## Abstract

The mountain cloud forest of Taiwan can be delimited from other forest types using a map of the ground fog frequency. In order to create such a frequency map from remotely sensed data, an algorithm able to detect ground fog is necessary. Common techniques for ground fog detection based on weather satellite data can not be applied to fog occurrences in Taiwan as they rely on several assumptions regarding cloud properties. Therefore a new statistical method for the detection of ground fog from MODIS data in mountainous terrain is presented. Due to the sharpening of input data using MODIS bands 1 and 2 the method provides fog masks in a resolution of 250 m per pixel. The new technique is based on negative correlations between optical thickness and terrain height that can be observed if a cloud that is relatively plane-parallel is truncated by the terrain. A validation of the new technique using camera data has shown that the quality of fog detection is comparable to that of another modern fog detection scheme developed and validated for the temperate zones. The method is particularly applicable to optically thinner water clouds. Beyond a cloud optical thickness of  $\approx 40$ , classification errors significantly increase.

## 1 Introduction

Cloud forests are a tropical and subtropical forest type ecosystem characterized by the frequent occurrence of ground fog conditions (Bruijnzeel et al., 2010). As they intercept water from cloud droplets and, due to their mostly wet canopy, have a decreased rate of transpiration, they play an important role as an ecosystem service provider increasing local water supplies (Mildenberger et al., 2009). Furthermore they are biodiversity hot spots with a high number of endemic species (Postel et al., 2005). This also holds true for the cloud forest of Taiwan (Hsieh, 2002). While cloud forest areas of Taiwan are already the subject of intensive research (cf. e.g. Mildenberger et al., 2009; Chu et al., 2012) Taiwan's cloud forest never has been completely mapped on a country-

wide scale. The most comprehensive information about the extent of cloud forest in Taiwan available today is given by Li et al. (2013), based on the National Vegetation Database of Taiwan. Since this data is based on field surveys it is of high reliability but it only does cover the area of 9822 plots (each with an area of 400–2000 m<sup>2</sup>) distributed over the whole country. Due to the inaccessibility of Taiwan's mountainous areas, those plots are mainly located close to roads.

For a spatial-explicit mapping, the usage of remote sensing data seems advisable. As the occurrence of cloud forest depends on the heavy influence of ground fog conditions, it has been shown by Mulligan and Burke (2006) that it can be discriminated from other forest types by the application of a threshold on maps of the ground fog frequency. The potential of this approach for the application in Taiwan has been shown by Thies et al. (2015) using low stratus frequency maps derived from Moderate-resolution Imaging Spectroradiometer (MODIS) data. Because no distinction has been made in this study between low stratus clouds (including clouds without ground contact) and ground fog, the explanatory power of the presented low stratus frequency maps is, however, limited. To obtain more significant ground frequency maps, an algorithm able to detect ground fog (defined here as any cloud with ground contact) in Taiwan from satellite data is necessary. Common techniques for ground fog detection are analysed with respect to their applicability for Taiwan in Sect. 2.1. A new method which is more suitable for mountainous areas is presented in Sect. 2.2.

## 2 A ground fog detection approach suited for Taiwan

### 2.1 Existing approaches

In order to detect ground fog from space, commonly a plane cloud base is assumed. The height of the cloud base is compared to a digital elevation model (DEM). If it is equal to or below the terrain height taken from the DEM, ground fog conditions can be assumed. Mulligan and Burke obtain the height of the cloud base surface by modelling

difference between the fog and the land surface is about 10 K, which would result in a height difference of at least several hundreds of meters if a reasonable lapse rate is assumed.

