Abstract

Amines are potentially important for atmospheric new particle formation and therefore the demand for highly sensitive gas phase amine measurements has emerged in the last several years. Nitrate Chemical Ionization Mass Spectrometry (CIMS) is routinely used for the measurement of gas phase-sulfuric acid in the sub-pptv range. Furthermore, Extremely Low Volatile Organic Compounds (ELVOCs) can be detected with a nitrate CIMS. In this study we demonstrate that a nitrate CIMS can also be used for the sensitive measurement of dimethylamine ((CH₃)₂NH, DMA) using the NO₃⁻(HNO₃)₁₋₂(DMA) cluster ion signals. This observation was made at the CLOUD aerosol chamber, which was also used for calibration measurements. Good linearity between 0 and ~ 120 pptv of DMA as well as a sub-pptv detection limit of 0.7 pptv for a 10 min integration time are demonstrated at 278 K and 38 % RH.

1 Introduction

The gas-phase abundance of amines in the atmosphere received considerable attention recently as amines are potentially an important agent contributing to atmospheric aerosol nucleation events in those regions where amines are emitted. A large variety of different amines exists in the atmosphere and various sources of amines are known such as animal husbandry or sewage, nevertheless, the gas phase concentrations of amines are expected to be low due to rapid uptake into acidic aerosols and high solubility (Ge et al., 2011). Despite concentrations expected to be typically 10 to 1000 times below atmospheric gas phase ammonia levels, amines such as methyl-, dimethyl- or trimethylamine were postulated to enhance the nucleation of sulfuric acid much more efficiently than NH₃ (Kurtén et al., 2008). Furthermore, it was found that typical concentration levels of H₂SO₄ and NH₃ in the boundary layer are too low to explain aerosol formation rates as frequently observed during nucleation events via nucleation mechanisms such as binary H₂SO₄-H₂O or NH₃-ternary nucleation (Kirkby et al., 2011).

Interactive Discussion

Participation of amines in nucleation was studied in the laboratory for the amine-sulfuric acid-water system (e.g. Berndt et al., 2010, 2014; Erupe et al., 2011; Zollner et al., 2012; Almeida et al., 2013; Kürten et al., 2014; Bianchi et al., 2014; Jen et al., 2015; Glasoe et al., 2015). Almeida et al. (2013) showed for dimethylamine ((CH₃)₂NH, DMA) that already the presence of a few pptv enhances the aerosol formation rates of sulfuric acid by several orders of magnitude and formation rates that are typical for atmospheric nucleation events are observed. Kürten et al. (2014) studied the formation of neutral (i.e. uncharged) H₂SO₄-DMA clusters and showed that the cluster formation process proceeds at or near the kinetic limit. This means that already for the low abundances of H₂SO₄ and DMA (H₂SO₄ at sub-pptv level, DMA at pptv level) the growth is limited only by the arrival rate of H₂SO₄ molecules and an efficient acid-base stabilization prevents even the smallest H₂SO₄-DMA clusters (i.e. the sulfuric acid dimer) from evaporation.

Evidence for the participation of amines in aerosol nucleation near ground has been found (e.g. Mäkelä et al., 2001; Smith et al., 2010; Zhao et al., 2011; Creamean et al., 2011; Yu et al., 2012; Chen et al., 2012). However, the extent to which amines are indeed participating in atmospheric nucleation is still not established. This lack of knowledge is to a large degree due to the difficulty of measuring amines in real-time at low pptv to sub-pptv mixing ratios. Mass spectrometric methods using chemical ionization (CIMS) have become available for amine measurements. These methods have sufficient time resolution and a low enough limit of detection for atmospherically relevant mixing ratios. Various amines were detected by positive-ion chemical ionization via ambient pressure proton transfer (Hanson et al., 2011; Freshour et al., 2014). Protonated ethanol or acetone ions were used as reagent ions by Yu and Lee (2012). Negative-ion detection of amines using bisulfate reagent ions has been described recently (Sipilä et al., 2015).

