# 1 **A Novel Approach for the Extraction of Cloud Motion Vectors Using Airglow**

## 2 **Imager Measurements**

3 **S. Satheesh Kumar, T. Narayana Rao\* and Alok Taori**

4 *National Atmospheric Research Laboratory (NARL), Gadanki, India*

### 5 **Abstract**

6         The paper explores the possibility of implementing an advanced photogrammetric  
7 technique, generally employed for satellite measurements, on airglow imager, a ground-based  
8 remote sensing instrument primarily used for upper atmospheric studies, measurements of clouds  
9 for the extraction of cloud motion vectors (CMVs). The major steps involved in the algorithm  
10 remain the same, including image processing for better visualization of target elements and noise  
11 removal, identification of target cloud, setting a proper search window for target cloud tracking,  
12 estimation of cloud height, and employing 2-D cross-correlation to estimate the CMVs.  
13 Nevertheless, the implementation strategy at each step differs from that of satellite, mainly to suit  
14 airglow imager measurements. For instance, climatology of horizontal winds at the measured site  
15 has been used to fix the search window for target cloud tracking. The cloud height is estimated  
16 very accurately, as required by the algorithm, using simultaneous collocated Lidar measurements.  
17 High-resolution, both in space and time (4 minutes), cloud imageries are employed to minimize the  
18 errors in retrieved CMVs. The derived winds are evaluated against MST radar-derived winds by  
19 considering it as a reference. A very good correspondence is seen between these two wind  
20 measurements, both showing similar wind variation. The agreement is also found to be good in  
21 both the zonal and meridional wind velocities with RMSEs  $< 2.4 \text{ m s}^{-1}$ . At the end, the strengths  
22 and limitations of the algorithm are discussed, with possible solutions, wherever required.

23

24 **Key words:** *Airglow imager, Photogrammetry, 2-D Cross-correlation, Cloud Motion Vectors*

## 1 **1 Introduction**

2           Clouds play a vital role in the Earth's hydrological cycle and also as 'atmospheric blankets'  
3 because of their shortwave scattering and longwave absorption of radiation. It is, therefore, highly  
4 essential to monitor the clouds and their motion on a continuous basis, which is being done  
5 primarily by geostationary meteorological satellites (Leese et al., 1971; Hutchison et al., 1995;  
6 Jolivet and Feijt, 2003; Glantz, 2010; Escrig et al., 2013). The capability of continuous monitoring  
7 of clouds by these satellites has been utilized to retrieve the cloud motion vectors (CMVs), by  
8 considering clouds as tracers of wind. Satellite-derived CMVs are extremely helpful in  
9 understanding synoptic-scale atmospheric dynamics and circulations and now have become  
10 potential input parameters to numerical weather prediction models (Menzel, 2001; Thies and Jörg  
11 Bendix, 2011 and references therein).

12           There is a tremendous progress in retrieval techniques for CMVs and their utilization for  
13 operational usage in the last few decades. The retrieval techniques improved from a simple cross  
14 correlation analysis in the beginning (Fujita, 1968; Izawa and Fujita, 1969; Leese et al., 1971;  
15 Hubert and Whitney, 1971) to those involving very advanced photogrammetry and satellite  
16 imagery analysis in recent times for obtaining CMVs with higher precision (Schmetz et al., 1993;  
17 Velden et al., 1997; Kishtawal et al., 2009; Deb et al., 2013; Kaur et al., 2014 and references  
18 therein). First level unrefined knowledge about a cloud element can be obtained from the cloud top  
19 temperatures, retrieved by Thermal infrared (IR) channel. This is the most commonly used means  
20 for CMV estimation, even to this day. However, tracking of low-level clouds ( $> 700$  hPa) will be  
21 difficult with IR measurements, because the low cloud top apparent temperature becomes so close  
22 to the surface temperature that the images lack contrast between the cloud and ground levels. Also,  
23 the geostationary satellites observe only cloud tops and, therefore, may not be able to detect the  
24 multilayered clouds, i.e., for instance a low-level cloud located beneath a high-level cloud.

