Hiranuma et al., 2010), as have various techniques involving the formation of 1-sulfonatoisindole followed by fluorescence measurement (Toda et al., 2010; Zhang et al., 1989).

An important limitation to many existing techniques for measuring ammonia and amines is deposition of the gas-phase analyte onto instrument surfaces prior to measurement, which varies with the compound (Hansen et al., 2013). Also, it has recently been shown that amines are irreversibly taken up onto surfaces that have been exposed

to a gas-phase acid, forming a non-volatile salt (Nishino et al., 2013). As a variety of acids and acid precursors are present in the atmosphere, this loss may have a significant effect on measurement efficiency for instrumentation where the gas-phase sample is in contact with surfaces such as tubing prior to measurement, even when these surfaces are heated. In addition, amines in aqueous solution are shown here to be subject to uptake on glass, with implications for sampling and measurement.

This work demonstrates the use of a weak cation exchange (WCE) resin as a substrate for efficient collection of gas-phase ammonia and amines at atmospherically relevant concentrations, followed by analysis by IC. Two approaches were developed. The first is applicable to higher (ppb) concentrations while the second, for which a custom high-pressure resin holder cartridge was designed for in-line extraction on an IC system, has detection limits in the tens of ppt range. These methods were developed to minimize the sampling losses reported previously, whilst also being capable of measuring ammonia and amines at the ppt level in air. Application to both laboratory and field measurements is demonstrated.

## 2 Experimental

### 2.1 Liquid-phase standards

Standard solutions for ammonia, methylamine (MA), dimethylamine (DMA), and trimethylamine (TMA) were prepared from their chloride salts in 0.1 M oxalic acid (Fluka). These include  $\text{NH}_4\text{Cl}$  (Sigma, 99.5%),  $\text{CH}_3\text{NH}_3\text{Cl}$  (Aldrich, 98.0%),  $(\text{CH}_3)_2\text{NH}_2\text{Cl}$  (Aldrich, 99.0%), and  $(\text{CH}_3)_3\text{NHCl}$  (Aldrich, 98.0%).

In the course of developing this method, there was some indication that amines and/or aminium ions in aqueous solution were being taken up in the walls of glass containers. To test whether, and to what extent, this was occurring, a standard solution containing between 10 and 30  $\text{ng mL}^{-1}$  of the ammonium and aminium species in nanopure water was placed in three 20 mL glass scintillation vials half filled with clean,

Interactive Discussion

dry glass beads and allowed to sit for 60 min. The original standard solution and those from the glass vials were then analyzed by IC. The peaks in the samples from the glass vials corresponding to ammonia and the amines were reduced, on average, by 13–23% compared to the original standard solution, indicating that amines are taken up by glass surfaces under neutral conditions. However, it should be noted that if the standard solution was acidic, no uptake on glass was observed. To avoid any potential wall loss, no glass was used in the preparation or storage of standards and samples used in this study.

### 2.2 Gas-phase standards

Mixtures of ammonia (Airgas; 0.812 ppm in N<sub>2</sub>), MA (Airgas; 10 ppm in N<sub>2</sub>), DMA (Airgas; 1.0 ppm in N<sub>2</sub>), and TMA (Airgas; 1.0 ppm in N<sub>2</sub>) in nitrogen were used to test the collection efficiency of the cation exchange resin (stated concentrations were those provided by the manufacturer but as discussed below, have considerable uncertainties associated with them). Gas-phase ammonia and amines from the gas cylinders were diluted with clean, dry air from an FTIR purge air generator (Parker-Balston; Model 75–62) for a total flow of 4.0 L min<sup>-1</sup> and analyte concentrations of approximately 2–1000 ppb as shown in Fig. 1. Gas cylinder and purge-air flows were maintained using mass flow controllers (Alicat).