Here we describe the detection of gas phase DMA at sub-pptv levels at the CLOUD aerosol chamber at CERN by use of a nitrate Chemical Ionization-Atmospheric Pressure interface-Time Of Flight-Mass Spectrometer (CI-API-TOF-MS, Jokinen et al.,

2.2 Gas system and calculated DMA mixing ratios

A schematic drawing of the gas system and the CLOUD chamber is shown in Fig. 1. In order to have precise control over the amount of dimethylamine that is fed into the chamber a specially designed gas system has been implemented at CLOUD. The gas system for each individual trace gas includes three calibrated mass flow controllers (MFCs) and several valves for diluting a mixture from a gas bottle with clean air before it is fed into the chamber close to the lower mixing fan.

The amount of DMA introduced into the chamber can be calculated from the fraction B of DMA inside the gas bottle and the MFC flow rates (see Fig. 1). When the bypass valve is closed, which was the case at all times during CLOUD7 and CLOUD10-T, the following amount of DMA enters the chamber:

$$A_{\text{DMA}} = \frac{\text{MFC1} \cdot \text{MFC3}}{\text{MFC1} + \text{MFC2}} \cdot B. \quad (1)$$

The flow rates (denoted with MFC1, MFC2, and MFC3) have units of $\text{cm}^3 \text{s}^{-1}$ (at standard temperature and pressure, in this case 293.15 K and 1013 hPa), and the quantity A_{DMA} is the flow rate of DMA. The volume mixing ratio (VMR) of DMA (in pptv) inside the CLOUD chamber can be derived from the following differential equation:

$$\frac{d\text{VMR}_{\text{DMA}}}{dt} = \frac{A_{\text{DMA}}}{V_{\text{ch}}} \times 10^{12} \text{ pptv} - k_{\text{wall}} \cdot \text{VMR}_{\text{DMA}} - k_{\text{dil}} \cdot \text{VMR}_{\text{DMA}}. \quad (2)$$

Here, V_{ch} is the chamber volume ($2.61 \times 10^7 \text{ cm}^3$, where V_{ch} denotes a physical volume), k_{wall} is the wall loss rate constant for DMA and k_{dil} is the dilution rate constant. The dilution rate constant can be calculated from the ratio of the clean gas flow rate that is required to replenish the gas taken by the instruments and the chamber volume. In this study, the flow rate of air into the chamber is 160 L min^{-1} at standard temperature and pressure, which yields a dilution rate constant (assuming homogenous mixing) of $1 \times 10^{-4} \text{ s}^{-1}$. The wall loss rate is not known a priori but at this point it can be compared

Interactive Discussion

to the one for sulfuric acid which has been experimentally determined as $2.2 \times 10^{-3} \text{ s}^{-1}$. Assuming that the walls act as a perfect sink the wall loss rate can be assumed to be proportional to the square root of the gas-phase diffusion coefficient (Crump and Seinfeld, 1981) and should therefore be faster for DMA because it is a lighter molecule compared to sulfuric acid.

Assuming steady-state in Eq. (2) yields

$$\text{VMR}_{\text{DMA}} = \frac{A_{\text{DMA}} \times 10^{12} \text{ pptv}}{V_{\text{ch}} \cdot (k_{\text{wall}} + k_{\text{dil}})} = \frac{\text{MFC1} \cdot \text{MFC3}}{\text{MFC1} + \text{MFC2}} \cdot \frac{B \times 10^{12} \text{ pptv}}{V_{\text{ch}} \cdot (k_{\text{wall}} + k_{\text{dil}})} = \frac{F}{k_{\text{wall}} + k_{\text{dil}}}. \quad (3)$$

The factor F describes the addition of DMA to the chamber in units of pptv s^{-1} . The unknown quantity k_{wall} could in principle be derived from Eq. (3) by calibration experiments if a reference instrument for the measurement of DMA were used. Alternatively, the wall loss rate can be determined from the decay rate of the signal, which is indicating the DMA mixing ratio in this study (see Sect. 3.1).