Different methods are also available for cloud geometrical thickness derivation (cf. Table 2). Simple approaches that use empirically derived relationships between the thickness and the liquid water path (LWP) of a cloud (Hutchinson, 2002) or its optical thickness (Minnis et al., 1997) lack precision because of oversimplification. More sophisticated approaches applied in ground fog detection schemes as pseudosounding (cf. eg. Chang and Li, 2002; Bendix et al., 2005) or an approach based on iteratively simulated LWPs used by Cermak and Bendix (2008) use more complex cloud parameterizations but do rely on many assumptions regarding cloud microphysical properties and their vertical distribution within the cloud. These assumptions may be valid for radiation fog. The typical Taiwanese mountain fog, however, seems to be – based on field experience and information given by Li et al. (2015) – more of advective nature. While it has not been tested if existing cloud thickness retrievals can be applied despite some inaccuracies, the main problem of an accurate cloud top height derivation would remain.

## 2.2 The new approach – theoretical preliminary considerations

The main problem in ground fog detection in Taiwan is the derivation of cloud top heights. A method that does not take this intermediate step and detects the cloud base directly instead seems to be suited to overcome it.

For an assumed plane-parallel cloud as shown in Fig. 1 the geometrical thickness is by definition the same for all parts of the cloud that do not touch the terrain. If that cloud is, however, cut off by the terrain in some parts (causing ground fog), its thickness would be reduced in this area. If it is additionally assumed that the cloud is horizontally homogeneous in its optical properties, the optical thickness of that cloud would correlate with its geometrical thickness. Therefore the optical thickness should be constant in the parts without ground contact. In the parts with ground fog it would be reduced (de-

areas that do cover the biggest part of the island, the method is suited for ground fog detection in Taiwan despite this limitation.

The optical thickness input and the DEM as well as other inputs that are necessary for the method are described in Sect. 3.

### 3 Input data and their processing

As shown in Sect. 2.2 one of the main inputs for DOGMA is a DEM. The ASTER GDEM 2 (property of METI and NASA) as distributed via the USGS global data explorer (United States Geological Survey, 2013) and resampled to a resolution of 250 m is used.

All other inputs (cf. Fig. 6) are based on MODIS Collection 051 Level 1B and Level 2 products. MODIS data has been chosen instead of the data of geostationary satellites (e.g. the Japanese Himawari series covering the area of Taiwan) because of the combination the long time span for which the data is available (MODIS: since 1999 (Terra)/2002 (Aqua); Himawari 7: since 2006; Himawari 8: since 2015) and its relatively high spatial resolution (MODIS: up to 250 m; Himawari 7: up to 1000 m; Himawari 8: up to 500 m). The latter is necessary due to the complex topography of Taiwan's mountains.

The cloud optical thickness is based on the MODIS MOD06 optical thickness derived from radiative transfer calculations (Platnick et al., 2015). As it is only available for daytime scenes, the application of DOGMA is restricted to those. (cf. Sect. 3.2)

Since fog is (with the exception of ice fog that can only be found in polar latitudes, Oke, 1978) completely in the water phase, DOGMA is only applied on water clouds. Additionally to the inputs mentioned in Sect. 2.2 a cloud mask including information about the cloud phase thus is necessary as an input. It is based on the MODIS MOD35 cloud mask product (cf. Sect. 3.3).

To be able to remove pixels that are considerably colder (because higher) than the rest of a cloud entity also cloud top temperatures are needed for the procedure. They

Interactive Discussion

are calculated for all water cloud pixels from MODIS thermal infrared (TIR) window channels (cf. Sect. 3.4).

To make use of the full 250 m resolution of MODIS, which is only available in the visible bands 1 and 2, different techniques (cf. Sects. 3.1–3.4) are applied to sharpen those inputs using the MODIS high-resolution bands.

### 3.1 Pan-sharpening of MODIS channels

MODIS channels are not necessary as an input for DOGMA. Some are, however, required to sharpen other MODIS products needed as an input. Therefore several infrared channels are transferred to the 250 m resolution of MODIS channels 1 and 2 using a suited pan-sharpening technique by Schulz et al. (2012). According to this method a high-resolution satellite channel is degraded to match the resolution of the low-resolution channel that is to be sharpened. This is done by averaging each group of  $4 \times 4$  high-resolution pixels the area of which corresponds to one and the same low-resolution pixel. Then a potential regression is used to explain the pixel values of the low-resolution channel with the pixel values of the degraded high-resolution channel. The same regression is applied on the original high-resolution channel in order to obtain a high-resolution version of the low-resolution channel. This procedure is, however, not applied on a scene globally as that would lead to a low coefficient of determination of the regression. This would result in a bad quality of the sharpened image. Instead, a channel is sharpened pixelwise using a different regression for each pixel. Each regression is based on an approximately round moving window with a diameter of 5 pixels centred at the pixel that is to be sharpened.