1           In this regard, ground-based instrumentation with a large field of view would augment  
2 satellite cloud observations (Seiz et al., 2002; Pfister et al., 2003; Souza-Echer et al., 2006; Smith  
3 and Toumi, 2008; Liu et al., 2013, Klebe et al., 2014). Such augmentation improves vertical  
4 distribution of clouds, albeit at the measurement locations. These sky-imaging devices (eg.,  
5 Whole-sky imager, Total-sky imager, All-sky imager, etc.) are automatized to achieve real-time  
6 hemispheric sky images and cloud fraction (Long et al., 2006; Yang et al., 2012; Kazantzidis et al.,  
7 2012).

8           Among these imagers, the airglow imager is designed primarily for monitoring emissions  
9 from the Mesosphere and Lower Thermosphere (MLT) with good spatial and temporal resolutions.  
10 The invent of commercial solid state imaging arrays in the eighties revolutionized airglow imaging  
11 observations and in resolving many technical issues in the image processing, such as long-lasting  
12 bands, transient short scale ripples, superimposed transversely propagating waves, airglow  
13 depletions (Taylor et al., 1995; Batista et al., 2000) and MLT dynamics, such as mesospheric wave  
14 signatures and gravity wave seeding of equatorial plasma bubbles (Taori et al.,2013 and references  
15 therein). Since, it is an optical device; the measurements are confined only to clear-sky and new  
16 moon periods. Nevertheless, its capability to observe clouds on a continuous basis provides an  
17 opportunity to derive the CMVs.

18           The main aim of the present article is to demonstrate the capability of an air-glow imager,  
19 developed recently at National Atmospheric Research Laboratory, Gadanki (13.45° N, 79.18° E),  
20 for deriving the CMV's, thereby extending its utilization to the lower atmosphere. In this article,  
21 an attempt has been made to adopt the advanced photogrammetry, image processing techniques  
22 and satellite CMV retrieval algorithms and implement on ground-based optical imager  
23 measurements to obtain the CMVs. The paper includes 6 sections, describing the instrumentation  
24 and database (Sect. 2), study region (Sect. 3), the algorithm and its implementation on a case study

1 (Sect. 4) and validation of the technique (Sect. 5). The strengths and limitations of the technique  
2 employed here are also discussed in Sect. 5. The results are summarized in Sect. 6.

### 3 **2 Instrumentation and Database**

4 The cloud imageries used in the present study are obtained from an airglow imager located  
5 at Gadanki. The imager uses a circular medium format F/4 Mamiya fish eye lens having a focal  
6 length of 24 mm. At peak wavelengths of 558 and 630 nm, it measures mesospheric O(<sup>1</sup>S) and  
7 thermospheric O(<sup>1</sup>D) emissions, respectively, while a wideband 800 – 900 nm filter for  
8 mesospheric OH\* emission. For observing clouds, OH\*OH filter is employed due to its high  
9 sensitivity in near infrared region. The exposure time for various filters is dependent on the  
10 compromise among the background luminosity, interference filter transmission and actual airglow  
11 brightness. At present, exposure time for OH\*OH filter is 16 seconds, however, as the time  
12 integration for O(<sup>1</sup>S) and O(<sup>1</sup>D) is 110 seconds each, the cadence time for capturing the OH\*OH  
13 (i.e., cloud images) is 4 min. These optical emissions are collimated through a series of Plano-  
14 convex lens and are passed through temperature controlled interference filters. The filtered rays are  
15 converged on the Charge-coupled device (CCD) detector which is a back illuminated CCD chip  
16 with 1024 x 1024 square pixels of 13.3 μm size, 100% fill factor and 16 bit depth. The intensity  
17 images thus captured are subjected to a 2 x 2 pixel binning for making an effective 512 x 512  
18 super-pixels image with enhanced signal-to-noise ratio (SNR). The final images are stored in  
19 portable network graphical mode (PNG format). More technical details of the imager can be found  
20 in Taori et al. (2013).