It should be noted that the effect of DMA condensation on aerosol particles, which are formed during nucleation experiments, is not taken into account in Eqs. (2) and (3). For the data shown in this study, either no sulfuric acid was generated when the DMA calibration measurements (see Sect. 3.2) were performed, or the condensation sink was so low that it had no effect on the DMA mixing ratio.

The assumption that the DMA mixing ratio is at equilibrium inside the pipes once the chamber valve is opened, i.e. that wall loss is negligible for the DMA inlet lines, is justified due to the following reasons. First, the gas lines are conditioned over a duration of at least 24 h before DMA is added to the chamber for the first time. During this time the purge valve is open and the chamber valve is closed (Fig. 1). Only the last $\sim 23 \text{ cm}$ between the chamber valve and the point where the DMA enters the chamber are therefore not conditioned. Second, the mixing ratio of DMA inside the gas lines is generally higher than several tens of ppbv even though the DMA inside the chamber is in the pptv-range due to the strong dilution inside the chamber. The high DMA mixing ratio enables a rapid equilibration of the short unconditioned section of the gas lines.

2.3 CI-API-TOF instrument

The Chemical Ionization-Atmospheric Pressure interface-Time Of Flight (CI-API-TOF) mass spectrometer has been described recently (Jokinen et al., 2012; Kürten et al., 2014). The CI-API-TOF combines an atmospheric pressure chemical ionization source based on the design by Eisele and coworkers (Eisele and Tanner, 1993) and a high resolution atmospheric pressure interface time-of-flight mass spectrometer (Tofwerk AG, Switzerland). The ion source uses a corona discharge for the primary ion generation (Kürten et al., 2011). Nitrate ions ($\text{NO}_3^-(\text{HNO}_3)_x$, $x=0-3$) are generally used for the detection of sulfuric acid and sulfuric acid-amine clusters but more recently it was found that they also allow for the detection of extremely low volatile organic compounds (ELVOCs, see e.g. Ehn et al., 2014).

As will be described in the next section dimethylamine ($(\text{CH}_3)_2\text{NH}$, DMA) can mainly be detected at integer mass m/z 170 Th ($\text{NO}_3^-(\text{HNO}_3)(\text{DMA})$ ion) and m/z 233 Th ($\text{NO}_3^-(\text{HNO}_3)_2(\text{DMA})$ ion); however, the exact masses of these ion clusters are 170.0419 and 233.0375 Th due to their mass defect. Owing to the high mass resolving power ($\sim 4500 \text{ Th Th}^{-1}$) and the high mass accuracy (better than 10 ppm) of the CI-API-TOF these ions can be unambiguously identified in this study if additional information like the isotopic pattern is taken into account. Especially in field measurements, where a lot of unknown compounds are potentially present, the high mass resolving power allows distinguishing between different ion species having the same integer mass which minimizes potential interferences.

On the contrary to CLOUD10-T where the CI-API-TOF was connected to the chamber by its own sampling line in CLOUD7 the instrument was connected to the chamber with a y-splitter. Therefore, the sampling line losses cannot be easily calculated in the same way as for a straight tube and laminar flow. Instead, the effective length method (Karlsson and Martinsson, 2003) was used after comparing the sulfuric acid concentrations measured by a Chemical Ionization Mass Spectrometer (CIMS) and the CI-API-TOF simultaneously. Since the CIMS was connected to the CLOUD chamber

have chosen the $\text{NO}_3^-(\text{HNO}_3)_2$ ion as the reference because it seems likely that this produces more stable cluster ions compared to $\text{NO}_3^-(\text{HNO}_3)$ due to an efficient acid-base stabilization mechanism (1 : 1-ratio between acid and base if the NO_3^- is regarded as a Lewis base). In previous CLOUD studies a similar scheme has been observed for ion clusters involving sulfuric acid and ammonia or dimethylamine (see Kirkby et al., 2011; Almeida et al., 2013; Kürten et al., 2014; Bianchi et al., 2014). This leads to the following equation for the DMA concentration:

$$[\text{DMA}] = C \cdot T \cdot \ln \left(1 + \frac{\text{CR}_{170} + \text{CR}_{233}}{\text{CR}_{188}} \right) \approx C \cdot T \cdot \frac{\text{CR}_{170} + \text{CR}_{233}}{\text{CR}_{188}}. \quad (4)$$