For DOGMA data pre-processing the pan-sharpening technique has been adapted to MODIS data. Since MODIS has two channels in the resolution of 250 m, both of them were degraded and used to sharpen the low-resolution channels using a multiple potential regression. In order to simulate what the high-resolution image would look like if captured by MODIS in its 1000 m resolution, the sensor's spatial response function is additionally incorporated in the degradation of the 250 m channels. In the averaging

Interactive Discussion

process of  $4 \times 4$  high-resolution pixels each high-resolution pixel is weighted by the sensor's spatial response function (taken from Huang et al., 2002) of the low-resolution pixel that is to be sharpened.

The described method is used to sharpen the unitless digital number (DN) values of the MODIS channels 20, 29, 31 and 32 as distributed via the MODIS MOD02/MYD02 product. After sharpening, the DNs of these channels are transferred to radiances using scale and offset values included in the MOD02/MYD02 product. The inverse Planck Function is used to calculate Black Body Temperature (BBT) values from the radiances.

BBTs are also calculated from the 1000 m DNs of the channels 20 and 31. From the DNs of channel 1 the reflectance is calculated using the appropriate scale and offset values from the MOD02/MYD02 product. A sharpening result for channel 31 is exemplarily shown in Fig. 7. An overview of the used channels is given in Table 3.

### 3.2 Cloud optical thickness

Over land surfaces the MOD06 optical thickness is mostly based on channel 1 (Platnick et al., 2003). Therefore an slightly adapted version of the pan-sharpening method used to process the 1000 m MODIS imagery (cf. Sect. 3.1) is suited to sharpen it. Instead of a multiple regression a simple regression incorporating only channel 1 (instead of channel 1 and 2) as the independent variable is used. An example result is shown in Fig. 7.

### 3.3 Cloud mask

As it is based on the solar MODIS high resolution channels 1 and 2 only, the 250 m cloud mask included in the MOD35 cloud mask product does not contain information about the cloud phase. Furthermore it is, for some scenes, heavily flawed in the area of Taiwan. Cities and riverbeds with high reflectance values are often wrongly classified as clouds (cf. Fig. 8). These problems do not occur in the MOD35 1000 m cloud masks. Therefore an own water cloud mask in 250 m resolution is created using the MOD35

1000 m cloud mask as a reference and sharpened as well as not-sharpened MODIS imagery as its basis. Before any further processing is applied thin cirrus are removed from the 1000 m MOD35 cloud mask based on the included cloud classification.

Cermak and Bendix (2008) have shown that a threshold applied on the difference  $BBT_{TIR} - BBT_{MIR}$  (further referred to as  $diff_{250}$  and  $diff_{1000}$  for the 250 m and the 1000 m version) between BBT values in the thermal (TIR) and medium infrared (MIR) is well suited to distinguish between cloud-contaminated and clear pixels using a threshold. The difference values are clearly negative for cloudy pixels and near to 0 for clear surfaces. For MODIS this difference can be calculated from the channels 31 (TIR) and 20 (MIR).

To identify a suitable threshold for a certain scene several iteratively adapted thresholds are applied on  $diff_{1000}$  in order to obtain masks in the 1000 m resolution. Those masks are compared to the MOD35 1000 m cloud mask in terms of the percentage of pixels being classified in agreement between the cloud mask derived from  $diff_{1000}$  and the MODIS reference product. The threshold resulting in the best agreement is chosen.

Since clouds are highly reflective in the visible spectrum, a threshold can also be applied on the reflectance of channel 1 (further referred to as  $ref_{250}$  and  $ref_{1000}$  for the 250 m and the 1000 m version) to distinguish between cloud-covered and cloud-free pixel to some degree. This threshold is determined in the same iterative way as the threshold derived from  $diff_{1000}$ .