21 The cloud observational data by airglow imager are augmented with a variety of other  
22 datasets, like a Rayleigh-Mie Lidar (RML) and Boundary Layer Lidar (BLL) for obtaining the  
23 height of the cloud, Global Positioning System (GPS) radiosonde-derived winds for building the  
24 wind climatology for the study region, and Mesosphere-Stratosphere-Troposphere (MST) radar-

1 derived winds for validating the derived CMVs. The Rayleigh-Mie Lidar has been in operation  
2 since 1998 at NARL and is extensively used for understanding cirrus clouds and mesospheric  
3 dynamics (Raghunath et al., 2000; Sivakumar et al., 2001). It is a monostatic biaxial system which  
4 uses [Neodymium: Yttrium Aluminium Garnet \(Nd:YAG\)](#) laser as light source and two telescopes  
5 (35 and 70 cm diameter telescopes for Mie and Rayleigh backscatter returns, respectively) as  
6 receivers. The transmitter part consists of laser source at the second harmonic of 532 nm with a  
7 maximum energy of about 550 mJ per pulse. The laser operates at a temporal resolution of ~1 min.  
8 Datasets originated from micro-pulsed Boundary Layer Lidar are also considered to fill the  
9 measurement gaps during the analysis period (Bhavanikumar et al., 2006).

10 For building the climatology of winds for the study region, 6 years (2007-2012) of GPS  
11 radiosonde measurements (Vaisälä RS-80, RS-92 and Meisei RS-01GII) at ~1200 [Universal Time](#)  
12 [\(UT\)](#) (1730 [Indian Standard Time \(IST\)](#)) are used. While developing the climatology, several  
13 quality checks have been done on the data to remove spurious outliers, if any exist, following  
14 Tsuda et al. (2006). First, the median and standard deviation (SD) of winds for each season are  
15 generated. Each profile in this season is then checked for seasonal consistency, i.e., whether or not  
16 it falls within 1 SD of median profile. Profiles that are consistent with the seasonal pattern (i.e.,  
17 those satisfy the above condition) are only considered further for developing the climatology of  
18 zonal and meridional winds.

19 The MST radar at Gadanki is a highly sensitive pulse-coded coherent VHF phased array  
20 radar, operating at 53 MHz with a peak power aperture product of  $3 \times 10^{10} \text{ Wm}^2$ . Complete technical  
21 and system specifications of the MST radar are given in Rao et al. (1995). The routine operation  
22 of MST radar for troposphere employs 6 beams for obtaining winds and turbulence parameters at 4  
23 min. and 150 m temporal and vertical resolutions, respectively. Important specifications of MST  
24 radar and different types of Lidars are given in Table 1.

1            Though the above remote sensing instruments are in operation for more than a year, but  
2 simultaneous measurements of all instruments are available only for few days (7 days) for the  
3 following reasons. During the rain, it is not possible to operate both airglow imager and Lidar. The  
4 laser beam cannot penetrate the low-level thick clouds and therefore is generally switched off  
5 whenever the low cloud persists. On many days, these instruments are in operation for some other  
6 experiment in a different mode. For instance, the airglow imager is in operation for MLT studies or  
7 MST radar is in operation for ionosphere or convection studies. Since the present article mainly  
8 aims to demonstrate the applicability of a satellite technique to a ground-based remote sensing  
9 device for deriving CMVs, the number of existing cases (7 days) is sufficient.

### 10 **3 Study region and background meteorology**

11            Gadanki (~375 m above the mean sea level) is located in a remote tropical environment in  
12 southern peninsular India, at about 90 km away from the East Coast (Fig. 1). It is located in a  
13 complex hilly terrain with hill heights varying in the range of 300-1000 m. This region receives  
14 rainfall from two major monsoon seasons, namely southwest monsoon (June-September) and  
15 northeast monsoon (October-December), besides premonsoon/summer (March-May)  
16 thunderstorms (Rao et al., 2009). Nevertheless, it receives an annual rainfall of only ~750 mm, as  
17 it is in the rain shadow region (east of Western Ghats). But different types of clouds, originated  
18 from a variety of processes, pass over this location frequently (Gadanki is covered with clouds for  
19 about 60-70% of time) (Fig. 1).