The factor C (in molecule cm^{-3}) can be derived from calibration measurements using the CLOUD chamber. Generally DMA mixing ratios are reported rather than concentrations and therefore the calibration factor has a different unit than in Eq. (4). However, the derived calibration constant can be converted to molecule cm^{-3} (see Sect. 3.2). An additional factor T is required to take into account losses of DMA molecules in the Cl-API-TOF sampling line during the transport from the chamber to the instrument; the parameters CR_{170} , CR_{233} , and CR_{188} denote the count rates at the exact masses for the $\text{NO}_3^-(\text{HNO}_3)_{1,2}(\text{DMA})$ and the $\text{NO}_3^-(\text{HNO}_3)_2$ ions, respectively. The factor T has a value of ~ 2.5 for CLOUD10-T. During CLOUD7 the factor has a value of ~ 4 and was evaluated based on the effective length method mentioned in the previous section. For the evaluation of T it was assumed that the diffusivity of H_2SO_4 at 278 K and 38 % relative humidity equals $0.07 \text{ cm}^2 \text{ s}^{-1}$ (Hanson and Eisele, 2000), while a value of $0.10 \text{ cm}^2 \text{ s}^{-1}$ was assumed for DMA which follows when applying a power dependency of 1.75 for the diffusion coefficient regarding the temperature for a reported value (Freshour et al., 2014).

To our knowledge the existence of ion clusters containing amines and nitrate has been reported only once by Luts et al. (2011). They added diethylamine ($\text{CH}_3\text{CH}_2\text{NHCH}_2\text{CH}_3$, DEA) to ions created from ambient air and identified the cluster $\text{NO}_3^-(\text{HNO}_3)(\text{DEA})$ (m/z 198 Th). Additionally, signals at m/z 261 and m/z 334 Th

3.2 Sensitivity and linearity

Different flow rates of DMA were applied to the chamber during both CLOUD campaigns and for certain periods the DMA was completely shut-off. The periods when the chamber was flushed with clean air for extended times, can be used to determine the background signal for the $\text{NO}_3^- (\text{HNO}_3)_{1-3}$ (DMA) cluster ions. We believe that this background is caused by electronic noise, since no DMA was detected in the clusters for the nucleation experiments conducted during these periods (Kürten et al., 2014). Since the CI-APi-TOF uses the same clean gas as the CLOUD chamber for the sheath gas it is also unlikely that there is any source of DMA inside the instrument.

Figure 5 shows the time series of the normalized DMA signal (red line) during CLOUD7 and CLOUD10-T together with the calculated DMA mixing ratio (shaded area) according to Eq. (2). It can be seen in Fig. 5a that even at the lowest set point of ~ 2.2 pptv DMA the signal is significantly elevated compared to background conditions. Further increase of the DMA flow leads to correspondingly higher signals.

The data from Fig. 5 and from other periods (not shown) has been averaged over sufficiently long periods where a constant DMA mixing ratio was applied to the chamber. These averaged normalized signals are shown as a function of the calculated DMA mixing ratio in Fig. 4. A linear fit has been applied to the data from each calibration yielding a correlation coefficient close to 1 ($R^2 = 0.99$). This indicates that the applied methodology is well suited to quantify DMA at low mixing ratios in the pptv range.