These two thresholds can then be applied on  $diff_{250}$  and  $ref_{250}$ . The results are two cloud masks in 250 m that still contain several flaws (e.g. cities and river beds being classified as clouds due to their high albedo in the channels 1 and 20). As the flaws often are in different areas the two cloud masks can be combined to a new cloud mask (further referred to as global cloud mask) that consists only of the pixels classified as clouds in both of them. It is of higher quality but still not completely flawless due to the threshold being applied on the full MODIS scene. Therefore thresholds are additionally identified for each 1000 m pixel  $p$  separately by using the iterative approach described above for a window of 20 pixels  $\times$  20 pixels around  $p$  only. The pixels of  $diff_{250}$

Interactive Discussion

and  $ref_{250}$  covered by  $p$  are then classified as cloud-contaminated or cloud-free using these thresholds. The results from the local approach and the global cloud mask are combined to a final 250 m cloud mask. A pixel is considered as cloudy if clouds are present according to the global cloud mask and

- (a) the pixel is cloud-contaminated according to the local thresholds applied on  $diff_{250}$  and  $ref_{250}$  or
- (b) the pixel is unambiguously cloudy according to the value of  $diff_{250}$  ( $diff_{250}$  is below the  $diff_{250}$  value of at least 50 % of the pixels in the 20 pixels  $\times$  20 pixels window that are considered as clouds according the MODIS 1000 m cloud mask).

The resulting mask does still not differentiate between water, ice and mixed phase clouds. Mixed and ice phase clouds are detected using the same threshold approach that is incorporated in the MODIS cloud phase classification. It is mainly based on radiative transfer calculations that have shown that the difference  $BBT_{29} - BBT_{31}$  between the MODIS channels 29 and 31 is high for ice clouds and low for water clouds (Chylek et al., 2006). Also BBTs from channel 31 can be incorporated to detect clouds that are obviously too cold to be in the water phase. The MODIS cloud classification combines these two approaches to identify cloud pixels that are not or not solely in the liquid phase as follows (Platnick et al., 2003):

(a) mixed phase:  $238 < BBT_{31} < 268$  K and  $-0.25 \leq BBT_{29} - BBT_{31} < 0.5$  K

(b) ice phase:  $BBT_{31} \leq 238$  K or  $BBT_{29} - BBT_{31} \geq 0.5$  K

Examples for the enhanced 250 m cloud mask are shown in Fig. 8.

### 3.4 Cloud top temperature

Cloud top temperatures are calculated for all water cloud pixels from the sharpened BBTs of the MODIS TIR window channels 31 and 32 using a split-window algorithm proposed by Jiménez-Munóz and Sobrino (2008). It allows to correct for atmospheric

absorption as well as emissivity effects. The latter, however, are ignored in our cloud top temperature retrieval as an emissivity of 1 for the cloud surface is assumed. This approximation for water clouds is possible for TIR wavelengths, if the cloud is supposed to have a thickness of at least several tens of meters (cf. e.g. Yamamoto et al., 1970; Hunt, 1973). The total atmospheric water vapour content, which is needed as an additional input for the cloud top temperature retrieval, is taken from the MOD05/MYD05 total precipitable water product. It is resampled to the 250 m resolution without sharpening.