20            Since a priori climatological wind information minimizes the error in retrieved CMVs,  
21 wind climatology is built from 6 years of GPS radiosonde observations. Figure 2 shows vertical  
22 profiles of mean zonal and meridional winds (solid line) along with standard deviation (error bars)  
23 and maximum and minimum (dash-dot lines) winds within the season. Clearly, strongest winds  
24 (predominantly easterlies) are observed during the main rainy season for this region, southwest

1 monsoon, in the upper troposphere. These strong winds, popularly known as Tropical Easterly Jet  
2 (TEJ), with a peak at 16 km are an integral part of monsoon circulation. The predominant  
3 occurrence of cirrus during the monsoon season is ascribed partly to TEJ, which sweeps the cirrus  
4 from neighbouring deepest convective regions and spreads over the entire peninsular India (Das et  
5 al., 2011). Although the mean zonal wind is small in other seasons, often it exceeds  $15 \text{ m s}^{-1}$  during  
6 the winter and early summer, mainly due to the intensification of upper tropospheric subtropical  
7 troughs. The meridional winds are generally weak with monthly mean values  $< 5 \text{ m s}^{-1}$ . The  
8 monthly mean meridional velocities show southerlies in the middle and upper troposphere in all  
9 seasons, except for the monsoon. From the range of wind variation (minimum to maximum winds)  
10 and the standard deviation, it is clear that the winds are steady and strong during the monsoon  
11 season. On the other hand, the winds vary considerably in other seasons, even they change the  
12 direction.

#### 13 **4 Description of the algorithm and its application on a case study (17 April 2012)**

14 This section describes the method adopted for the retrieval of cloud motion with the help of  
15 airglow imager data collected on 17 April 2012. In fact, a variety of retrieval techniques for CMVs  
16 using satellite brightness temperatures (from thermal satellite imagery) are now available  
17 (Kishtawal et al., 2009; Deb et al., 2013; Kaur et al., 2014 and references therein). The present  
18 algorithm adopts one such retrieval technique for the estimation of CMVs and modifies it to suit  
19 airglow imager observations. In the following subsections, the major processing steps involved in  
20 the algorithm are discussed in detail.

- 21 i) Image processing to remove the noise, enhancing the image and identifying the target cloud
- 22 ii) Estimation of cloud height and pixel width
- 23 iii) Estimation of cloud movement using a cross-correlation technique and CMVs.

24 Figures 3-5 show the output of each of the above processing steps.

## 1 **4.1 Image processing and target cloud identification**

2           The first and most important step of the algorithm is to process the image for better  
3 identification of the target cloud. The image processing involves correction of coordinates,  
4 removal of noisy structures (like stars), improving the image contrast for better visualization of  
5 target elements (clouds in our case) (Fig. 3). The original 512 x 512 pixel images are cropped to  
6 256 x 256 pixels to remove the pixels that are affected by the housing of the airglow imager (Taori  
7 et al., 2013) (Fig. 3b). The cropped image corresponds to 90° circular field of view. During the  
8 measurements, the boundaries of the instrument roof were marked by the directions identified by  
9 the magnetic compass, which appears to be reversed along N-S directions in the raw images.  
10 Hence the cropped images are flipped vertically so as to correct for geographical coordinates. We  
11 enhanced the image contrast by using Gray-Level Histogram method (Otsu, 1979). This involves  
12 mapping the intensity values on gray scale image to new values such that 1% of data is saturated at  
13 low and high intensities of the image. This increases the contrast of the output image (Fig. 3c).  
14 The appearance of stars and other galactic objects in the image caps the cloud structures and  
15 decreases the image SNR. These ‘noisy’ structures need to be removed before identifying the  
16 target cloud(s) in the image. These bright objects (stars and clouds) are detected using an edge  
17 detection technique.

18           Edge detection is one of the very basic concepts used for image processing to identify the  
19 target elements. The edge detection techniques are basically of two types; gradient-based and  
20 Laplacian- based techniques (Argyle, 1971; Grimson and Hildreth, 1985; Torre and Poggio, 1986;  
21 Canny, 1986). While the former detects the edges from the gradient (first derivative) of pixel  
22 intensities, the later detects edges from zero crossings in the second-order derivative of pixel  
23 intensities. Canny edge-detection method (Canny, 1986), which follows the gradient method with  
24 the following optimization criteria, has been used in the present study.