### 2.3 Cartridge preparation and analysis for higher (ppb) concentrations

Sampling cartridges were prepared by filling 2.5 mL non-fluorous polypropylene cartridges (Supelco; model 57602-U) with WCE resin (Resintech, model WACG) between two polyethylene frits (Supelco) as shown in Fig. 1 (inset). WCE resin consists of acrylic/divinylbenzene beads terminated with carboxylic acid groups. The design of the cartridges minimizes the surfaces in contact with the sample prior to adsorption on the WCE resin, and those that are exposed are subsequently extracted with the resin. These cartridges were used to sample gas-phase standards in the ppb–ppm range in

air to characterize the collection and extraction efficiency of WCE resin, and will be referred to as “high-concentration cartridges”.

Samples were collected for 20 min at 1–2 L min<sup>-1</sup> maintained using a mass flow controller (Alicat). Two cartridges in series (Fig. 1, hereafter referred as “primary” and “backup” cartridges) were used in all experiments to determine collection efficiency. Cartridges were extracted and regenerated by flushing five times with 10.0 mL 0.1 M oxalic acid (Fluka) to remove the collected ammonia and amines and return the resin to its protonated (-R-COOH) form. The first 10.0 mL extract was used as the sample. For the primary cartridge, the first two 10.0 mL extractions were analyzed to determine extraction efficiency. The cartridge was flushed another 3 times with 10.0 mL 0.1 M oxalic acid and the final rinse was used as a blank for the subsequent sample. Samples were stored in 11 mL polypropylene vials (Metrohm, KITIC0008) prior to measurement.

Samples were analyzed by IC (Metrohm, model 850) with a Metrosep C4 – 250/4.0 cation column and equipped with a conductivity detector. The IC eluent was 0.00375 M oxalic acid and the flow rate was 0.9 mL min<sup>-1</sup>. The IC column temperature was maintained at 30 °C. The sample loop was 20 µL, and the total elution time was 24 min.

## 2.4 Cartridge preparation and analysis for lower (ppt) concentrations by in-line extraction and analysis

For ambient sampling, modified cartridges (Fig. 2) that could be used under the high-pressure conditions of the IC were designed for gas-phase collection and in-line extraction (see below). It should be noted that “in-line” here refers to the method of extraction on the IC column and does not indicate that this is an on-line measurement technique. These cartridges were prepared using a PEEK analytical guard cartridge holder (Hamilton; model 79477) designed for use on high-pressure liquid chromatography systems and a custom-built stainless-steel insert containing WCE resin (Resintech, model WACG) between two polyethylene frits (Supelco). These are referred to as “low-concentration cartridges” in the subsequent discussion. As for the “high-concentration” cartridge, this design minimizes the amount of surface area that gas-phase samples

are in contact with prior to adsorption on the WCE resin to  $\sim 1 \text{ cm}^2$  of stainless steel and one of the polyethylene frits; however, adsorbates on both the frit and stainless steel are extracted along with those on the resin.

Prior to sampling, the low-concentration cartridges were flushed three times with 10.0 mL 0.1 M oxalic acid followed by clean, dry air for 20 min at  $150 \text{ cm}^3 \text{ min}^{-1}$  to remove residual water from the last rinse. Gas-phase samples were pumped through the cartridge at  $150 \text{ cm}^3 \text{ min}^{-1}$  for 45–50 min in the direction indicated in Fig. 2. After sampling, the cartridge was filled with 60–80  $\mu\text{L}$  0.00375 M oxalic acid (IC eluent) in the same direction as the gas-phase sample (Fig. 2), to avoid injecting air into the IC system.

Extraction and analysis were performed in-line on the IC by using two injectors in series, as shown in Fig. 3. This procedure eliminates the separate extraction step and allows the entire collected sample to be injected onto the IC column, as opposed to extracting the cartridge with 10 mL of 0.1 M oxalic acid and then analyzing a 20  $\mu\text{L}$  portion of the extract on the IC. Having the entire collected sample injected onto the IC column lowers the detection limit to a range suitable for atmospheric concentrations (Table 1). The first injector sample loop was loaded with 20  $\mu\text{L}$  0.1 M oxalic acid and the second injector was fitted with the low-concentration cartridge in place of a sample loop, oriented so the IC eluent flow will be in the direction indicated in Fig. 2. All other IC conditions were as described in Sect. 2.3.

