Abstract.

Oxidation flow reactors that use low-pressure mercury lamps to produce hydroxyl (OH) radicals are an emerging technique for studying the oxidative aging of organic aerosols. Here, ozone (O_3) is photolyzed at 254 nm to produce $O(^1D)$ radicals, which react with water vapor to produce OH. However, the need to use parts-per-million levels of O_3 hinders the ability of oxidation flow reactors to simulate NO_x-dependent SOA formation pathways. Simple addition of nitric oxide (NO) results in fast conversion of NO_x (NO + NO_2) to nitric acid (HNO_3), making it impossible to sustain NO_x at levels that are sufficient to compete with hydroperoxy (HO_2) radicals as a sink for organic peroxy (RO_2) radicals. We developed a new method that is well suited to the characterization of NO_x-dependent SOA formation pathways in oxidation flow reactors. NO and NO_2 are produced via the reaction $O(^1D) + N_2O \rightarrow 2NO$, followed by the reaction $NO + O_3 \rightarrow NO_2 + O_2$. Laboratory measurements coupled with photochemical model simulations suggest that $O(^1D) + N_2O$ reactions can be used to systematically vary the relative branching ratio of RO_2 + NO reactions relative to $RO_2 + HO_2$ and/or $RO_2 + RO_2$ reactions over a range of conditions relevant to atmospheric SOA formation. We demonstrate proof of concept using high-resolution time-of-flight chemical ionization mass spectrometer (HR-ToF-CIMS) measurements with nitrate (NO_3^-) reagent ion to detect gas-phase oxidation products of isoprene and α-pinene previously observed in NO_x-influenced environments and in laboratory chamber experiments.

1 Introduction

Recent atmospheric observations supported by experimental and theoretical studies show that highly oxygenated, extremely low-volatility organic compounds (ELVOC), together with sulfuric acid, are involved in the initial nucleation steps leading to new particle formation (NPF) (Donahue et al., 2013; Riccobono et al., 2014). ELVOC form rapidly in the gas phase via

Atmospheric Measurement Techniques Discussions

auto-oxidation processes (Crounse et al., 2013; Rissanen et al., 2014) and tend to condense irreversibly (Ehn et al., 2014). Following NPF, semivolatile organic compounds (SVOC) with higher vapor pressures condense on newly formed aerosols at rates influenced by their volatility (Donahue et al., 2012), ultimately driving nanoparticle growth towards formation of cloud condensation nuclei (CCN) (Pierce et al., 2012; Riipinen et al., 2012). NPF events may produce as much as 50% of global CCN (Merikanto et al., 2009; Yu and Luo, 2009). However, mechanisms that govern the formation of specific ELVOCs and condensation of SVOCs in various source regions are largely unknown.

The extent to which NPF and growth is influenced by natural and anthropogenic emissions separately and together, is still unknown. In some locations, biogenic SOA formation is enhanced by anthropogenic carbonaceous aerosol particles, SO_x and/or NO_x (Carlton et al., 2010; Shilling et al., 2013; Xu et al., 2015). At the moment, one can only speculate about some of the possible synergistic or antagonistic chemical mechanisms regulating these processes. For example, anthropogenic emissions can enhance biogenic SOA formation by providing seed particles for condensable biogenic vapors. On the other hand, isoprene can slow down the formation of SOA from other volatile organics, possibly by depleting the local concentration of OH without itself producing significant SOA yields (Pugh et al., 2011). Globally the source strength of anthropogenic SOA is poorly constrained, with an uncertainty of at least a factor of 2 or 3 (Spracklen et al., 2011). Large uncertainties in pre-industrial aerosol emissions and processes further confound our understanding of the direct and indirect effects of anthropogenic aerosol emissions (Carslaw et al., 2014) and the impact of aerosols on climate (Andreae and Gelencsér, 2006).

To date, environmental chamber experiments have generated most of the laboratory SOA yield data used in atmospheric models, especially in simulations of polluted atmospheric conditions with elevated NO_x concentrations. However, NO_x-dependent chambers studies are complicated by the need to use multiple OH radical precursors such as hydrogen peroxide (H_2O_2) and nitrous acid (HONO) or methyl nitrite (CH_3ONO) to span the relevant range of NO_x levels (typically, H_2O_2 for low-NO_x conditions and HONO or CH_3ONO for high-NO_x conditions) (Ng et al., 2007). Additionally, chambers have relatively low throughput and are limited to residence times of several hours due to chamber deflation and/or loss of particles and oxidized vapors to the chamber walls (Zhang et al., 2014). This restricts environmental chambers to simulating atmospheric aerosol particle lifetimes and SOA yields only up to 1 or 2 days, therefore limiting the study of formation of highly oxygenated SOA characteristic of aged atmospheric organic aerosol PM (Ng et al., 2010) unless very low VOC precursor concentrations are used (Shilling et al., 2009; Pfaffenberger et al., 2013).