- 1        1) Minimizing the incorrect marking of non-existing edge points and missing the real edge  
2            points, i.e., Good detection or low error rate.
- 3        2) The distance between the detected and the actual edge pixels should be minimized, i.e.,  
4            good localization.

5            To avoid small statistical fluctuations in pixel intensities being detected as target elements  
6 or noisy structures, the image is smoothed using the Gaussian smoothing filter. The algorithm then  
7 estimates the spatial derivative of pixel intensities and this gradient matrix is subjected to  
8 hysteresis analysis to identify the edges. Hysteresis uses two thresholds, a high and a low. Any  
9 pixel in the gradient matrix that has a value greater (lower) than high (low) threshold is identified  
10 as (not) an edge pixel. The pixel is also treated as an edge pixel, if it has a value between the two  
11 thresholds and is connected to an edge pixel. Later contiguous edge pixels are connected to  
12 generate contours of target objects (clouds, stars, etc.) with high intensities overlaid on the  
13 background of low intensities (Fig. 3d).

14            Since stars and other noisy structures appear as small objects in Fig. 3c, they can be  
15 removed by imposing a threshold for number of pixels. In the present study, the contours of large  
16 gradient (or simply target objects) having pixels less than 1000 are considered as noisy structures  
17 or stars and are removed for further analysis (Fig. 3e). The above threshold is not arbitrary, rather  
18 chosen by examining several images. The target cloud is then identified from the cleaned image  
19 (after the removal of noisy structures). In the present study, the target cloud is identified as the  
20 cloud that is having highest gradient value and number of pixels (Borde and García-Pereda, 2014)  
21 and at the same time should be isolated and persists for some time (at least in the next image).  
22 Further, priority is given to that cloud (if more than one cloud satisfies the above criteria) which is  
23 at the center of the image. This condition is important because the cloud height is later estimated

1 from Lidar measurements made at Gadanki. The center of the image in geometric coordinates  
2 roughly corresponds to the location of Gadanki.

3

#### 4 **4.2 Estimation of cloud height and pixel width**

5 Estimation of cloud base height is an important step in the extraction of CMVs for two  
6 reasons, i) the pixel width and thereby the distance travelled by the cloud is estimated from the  
7 height of cloud base and ii) the estimated CMV is assigned to this height. Any error in the  
8 estimation of cloud base height will lead to significant errors in both pixel width and velocity of  
9 cloud (Park et al., 2012; Borde and García-Pereda, 2014 and references therein). Since height  
10 information is very crucial, a Lidar, which provides the cloud information at a resolution of 30 m,  
11 is employed in the present study. The photon counts are range corrected and the height of their  
12 maximum positive vertical gradient (above 5 km) is identified in each profile and is treated as the  
13 cloud base height (CBH). The threshold of 5 km is chosen to avoid confusion caused by the  
14 gradients due to aerosol layers. The CBH identified from successive vertical profiles of photon  
15 counts are examined for their continuity. In other words, the successive CBH measurements should  
16 not vary by more than 300 m. Figure 4a shows the temporal variation of CBH retrieved from the  
17 photon counts of boundary layer Lidar during 21:40 – 22:04 IST. Once the height of cloud is  
18 known, the estimation of pixel width is simple. Since the angle subtended by the cropped image at  
19 the location of measurement is 90°, the pixel width at different altitudes can be estimated by a  
20 simple mathematical relation,

$$21 \quad \text{Pixel width} = R \cdot \tan (45)/128,$$

22 where  $R$  is the height of cloud base. The vertical variation of pixel width estimated from the above  
23 relation is shown in Fig. 4b. The images need to be unwrapped to convert angular scales into linear  
24 scales for estimating the pixel width (in m). To estimate the lens curvature effects, an experiment

1 has been carried out, in which grids with known scale sizes were imaged. Within 90° field of view  
2 (out of full field of view), the scale of pixel size increases from 1 at the centre to 1.036 at the edges  
3 (Sivakandan et al., 2015). It is in good agreement with Kubota et al. (2001), who shown that the  
4 maximum effect arising from lens curvature and Van-Rhijn factor is < 0.9.