## 4 Methodology

### 4.1 DOGMA – detailed description

DOGMA is fed with the inputs described in Sect. 3 (cf. Fig. 9). Pixels classified as ice cloud or mixed phase cloud in the 250 m cloud mask are removed from the analysis and marked as unclassifiable as they might block the view to lower fog layers. The algorithm runs through each 250 m water cloud pixel  $p$  of a MODIS scene and calculates  $\rho_{\text{below } p}$ ,  $\rho_{\text{above } p}$  and  $\rho_{\text{diff } p}$  (cf. Fig. 10a) from a round window with a diameter of 40 pixels around  $p$  as described in Sect. 2.2. The scene is then scanned for local maxima of  $\rho_{\text{diff } p}$  in order to detect pixels at the cloud base height (further referred to as CBH pixels). This is done by comparing each water cloud pixel  $p$  to all other water cloud pixels in a round window with a diameter of 20 pixels centred at  $p$ . Pixels which are higher than the lowest direct neighbour of  $p$  or lower than the highest direct neighbour of  $p$  are excluded from this comparison as they would (if  $p$  is actually a CBH pixel) most probably be CBH pixels of the same cloud base as  $p$ .  $p$  is marked as a *low certainty CBH pixel* (cf. Fig. 10b) if

(a)  $p$  has a higher  $\rho_{\text{diff } p}$  than all the pixels it is compared to and

(b)  $\rho_{\text{diff } p}$  is below 0 and

tected CBH pixels (which is necessary to capture small scale variations in the cloud bottom height as precise as possible), DOGMA goes back to the original low certainty CBH pixels and filters them again based on their vertical distance to an assumed cloud base surface that can be defined from the high certainty CBH pixels. This cloud base surface is modelled for each water cloud entity separately by interpolating the heights of all high certainty CBH pixel belonging to that cloud entity using Inverse Distance Weighting (IDW, Shepard, 1968). All low certainty CBH pixels that are within a vertical distance of less than 400 m to this surface (further referred to as *final CBH pixels*) are used for the discrimination of ground fog.

For the final ground fog discrimination, the heights of all final CBH pixels of each water cloud entity as well as their temperature taken from the cloud top temperature image are interpolated using IDW interpolation (cf. Fig. 10c). Each pixel  $p$  in which the interpolated height of the cloud base is below or equal to the height taken from the DEM are ground fog pixels if the IDW interpolated temperature of  $p$  is not more than 3 K higher than the temperature taken from the cloud top temperature image. If the measured temperature was much colder,  $p$  would be significantly higher than the pixels used for the IDW interpolation. Therefore it would either belong to another cloud level or the assumption of a cloud top surface that can locally be approximated as plane would be wrong for  $p$ .

So far the existence of a cloud base surface that has a one-dimensional intersection with the terrain has been assumed. If a fog cloud does, however, touch the terrain with its entire base (= complete valley fill), such an intersection does not exist. Therefore the cloud would not be identified as fog by the tests described so far. In order to detect those clouds nevertheless, each cloud entity from the water cloud mask is further examined if no fog has been detected in it. For each pixel  $p$  of the entity  $\rho$  is calculated from the pixels in a round window with a diameter of 40 pixels that is centred at  $p$ . If the median of all  $\rho$  is below  $-0.3$ , all pixels of the entity are considered as ground fog pixels.

The final ground fog mask is shown in Fig. 10d.

ble the following statistical measures have been calculated (cf. Mason (2003); Matthew (1975); see Appendix A for formulas):

- Proportion Correct (PC);
- Bias;
- Probability Of Detection (POD);
- Probability Of False Detection (POFD);
- False Alarm Rate (FAR);
- Matthews Correlation Coefficient (MCC).

#### 4.2.2 Validation of the DOGMA cloud base height

As the quality of the DOGMA ground fog product is a direct result of the cloud base surface height (cf. Fig. 10c), the latter has been validated separately. This was done using the ceilometer as well as camera 7. The ceilometer is located in the valley of Xitou where a high fog frequency can be observed. The camera is located near the lower end of a valley on Chi-Lang Mountain facing up the valley. While the camera location is usually fog free, the upper parts of the valley are often fog immersed. The intersection between the cloud base and the terrain can be observed by the camera in these cases.