At the beginning of the run, the sample loop containing the acid and the low-concentration cartridge were simultaneously injected. This allows the concentrated oxalic acid plug to extract the cartridge and push the analyte onto the column. After 0.25 min, the cartridge injector was returned to fill mode. Three to five sequential extractions of the cartridge were performed for each sample, depending on the measured ammonia and/or amine concentrations.

A series of experiments was performed to determine if breakthrough occurs in the low-concentration cartridges under conditions of high ammonia concentration as is often seen in the field samples (Ge et al., 2011a, b). Three low-concentration cartridges

were prepared as described above, and one was kept as a blank. Gas-phase ammonia in  $N_2$  from a gas cylinder (Airgas; 0.812 ppm in  $N_2$ ) was then flowed through the remaining two cartridges in series for 50 min at  $150 \text{ cm}^3 \text{ min}^{-1}$ . Three sets of samples were taken. After background subtraction, the measured  $NH_3$  concentration on the backup cartridge was less than 7% of the total measured  $NH_3$  (primary + backup) in all three cases, and was 4% of the total measured  $NH_3$  on average. These results suggest minimal breakthrough occurs, even with high ammonia concentrations.

## 2.5 Field measurements in an agricultural area

Several field measurements using the low-concentration cartridges were performed in Chino, CA, USA. A 40 L steel chamber under vacuum was used as the pump. It was evacuated, fitted with a battery-powered mass flow controller (Alicat) and used to maintain sample flow through the cartridges. This allowed sampling to be performed away from a power source without the need for a generator, which could have introduced exhaust-related artifacts. Samples were taken approximately 50 m away from cattle pens between 4 a.m. and 6 a.m. (before sunrise) between 28 August and 12 September 2013. On each day, one cartridge was prepared as described in Sect. 2.4 and kept as a blank. These blanks were used for background subtraction of the sample chromatograms.

## 3 Results and discussion

A typical chromatogram for the liquid standards is shown in Fig. 4. Peaks corresponding to  $NH_4^+$ , MA- $H^+$ , DMA- $H^+$ , TMA- $H^+$  and a small amount of  $Na^+$  are present. Table 1 summarizes retention times and liquid-phase detection limits for ammonia, MA, DMA and TMA, calculated from the average of the signal corresponding to 3/5 peak-to-peak noise from 10 typical cartridge measurements. For the high-concentration cartridges, gas-phase detection limits were calculated for 20 min samples at  $1.0 \text{ L min}^{-1}$  sample

Interactive Discussion

flow followed by extraction in 10 mL 0.1 M oxalic acid and injection of 20  $\mu$ L of this extract in the IC. For the low-concentration cartridges, gas-phase detection limits were calculated for 60 min samples at 150  $\text{cm}^3 \text{min}^{-1}$  sample flow followed by in-line extraction on the IC. Detection limits for the high- and low-pressure cartridges were in the low ppb and ppt range, respectively (see Table 1). It should be noted that with the current design of the low-concentration cartridges, 150  $\text{cm}^3 \text{min}^{-1}$  is the maximum sample flow possible, however redesigning the cartridge to allow higher sampling flow would further lower the detection limits for this method.

### 3.1 Gas-phase standards using the high-concentration cartridges with off-line extraction

Oxalic acid is not retained by the cation column used in the IC and elutes at  $\sim 2.5$  min. The high concentration (0.1 M) of oxalic acid in the cartridge extracts compared to that of the IC eluent (0.00375 M) results in a characteristic negative broad signal initially as can be seen in a typical cartridge blank (Fig. 5a). For this reason, blanks are subtracted from cartridge samples before the peaks are integrated. A typical background-subtracted chromatogram for a DMA sample is shown in Fig. 5b. Results from the gas-phase standard measurements are presented in Fig. 6 and show measured ammonia and amine concentrations for the first and second extract of the primary cartridge, the first extract of the backup cartridge, as well as the total measured concentration (first and second extract of the primary cartridge plus the first extract of the backup cartridge).