### 5 **4.3 Tracking the target cloud and the estimation of CMV**

6 Tracking the target cloud is very essential for the estimation of CMV. Three factors are  
7 crucial in tracking the target cloud and dictate the accuracy of CMV: search window, temporal  
8 resolution between the images and identification of the same cloud in successive images. To  
9 reduce the computational load and to avoid other clouds or noisy structures, if any remain, entering  
10 into the area of interest; it is a common practice to track the target cloud in a smaller search  
11 domain in successive images. While the large target window allows other unwanted noisy  
12 structures enter into the search domain, too small window increases false alarms (Bresky et al.  
13 2012). Conventionally, wind guess (WG) information supplements this exercise and to set the  
14 coordinates of smaller windows in the later image before matching (Velden et al., 1997; Bedka and  
15 Mecikalski, 2005; Bresky et al., 2012). In the present study, the horizontal wind climatology  
16 discussed in Sect. 3 is used to set the search window. The spatial search window is fixed based on  
17 the maximum wind speed (at the cloud height) obtained from wind climatology and the time  
18 interval between the successive images. For instance, the cloud would move 2.4 km in the  
19 presence of 10 m s<sup>-1</sup> wind speed in 4 min. Therefore, a search window length of 30 pixels is  
20 required, if the target cloud is at 10 km altitude. The time interval between successive images has  
21 a significant impact on the quality of the derived CMVs. Though satellites generally use 30 min.  
22 intervals to derive the CMVs, earlier studies have shown that a temporal gap of 5 min for 1 km  
23 pixel size would produce largest number of valid motion vectors (Garcia-Pereda and Borde 2014).  
24 The time interval between the successive images in the present study is 4 min, which is nearly

1 equal to the optimum time gap suggested by ~~earlier reports~~ [Garcia-Pereda and Borde \(2014\)](#).  
2 Identification of the same target cloud in successive images is very important. Since the air-glow  
3 imager is a vertically up-looking system with a limited field of view ( $90^\circ$ ), there is possibility that  
4 it identifies two different clouds in successive images (for example, a low cloud can suddenly  
5 mask a high cloud). It is therefore required to use a proper pattern recognition method to estimate  
6 the cloud motion. In the present study 2D cross correlation method is employed for this purpose.  
7 The images were discarded if the correlation coefficient obtained from the cross-correlation of two  
8 successive images is  $< 0.5$ .

9         Figure 5 shows a typical example of identified target cloud in 4 successive images on 17  
10 April 2012. The target cloud imageries are cross-correlated to obtain the lag/lead at the maximum  
11 correlation. Though it is possible to obtain the lag/lead information from two successive images, it  
12 may be worthwhile, wherever possible, to consider many such correlation pairs for consistency  
13 (Deb et al., 2013). Figure 6 depicts time sequence of normalized cross-correlated images. From  
14 these images, the lag/lead of the maximum correlation pixel in both east-west (x-axis) and north-  
15 south (y-axis) planes is identified. The distance travelled by the cloud in x and y directions is  
16 estimated from the number of pixels displaced from 0 and pixel width, which is obtained from  
17 Lidar-CBH (Fig. 4). The zonal and meridional velocities are then estimated simply by dividing the  
18 distance travelled in x and y planes, respectively, with time interval between the successive images  
19 (4 min. in our case). During the observational period of 20 min, the CBH is found to be nearly  
20 constant (variations are within 300 m), whereas the zonal and meridional wind velocities varied  
21 from  $1.49$  to  $3.71 \text{ ms}^{-1}$  and from  $-0.89$  to  $-4.86 \text{ ms}^{-1}$ , respectively. The velocity resolution of the  
22 wind vector derived with this method depends on the accuracy with which one derives the  
23 displacement of the cloud. Since it depends on the height-dependent pixel width (Fig. 4b), the

1 velocity resolution also varies with height. For instance, the resolution varies from  $0.16 \text{ ms}^{-1}$  at 5  
2 km to  $0.32 \text{ ms}^{-1}$  at 10 km.