#### Cloud base validation using ceilometer data

The ceilometer validation has been conducted for all MODIS overflights in which the DOGMA cloud base product provides information for the ceilometer location and the ceilometer provides cloud base information as it is neither cloud immersed nor is the pixels it is located in cloud free. For these overflights, the DOGMA cloud base height has been extracted for the pixel of the ceilometer location. The mean deviation

Interactive Discussion

has been calculated between ceilometer reference data and the extracted cloud base heights. All scenes in which the ceilometer obtained cloud base height is above the height of the highest pixel in the valley of Xitou that is cloud covered (according to the 250 m water cloud mask) were excluded from this calculation. This was necessary as DOGMA extracts the height of the cloud base from the DEM and is therefore – as a matter of principle – not able to detect any cloud base that does not touch the terrain. For ground fog detection information about higher cloud bases is not of interest. Also scenes in which the DOGMA cloud base is below the ceilometer location needed to be excluded from the calculation as ceilometer data (which is only available if the cloud base is above the ceilometer) would only be available if the DOGMA cloud base height is wrong. This would result in a biased validation.

### Cloud base validation using camera data

While cloud bottom heights recorded by the ceilometer could be directly compared to the height of the DOGMA cloud base, the camera footage needed to be processed manually in order to obtain reference cloud bottom heights. All images taken at MODIS overflights were assessed to determine whether the captured slopes of Chi-Lan Mountain are cloud immersed as it is shown in Fig. 12. Scenes for which that is not the case and scenes for which the weather conditions (e.g. ground fog at the camera location) did not allow an unequivocal identification of the cloud base where excluded from further analysis. For the remaining scenes the intersection of the cloud base height and the terrain was marked manually in the image (red lines in Fig. 12). For those image pixels that have been marked as intersection pixels the altitude was extracted from the ASTER GDEM 2 reprojected to the view of the camera (cf. Schulz et al. (2014) for details about the reprojection). IDW interpolation has been used to model a cloud base surface from the heights and positions of those pixels in a resolution of 250 m for a domain defined by their bounding box. For each MODIS scene for which the cloud base obtained from the camera data has been calculated and also the DOGMA cloud base product contains information inside the bounding box domain, the median of the

deviations in height between all pixels of the camera obtained cloud base surface and the corresponding DOGMA cloud base surface pixels was then calculated. The result is a single value for each scene that describes the deviation between the camera obtained cloud base and the DOGMA cloud base for the whole view shed of the camera.

5 From those deviations the mean deviation has been calculated.

## 5 Validation results and discussion

The results of the validation of the DOGMA ground fog product are shown in Tables 5 and 6. Also the results of a validation carried out by Cermak and Bendix (2011) for their own method using METAR data from a European domain are included. As the two validations are based on different data sets from different areas, they should not be directly compared to each other. The validation by Cermak and Bendix should only be seen as a reference for the current quality of ground fog detection from space born sensors.

15 As shown in Table 6 both methods have a relatively similar overall fog detection quality (MCC). DOGMA tends to underestimate the fog frequency while the method by Cermak and Bendix generally overestimates it (Bias). In detail that means that a lower ratio of fog pixels is correctly classified as fog by DOGMA than by the method of Cermak and Bendix (POD) but also that a lower ratio of all pixels that are classified as fog contaminated is wrongly classified (FAR). A higher ratio of fog free pixels is, however, wrongly classified as fog by DOGMA (POFD). The main issue with both methods is a relatively high FAR in combination with a relatively low POD.

20 The shortcomings of DOGMA might mostly be caused by clouds that can not locally be approximated as plane-parallel and horizontally homogeneous as it is assumed by the method. Also clouds with a very high optical thickness that do often cover Taiwan can cause problems. The footage of the cameras shows that optically thick clouds do often touch the ground, even if it is not possible for a human observer to distinguish ground fog in a satellite image. Also DOGMA has problems to detect fog in these

situation. An optical thickness of 40 – a value that is surpassed in 13.31 % of the pixels that have been used for the validation – corresponds to a transmittance of  $4.24 \times 10^{18}$ . With such a low transmittance almost no light – and therefore hardly any information – from the cloud base does reach the sensor. In order to assess the impact of those very thick clouds, a validation excluding all reference observations during which the camera or ceilometer has been located below a cloud with an optical thickness of more than 40 has been carried out. As shown in Table 6 this increases the overall detection quality (MCC), mainly due to a better POD.