The slopes of the calibration line from Fig. 4 are a measure of the sensitivity of the nitrate CI-APi-TOF towards DMA. After converting the mixing ratio of DMA into a concentration (1 pptv corresponds to 2.61×10^7 molecule cm^{-3} at 278 K and 1 bar), the calibration constant from Eq. (4) can be evaluated as $C = 1.48 \times 10^{11}$ molecule cm^{-3} for CLOUD7 and $C = 3.45 \times 10^{11}$ molecule cm^{-3} for CLOUD10-T from the slope of the individual linear fit. Compared to the calibration constant for sulfuric acid this value is about 1 to 1.5 orders of magnitude higher (Kürten et al., 2012; Kürten et al., 2014) and therefore indicates a lower sensitivity for DMA compared to sulfuric acid. One expla-

4 Conclusions

It is demonstrated that dimethylamine (DMA) can be detected at low mixing ratios using nitrate chemical ionization mass spectrometry. DMA is mainly detected in a cluster containing the nitrate ion plus additional nitric acid molecules ($\text{NO}_3^-(\text{HNO}_3)_{1-3}(\text{DMA})$).

5 Calibration of the CI-API-TOF used during the CLOUD7 and CLOUD10-T campaign indicates very good linearity in the range between 0 and ~ 120 pptv of DMA. The detection limit under ideal conditions at the CLOUD chamber was below 1 pptv for an integration time of 10 min at a temperature of 278 K and a relative humidity of 38%. While there are other techniques yielding similar or even better detection limits for
10 DMA (or amine measurements in general) the method introduced in this study has the benefit of not being restricted to amine measurements. Nitrate chemical ionization can be used at the same time and with the same instrument for highly-sensitive measurements of sulfuric acid and extremely low volatile organic compounds (ELVOCs). These compounds are thought to play an essential role in the formation of new particles. Being
15 capable of measuring DMA together with sulfuric acid and ELVOCs makes nitrate CI an even more versatile tool for studying NPF than previously thought.

Future studies will focus on the effect of temperature and RH regarding the sensitivity of nitrate CI towards DMA. Furthermore, the detection of other amines will be tested and the method will be deployed in field studies. For this an amine source providing
20 well-defined concentrations periodically to the CI-API-TOF would be desirable (see e.g. Freshour et al., 2014).

Acknowledgements. We thank CERN for supporting CLOUD with important technical and financial resources and provision of a particle beam from the proton synchrotron. This research received funding from the EC Seventh Framework Programme (Marie Curie Initial Training Network MC-ITN “CLOUD-TRAIN” no. 316662), the German Federal Ministry of Education and
25 Research (project no. 01LK1222A) as well as the Swiss National Science Foundation (project no. 200020_152907). We thank the tofTools team for providing tools for mass spectrometry analysis.