### 3 **5 Discussion**

4 It is important and necessary to evaluate the performance of any new algorithm or  
5 technique or instrument as it gives credibility to the final product. A similar exercise has been  
6 done, in which CMVs derived from all the cases were compared against a reference. In the present  
7 study, MST radar-derived winds measured simultaneously are taken as a standard reference for  
8 comparison. Figure 7 shows the comparison of zonal and meridional winds as derived by both air-  
9 glow imager (CMVs) and MST radar. Clearly, the airglow imager-derived winds show good  
10 correspondence with radar-derived winds in both zonal and meridional components with similar  
11 variations. Even the wind magnitude matches well between the two datasets with root mean  
12 square error (RMSE) values  $< 2.25 \text{ ms}^{-1}$ . The agreement is much better in the zonal component  
13 (RMSE is 1.60) than in meridional (RMSE is 2.24). It appears from Fig. 7 that there is no bias in  
14 airglow imager-derived winds and the difference between the wind estimates is due to statistical  
15 error.

16 Although the performance of the algorithm is fairly good and the technique is having  
17 several advantages (like better temporal resolution, pixel resolution, etc.), but it also suffers with  
18 the following drawbacks. i) Since the airglow imager is an optical instrument, observations are  
19 limited to non-rainy days. ii) Though the imager detects the target cloud and tracks it, but it will  
20 not be able to estimate the height of the target cloud. As discussed above, CBH information is  
21 crucial not only for assigning the derived winds to that height, but also to estimate the pixel width  
22 (Fig. 4b) and thereby the cloud displacement for CMV estimation. Though we used a Lidar for  
23 obtaining CBH as those measurements are readily available, it is a costly proposition. A ceilometer  
24 would suffice the purpose. iii) The limited field of view imposes a limit on the applicability of the

1 algorithm to certain clouds. Since the algorithm needs isolated clouds for tracking, the clouds with  
2 dimensions much less than the field of view of the imager can only be used as target clouds. iv) As  
3 the cloud is not a frozen body but an evolving system, the cloud boundaries do change with time.  
4 Since the time interval between two successive images is only 4 min, the changes may not be  
5 significant and ignored. But during a period of few 10's of minutes, the periods typically used in  
6 satellite retrievals of CMVs, the cloud appearance can change significantly (Fig. 5). It reiterates  
7 the requirement of small interval between the successive images and proper selection of target  
8 cloud (rapidly evolving clouds should not be considered as target clouds) for better extraction of  
9 CMVs.

10

## 11 **6 Summary**

12 The present study utilizes the 865 nm channel of the airglow imager to take high-resolution  
13 images of clouds. These bi-products of airglow imager have been used to estimate CMVs by  
14 adopting advanced satellite retrieval algorithms and implementing them, after suitable  
15 modifications, on airglow imager-derived cloud imageries. The present article describes an  
16 algorithm and implementation steps adopted while deriving the CMVs. The images are first  
17 processed with advanced image processing tools and later detected the target cloud within the  
18 image. Climatological wind profiles developed from GPS radiosonde data have been utilized for  
19 fixing a proper search window to minimize the errors. The tracking of target cloud from sequential  
20 images has been done by subjecting 2-D cross-correlation on the successive images. The  
21 displacement of cloud due to the horizontal wind in both east-west and north-south planes is  
22 identified from the lead/lag position of maximum correlation. To convert the cloud displacement  
23 from number of pixels to distance and to assign the derived winds to a height, accurate estimation  
24 of cloud height is essential. High-resolution measurements of collocated Lidar were used for this

1 purpose. The derived winds are then evaluated against a reference (MST radar-derived winds in  
2 the present study). Good correspondence is seen between the two measurements of wind (airglow  
3 imager and MST radar), as both of them show similar variation. The magnitude of wind also  
4 matches well with the reference wind (obtained by the MST radar) with a small RMSE ( $<2.4 \text{ ms}^{-1}$ ).  
5 The strengths and limitations of the algorithm are highlighted with possible solutions, wherever  
6 required.

7