The mean deviation of the DOGMA cloud base height is given in Table 7. DOGMA does not directly calculate a cloud base height. Instead CBH pixels are detected in a two-dimensional image (cf. Sect. 4.1). As the validated DOGMA cloud base height is interpolated from the height of the DEM extracted from these pixels, its precision is (if inaccuracies of the interpolation are ignored) a result of the correctness of the detection of CBH pixels in combination with the topography and its mapping in the 250 m resolution of the DEM. The mean steepness of the slopes of both valleys incorporated in the cloud base validation is approximately 50–60 %. As a pixel with sides of 250 m in length has a diagonal of about 354 m, height differences of 177 m (50 % of 354 m) to 212.4 m (60 % of 354 m) inside a single pixel are possible and height differences between 125 m (50 % of 250 m) and 150 m (60 % of 250 m) are unavoidable. This means that even CBH pixels that have been detected in the correct position may result in relatively imprecise cloud base heights, although the delimitation of the fog immersed area would be perfect. Conversely, this implies that the  $\sim 200$  m error of the DOGMA cloud base is the result of a relatively small mean error of less than two pixels in the horizontal positions of the CBH pixels. Therefore the DOGMA cloud base height product is suited for ground fog delimitation but should not be used for other purposes.

## 6 Conclusion and outlook

Common fog detection schemes that have been developed for radiation fog are not applicable in Taiwan as they rely on assumptions (cf. Sect. 2.1) that are not met by most fog occurrences in Taiwan. Therefore the presented method has been developed. DOGMA does not calculate the cloud base height from the difference between the cloud top height and the cloud thickness. Instead pixels at the cloud base are directly detected using a statistical approach that is based on a negative Spearman's rank correlation coefficient between the optical thickness and the terrain height of fog immersed pixels extracted from the DEM. As it relies on clouds that can be at least locally approximated as plane-parallel and horizontally homogeneous and also the MOD 06 optical thickness product is based on a radiative transfer calculations using a plane-parallel cloud model (Platnick et al., 2003), also DOGMA does rely on some assumptions. The necessary degree of plane-parallelism and horizontal homogeneity is, however, low enough, so that the method is applicable to sea of clouds situations (cf. Fig. 2) as they are typical for Taiwan. As the comparison to the method of Cermak and Bendix (cf. Sect. 5) has shown, the overall quality of DOGMA's fog detection is (despite some problems with fog clouds with a very high optical thickness) comparable to that of a modern fog detection scheme developed and validated for the temperate zones. It therefore seems to be applicable for the creation of ground fog frequency maps that can be used for the country-wide mapping of Taiwan's cloud forests.

DOGMA is restricted to mountainous areas. If perfectly plane-parallel and horizontally homogeneous fog clouds are assumed, it should work even for slightest slopes. As those perfect conditions actually won't be met, it will be the subject of future work to find out for which areas DOGMA is suited. It would e.g. be conceivable that the method works for very plain radiation fog in the valleys of low mountain ranges.

As the only necessary inputs for DOGMA are a DEM, a cloud mask, the optical thickness and cloud top temperatures, its implementations to the imagery of other satellites than MODIS should be possible without problems. MODIS has been chosen for the first

implementation of DOGMA due to its high spatial resolution and the long time span for which its data is available. The drawback of a polar-orbiting satellite is, however, its bad temporal coverage. Therefore the imagery of the new Himawari 8 satellite with a resolution of up to 500 m pixel<sup>-1</sup> and a sampling rate of 10 min would be well suited for future implementations of DOGMA in order to obtain information about ground fog in Taiwan.