WCE resin was originally designed to remove alkaline components from liquid solutions by reaction with the surface carboxylic acid groups (Kunin and Barry, 1949). To the best of our knowledge, its ability to take up gas-phase species has not been reported. For the three amines, the measured concentration from the backup cartridge was less than 5 % of that of the primary cartridge (Fig. 6). This small amount of breakthrough indicates that WCE resin efficiently takes up gas-phase amines even at the relatively high flow rate of 1.0  $\text{Lmin}^{-1}$ . For ammonia, this value is slightly higher ( $< 10$  % of the

primary cartridge), suggesting that the less-basic, more-volatile ammonia is trapped less efficiently than the amines.

For cartridge extraction, an appropriate solvent must be able to efficiently extract the ammonia and amines, and be low enough in concentration to minimize effects on the baseline in the ion chromatogram (Fig. 5a). For regeneration of the WCE resin, the manufacturer recommends dilute hydrochloric or sulfuric acids. In our experiments, we chose oxalic acid as the extraction solvent due to its weak acidity [ $pK_{a1} = 1.25$ ;  $pK_{a2} = 3.81$ ] (Haynes, 2013) and its use as the IC eluent. As seen in Fig. 6, the second extract of the primary cartridge using 10.0 mL of 0.1 M oxalic acid contains less than 15% of the analyte compared to that of the first extraction, indicating this method efficiently extracts the collected species. However, oxalic acid concentrations lower than 0.1 M were shown not to be sufficient. For DMA and TMA, a slight trend of increasing concentration of amine measured from the second extraction of the primary cartridge is evident, suggesting that at higher gas-phase concentrations, a shorter sample time, lower flow rate or multiple extractions may be required. However, such high concentrations of the amines (> 0.5 ppm) have not been reported in air and hence are unlikely to present an analytical limitation for this technique as an ambient sampling method.

Figure 6 shows weighted least-squares fits (green lines) forced through (0,0) of the total measured concentrations of ammonia and the amines. These data indicate a linear trend of measured concentration with dilution of the gas standards and suggest good measurement efficiency for each of the gas-phase amines and ammonia. As can be seen in Fig. 6, the measured concentrations without dilution are lower than the manufacturer-provided concentrations of the gas cylinders (see Sect. 2.2). While this could potentially be due to uptake of the amines on tubing prior to measurement, this seems unlikely as the system was conditioned for several hours at each concentration prior to sampling and no trend of increasing concentration was observed after conditioning. It is possible that the labeled concentrations of the cylinders are artificially high, as the manufacturer has expressed difficulty in preparing such low concentrations of these sticky compounds. However, the linear trend with dilution along with the

negligible amounts measured in the backup cartridge and second extract of the primary cartridge indicate efficient measurement for this technique. This comparison of measured to nominal concentrations also provides a cautionary note in terms of using commercially supplied amine or ammonia gas mixtures as calibration standards.

5 All the samples for the gas-phase standard measurements (both primary and backup) were collected on four high-concentration cartridges. These cartridges showed no noticeable degradation in collection or extraction efficiency, even after hundreds of extractions without replacing the WCE resin.

### 3.2 Results for field measurements using low-concentration cartridges

10 A typical chromatogram from an air sample taken in Chino, CA, on 28 August 2013 is shown in Fig. 7. On each of the three days of sampling (28 August, 04 and 12 September 2013), two 45–50 min samples were taken. The results from all field measurements are presented in Table 2. Also included in Table 2 are the temperature, relative humidity and weather conditions for each sample as reported by NOAA for the Chino Airport, which is < 1 mile away from the sampling site (NOAA, 2014).

15 In all samples, peaks corresponding to  $\text{NH}_3$  and TMA were observed, and in several samples a peak for MA and/or a peak at  $\sim 14$  min were present. In addition to the standards described in Sect. 2.1, those for isopropylamine, ethylamine, diethylamine, butylamine and aniline were obtained and analyzed by IC, however their retention times did not correspond to the peak at  $\sim 14$  min, which remains unidentified. Also, diethylamine has been reported to coelute with TMA in some Dionex IC columns (Murphy et al., 2007; VandenBoer et al., 2011, 2012). However, using the Metrohm column and IC conditions described in Sect. 2.3, these two species were sufficiently well resolved to identify.