Detection of DMA in the low pptv range using a nitrate CIMS

M. Simon et al.

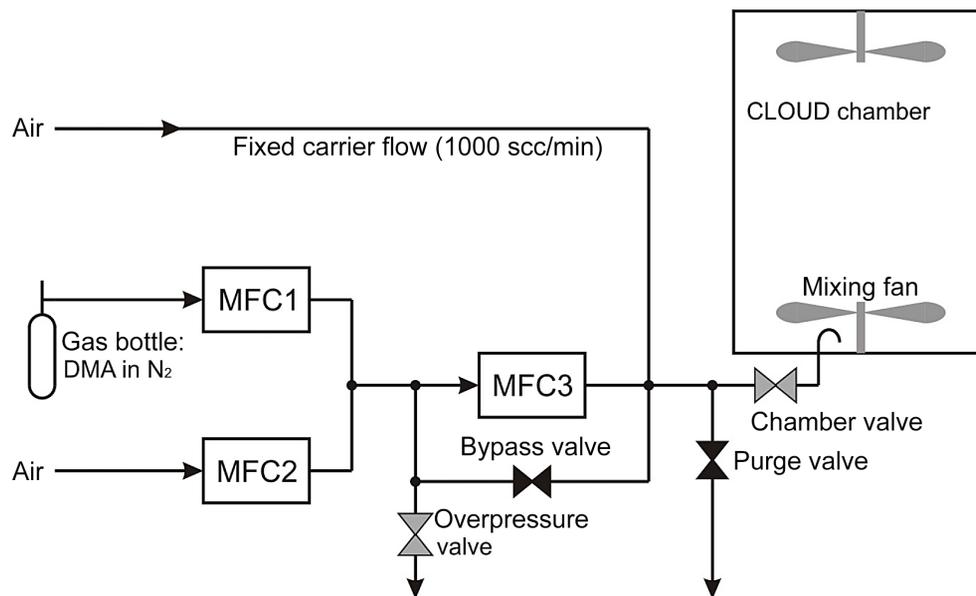

Figure 1. CLOUD chamber and gas system for delivering DMA to the chamber. Three mass flow controllers (MFC1 to MFC3) and several valves are used to control the flow rates. The figure indicates a setting where the bypass and the purge valve are closed while the other valves are open.

Detection of DMA in the low pptv range using a nitrate CIMS

M. Simon et al.

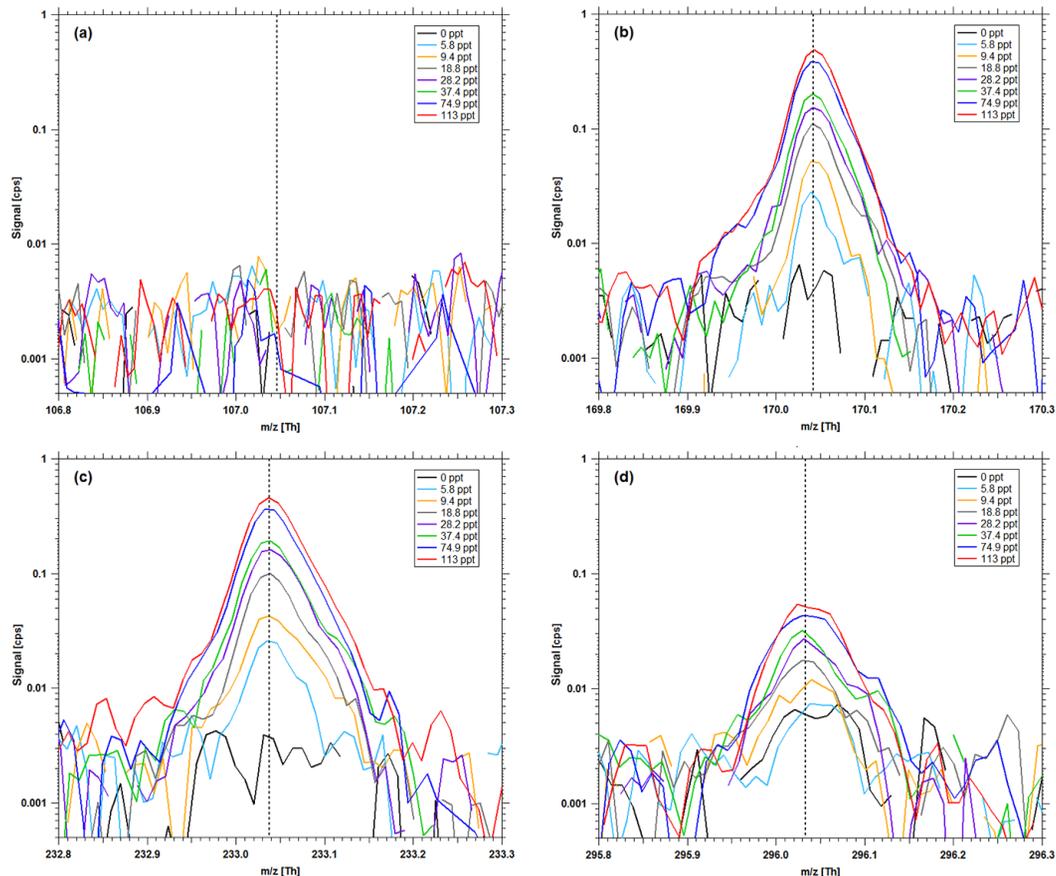

Figure 2. High resolution mass spectra for narrow ranges of m/z values corresponding to $\text{NO}_3^-(\text{HNO}_3)_{0-3}(\text{DMA})$ ions. The colors indicate different mixing ratios that were established in the CLOUD chamber during calibration measurements and the dashed vertical lines show the exact mass of the cluster ions.