## Appendix A: Formulas used in the validation of the ground fog product

The following formulas were used for the calculation of the statistical measure used in Sect. 4.2.1. Cf. Table 5 for explanations of  $n_{11}$ ,  $n_{10}$ ,  $n_{01}$  and  $n_{00}$ .

$$MCC = \frac{n_{11} \cdot n_{00} - n_{01} \cdot n_{10}}{\sqrt{(n_{11} + n_{01}) \cdot (n_{11} + n_{10}) \cdot (n_{00} + n_{01}) \cdot (n_{00} + n_{10})}} \quad (A1)$$

$$PC = \frac{n_{11} + n_{00}}{n_{11} + n_{10} + n_{01} + n_{00}} \quad (A2)$$

$$Bias = \frac{n_{11} + n_{01}}{n_{11} + n_{10}} \quad (A3)$$

$$POD = \frac{n_{11}}{n_{11} + n_{00}} \quad (A4)$$

$$POFD = \frac{n_{01}}{n_{01} + n_{00}} \quad (A5)$$

$$FAR = \frac{n_{01}}{n_{11} + n_{01}} \quad (A6)$$

*Acknowledgements.* This research was funded by a grant (TH 1531/2-1) from the German Research Council (DFG) in cooperation with the Ministry of Science and Technology of the Republic of China. The authors would also like to thank Po-Hsiung Lin and Yen-Jen Lai for the access to the ceilometer data.

Interactive Discussion

**Table 1.** Different cloud height retrieval methods.

Reference	Basic idea of the method	Problems
Menzel et al. (1983)	CO <sub>2</sub> slicing: due to CO <sub>2</sub> absorption increasing with wavelength in the CO <sub>2</sub> band around 15 μm, different channels in this band are sensitive to different levels in the atmosphere.	The CO <sub>2</sub> absorption is very high for low levels (< 3 km) of the atmosphere. This results in bad signal-to-noise ratios for low level clouds such as fog.
Bendix and Bachmann (1993)	DEM extraction: for a fog entity that is horizontally restricted by the terrain the height of its outermost pixels can be read from a DEM.	Only possible for fog that is restricted by the terrain in its horizontal extent.
Yi et al. (2015)	The top height of radiation fog that is restricted in its vertical extent by an temperature inversion is equal to the base height of that inversion. The base height of the inversion can be calculated from satellite data.	Highly experimental. Works only for radiation fog. The fog occurrence in Taiwan, however, is mainly caused by moist air masses being uplifted by the Taiwanese mountains (Li et al., 2015).
e.g. Cermak and Bendix (2008); Platnick et al. (2003)	Under the assumption of a fixed negative temperature lapse rate or an atmospheric profile the cloud top height can be calculated from the cloud top temperature.	Neglects material parameters. This is crucial for ground fog in Taiwan. An assumed temperature lapse rate/profile might be very wrong for many scenes.

**Table 2.** Different cloud thickness retrieval methods.

Authors	Basic idea of the method	Problems
Hutchinson (2002)	As the liquid water path (LWP) is the column integration of the the liquid water content (LWC), the cloud thickness can be calculated from the satellite retrieved liquid water path (LWP) under the assumption of a fixed liquid water content (LWC) for certain cloud types.	The LWC is vertically not constant. For thin clouds, however, a vertically constant LWC can be approximated.
Minnis et al. (1997)	The cloud thickness is calculated from the satellite retrieved cloud optical thickness using empirical formulas. For clouds in different heights, different formulas are used.	Due to oversimplification, the approach can only be seen as a crude approximation.
e.g. Chang and Li (2002); Bendix et al. (2005)	Pseudosounding: measured albedos in different channels of the solar spectrum are compared to theoretical albedos that were simulated for clouds with different thicknesses using radiative transfer calculations and stored in lookup tables. The thickness of the simulated cloud with the smallest deviation between its albedos and the measured albedos is then assumed for the real cloud.	For the radiative transfer calculations several assumptions about the cloud microphysics are necessary. These assumptions may be not true for Taiwanese fog clouds.
Cermak and Bendix (2008)	Clouds with different cloud thicknesses are iteratively simulated using a three-layer cloud model. The LWC of the simulated cloud is integrated over the cloud thickness in order to obtain the LWP. This theoretical LWP is compared to a satellite retrieved LWP. If they match, the thickness of the simulated cloud is assumed for the real cloud.	Several assumptions about the cloud microphysics are necessary. These assumptions may be not true for Taiwanese fog clouds.