25 Each sample cartridge was extracted in-line and analyzed sequentially by IC five times. The TMA peaks for the five extracts from a sample take on 28 August 2013 are shown in Fig. 8. The trend in integrated peak areas with extraction for TMA (shown in parentheses in Fig. 8) indicates that five extractions are necessary to measure > 97 %

of the collected species. Results for ammonia show the same trend. While ammonia and TMA peaks were usually still present in the fifth extract, they represented  $3 \pm 2\%$  ( $2s$ ) for  $\text{NH}_3$  and  $1 \pm 3\%$  ( $2s$ ) for TMA of the total over five extractions. However, the need for five extractions ( $\sim 2.5$  h IC run time) is a limitation of this method over existing on-line techniques. Optimization of this method (e.g. modifying cartridge dimensions, extraction solvent, IC parameters, etc.) may be able to reduce the number of required extractions, thereby improving the efficiency of this technique.

The first measurement on 12 September 2013 showed noticeably lower ammonia and TMA concentrations compared to the previous sampling periods. Several factors may contribute to this difference. The temperature was lower and the relative humidity higher on 12 September compared to the two previous sampling days. Also, mist was reported by the Chino Airport weather station on 12 September that had completely cleared up sometime between 5:38 a.m. and 5:53 a.m. Wet deposition onto mist droplets could account for the lower  $\text{NH}_3$  and TMA concentrations on this day and also explain the increase in concentration between the first and second sample as the mist evaporated.

The results of these field measurements are consistent with the range of published data on ammonia and amine concentrations in agricultural areas. Concentrations of ammonia and TMA near cattle feedlots and enclosures in the range of 0.7–34 ppm  $\text{NH}_3$  (Hiranuma et al., 2010; Huang et al., 2009; Trabue et al., 2011) and 0–400 ppt TMA (Fujii and Kitai, 1987; Kuwata et al., 1983; Trabue et al., 2011) have been reported. Inside cattle enclosures, TMA concentrations up to 0.6–7.6 ppb have been measured (Fujii and Kitai, 1987; Kallinger and Niessner, 1999; Kuhn et al., 2011). The ratio of TMA to  $\text{NH}_3$  in this study,  $(4\text{--}9) \times 10^{-3}$ , is similar to that reported for indoor cattle enclosures as well as emissions from hay and silage (Kuhn et al., 2011).

## 4 Conclusions

This technique involving weak cation exchange resin as a substrate for collection of gas-phase ammonia and amines offers an accurate, reproducible, and inexpensive means of measurement at atmospherically relevant concentrations that is useful for both laboratory and field studies. It minimizes losses on inlets and sampling lines, and avoids uptake of aqueous amines onto glass surfaces. In addition, it is simple and relatively easy to implement, and uses commonly available instrumentation. The custom-designed high-pressure cartridge used as a carrier for the resin combined with a technique for in-line extraction of the compounds and analysis by ion chromatography gives detection limits in the tens of ppt range.

*Acknowledgements.* The authors are grateful to Greg DeMattia and Metrohm USA for helpful discussions and access to the ion chromatography equipment. M. Dawson thanks Metrohm USA and the ARCS Foundation for scholarships. A. Gomez was supported by the NIH MARC program at Cal State LA (Grant #GM08228). This work was performed under a grant from the Department of Energy (grant #ER65208).

**Table 1.** Retention times and calculated detection limits for ammonia and amines. Errors shown are  $\pm 2s$ .

Species	Retention Time (min)	Liquid Phase Detection Limit <sup>a</sup> ( $M \times 10^{-7}$ )	Gas Phase Detection Limit <sup>a, b</sup>	
			High-Concentration Cartridge (ppb in air)	Low-Concentration Cartridge (ppt in air)
Ammonia	7.5	$2.3 \pm 1.6$	$2.8 \pm 1.9$	$12 \pm 8$
Methylamine	8.8	$2.6 \pm 1.7$	$3.1 \pm 2.1$	$14 \pm 9$
Dimethylamine	11.8	$3.5 \pm 2.4$	$4.3 \pm 3.0$	$19 \pm 13$
Trimethylamine	20.7	$8.2 \pm 5.6$	$10 \pm 7$	$45 \pm 31$

<sup>a</sup> Detection limits are calculated from the average of the signal corresponding to 3/5 peak-to-peak noise from 10 cartridge samples.