Detection of DMA in the low pptv range using a nitrate CIMS

M. Simon et al.

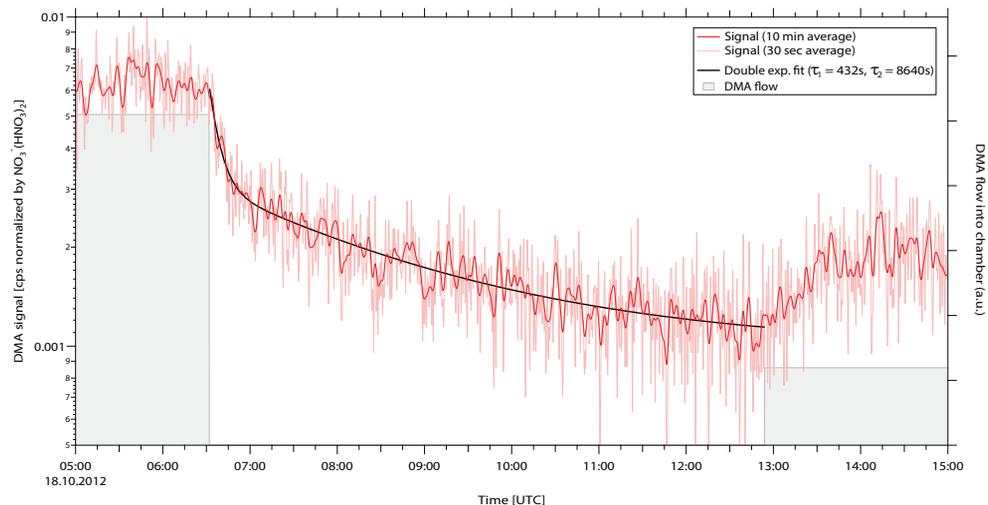

Figure 3. Decay of the normalized cluster ion signal indicating the DMA concentration with 10 min time resolution (red line) and 30 s time resolution (light red line). The DMA flow (grey line and area) into the chamber is shut-off at $\sim 06:32$ UTC and turned on again (at a lower setpoint) around $12:54$ UTC. Using a double-exponential fit (black line) the decaying signal can be well represented. The first inverse decay constant represents the wall loss rate ($1/\tau_1 = 2.3 \times 10^{-3} \text{ s}^{-1}$), while the second decay ($1/\tau_2 = 1.2 \times 10^{-4} \text{ s}^{-1}$) represents a source term due to slow re-evaporation of DMA from the chamber walls superimposed by dilution.