<sup>b</sup> Gas-phase detection limits for the high-concentration cartridge samples are based on 1 LPM sampling for 20 min, extraction in 10 mL oxalic acid, and injection of 20  $\mu$ L of the solution. For the low-concentration cartridge, detection limits are based on 150  $\text{cm}^3 \text{min}^{-1}$  sampling for 60 min and in-line extraction on the IC.

## Measurement of gas-phase ammonia and amines in air

M. L. Dawson et al.

**Fig. 6.** Results for measurements of gas-phase standards of **(a)** ammonia, **(b)** MA, **(c)** DMA, and **(d)** TMA using high-concentration cartridges, including the first and second extract of the primary cartridge and the first extract of the backup cartridge, as well as the total measured concentrations. The dilution factor for ammonia or amine from the gas cylinders diluted with air is shown on the *x* axis, where 1.0 is the undiluted standard and 0.1 is a 10% mixture. Data points marked with an asterisk (\*) do not have sufficient replicates to include error bars. The green lines are weighted least-squares fits, where the weights for each point are given by  $w = (1/s^2)$  and  $s$  is the sample standard deviation of the measurements at each dilution. Slopes of fitted lines are shown in green ( $\pm 2s$ ). Manufacturer labeled concentrations for the undiluted standards were: 0.812 ppm NH<sub>3</sub>, 10 ppm MA, 1.0 ppm DMA, and 1.0 ppm TMA.

and amines in air**

M. L. Dawson et al.

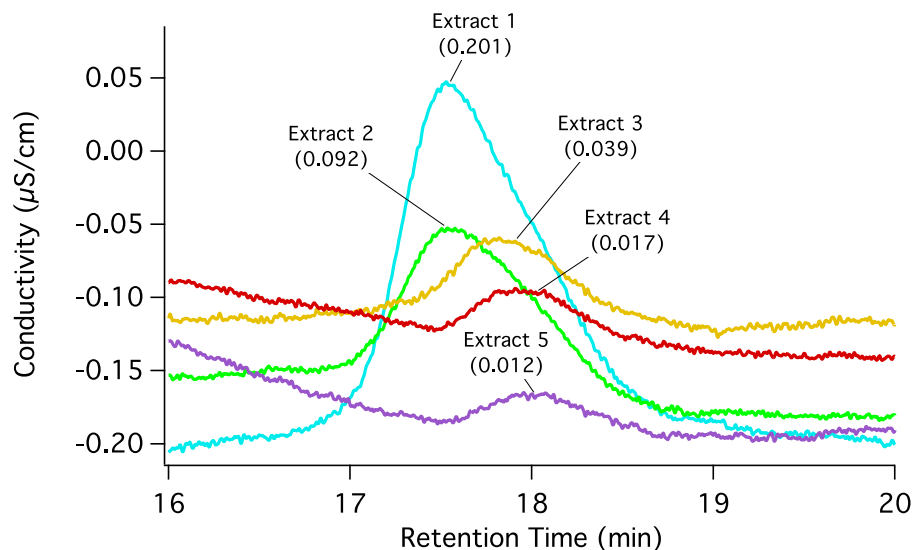

**Fig. 7.** The background-subtracted chromatogram from the first extract of the cartridge for the sample taken 28 August 2013 at 4:22 a.m. in Chino, CA. Inset: same chromatogram magnified to show peaks for MA and TMA.

**Measurement of gas-phase ammonia and amines in air**

M. L. Dawson et al.

**Fig. 8.** The background-subtracted chromatograms from all five extracts of the cartridge for the sample taken 28 August 2013 at 5:08 a.m. in Chino, CA. Image is magnified to show TMA peak. Integrated peak areas in  $(\mu\text{Smin}) \text{cm}^{-1}$  are shown in parentheses. The slight shift in retention time at lower peak size was typical for TMA in both standards and samples.