Interactive Discussion

Detection of DMA in the low pptv range using a nitrate CIMS

M. Simon et al.

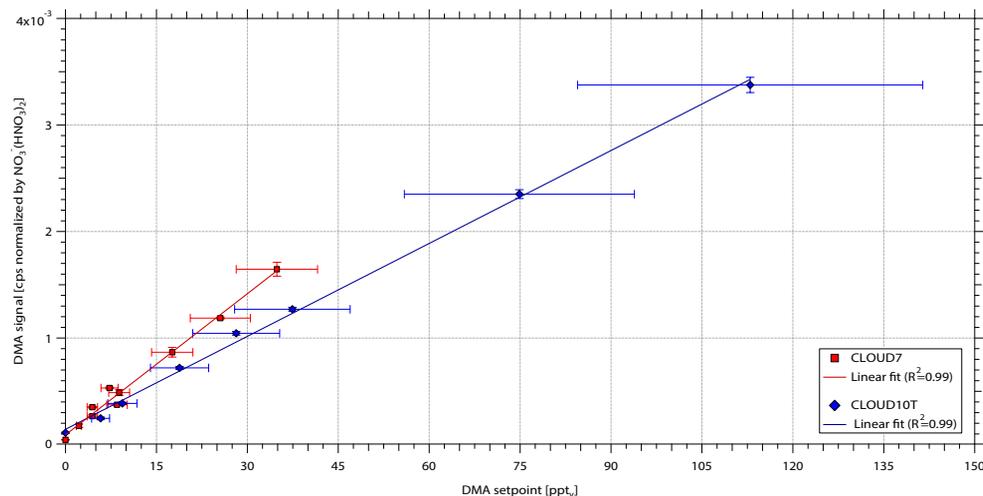

Figure 4. Calibration curves for the average DMA signals as a function of the DMA mixing ratio during CLOUD7 (red symbols) and CLOUD10-T (blue symbols). The linear fit for the CLOUD7 calibration follows the expression $y = 9.13 \times 10^{-5} + 4.41 \times 10^{-5} \text{ pptv}^{-1} \times x$. The expression for the linear fit of the CLOUD10-T (blue) calibration follows $y = 14.35 \times 10^{-5} + 2.91 \times 10^{-5} \text{ pptv}^{-1} \times x$. Error bars for the DMA setpoint values are based on a $\pm 10\%$ uncertainty for each of the MFC flow rate settings and the standard deviation of the fit parameter for k_{wall} . The errors for the measured DMA signals are based on the standard deviation of the mean.

Detection of DMA in the low pptv range using a nitrate CIMS

M. Simon et al.

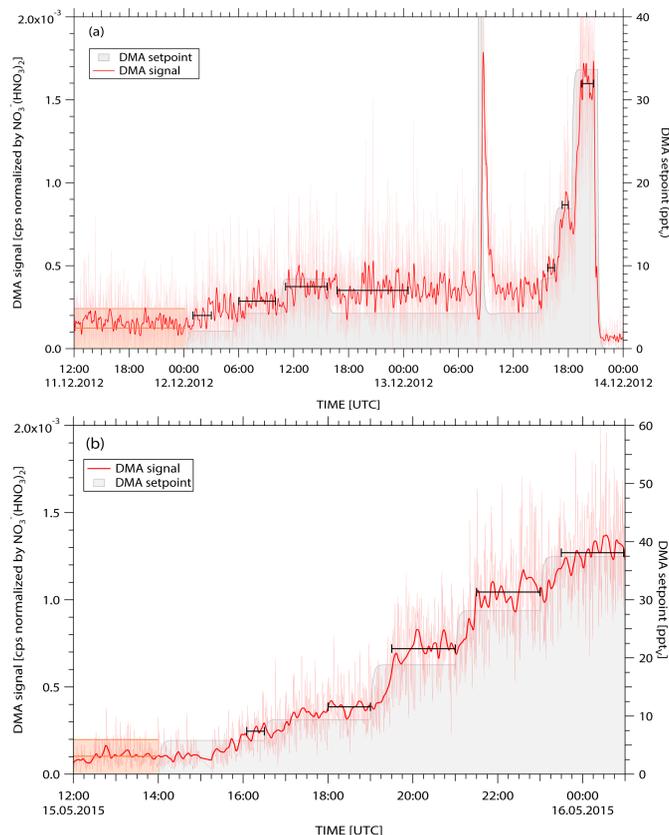

Figure 5. Time series of the normalized cluster ion signal indicating the DMA concentration with 10 min resolution (red lines) and 30 s time resolution (light red line) during the CLOUD7 **(a)** and CLOUD10-T **(b)** calibration. The grey lines and areas indicate the targeted DMA mixing ratios due to the MFC setting for the gas system. The average background signals including the 3σ -standard deviation are shown by the horizontal orange lines and the light orange bands. The black lines illustrate the averaged periods.