Oxidation flow reactors have recently been developed to study SOA formation and evolution over time scales ranging from hours to multiple days of equivalent atmospheric OH exposure. In these reactors, O_3 is photolyzed at 254 nm to produce $O(^1D)$ radicals, which react with water vapor to produce OH radicals. OH concentrations are typically 10^8 cm^{-3} or greater. Under these conditions, atmospheric photochemical aging timescales up to $\sim$10 days can be simulated at flow tube residence times of a few minutes or less. Recent experimental studies suggest that flow reactor-generated SOA particles have compositions similar to SOA generated in smog chambers (Bruns et al., 2015; Lambe et al., 2015) and in the atmosphere (Tkacik et al., 2014; Ortega et al., 2016; Palm et al., 2016). Modeling studies suggest that flow reactors can simulate tropospheric oxidation reactions with minimal experimental artifacts (Li et al., 2015; Peng et al., 2015, 2016). A limitation of flow reactors is the need to use parts-per-million levels of O_3, hindering the possibility to efficiently simulate NO_x-dependent SOA formation pathways. Simple

Atmospheric Measurement Techniques Discussions

addition of NO to flow reactors, while possible (Liu et al., 2015), cannot sustain NO_x mixing ratios at levels that are sufficient to compete with hydroperoxy (HO_2) radicals as a sink for organic peroxy (RO_2) radicals due to fast conversion of NO_x to nitric acid (HNO_3). Here, we present a new method well suited to the characterization of NO_x-dependent SOA formation pathways in oxidation flow reactors. We validate the concept using high-resolution time-of-flight chemical ionization mass spectrometer measurements (HR-ToF-CIMS) to detect gas-phase oxidation products of isoprene and α-pinene that have been observed in NO_x-influenced environments and laboratory chamber experiments.

2 Experimental

Experiments were conducted using an Aerodyne Potential Aerosol Mass (PAM) oxidation flow reactor, which is a horizontal 13.3 L aluminum cylindrical chamber (46 cm long × 22 cm ID) operated in continuous flow mode (Kang et al., 2007; Lambe et al., 2011a). The average residence time was 80 s. The relative humidity (RH) in the reactor was controlled in the range of 3–35 % at 22°C, corresponding to H_2O mixing ratios of approximately 0.07 - 1%. The irradiance in the reactor was measured using a photodiode (TOCON-C6, sglux Gmbh). The gas-phase SOA precursors used in these studies include two biogenic compounds (isoprene, α-pinene) that were prepared in compressed gas cylinders and introduced to the reactor at controlled rates using a mass-flow controller. Mixing ratios of the gas-phase precursors entering the reactor were 36 ppb for isoprene (diluted from 1000 ppm in N_2, Matheson) and 15 ppb for α-pinene (diluted from 150 ppm in N_2, Matheson). These mixing ratios are a factor of 3 to 10 lower than mixing ratios that are typically required to induce homogenous nucleation of condensible oxidation products in related oxidation flow reactor studies (Lambe et al., 2011b).

2.1 OH radical and NO_x generation

OH radicals were produced in the reactor via the reaction $O(^1D) + H_2O \rightarrow 2OH$, with $O(^1D)$ radicals produced from the reaction $O_3 + h\nu \rightarrow O_3 + O(^1D)$. O_3 (∼5 ppm) was generated outside the flow reactor by O_2 irradiation at 185 nm using a mercury fluorescent lamp (GPH212T5VH, Light Sources, Inc.). $O(^1D)$ was produced by photolysis of O_3 at 254 nm inside the reactor using two mercury fluorescent lamps (GPH436T5L, Light Sources, Inc). A fluorescent dimming ballast was used to regulate current applied to the lamps. To vary [OH] inside the reactor, I_{254} was varied by changing the dimming voltage applied to the ballast between 1.6 and 10 VDC. At these conditions, I_{254} ranged from approximately (0.064 – 3.2) $\times 10^{15}$ ph cm^{-2} sec. The highest I_{254} value was calculated from the internal surface area of the reactor and the lamp output at maximum intensity (e.g. 10 VDC) specified by the manufacturer. Lower I_{254} values were calculated from the measured irradiance at lower dimming voltage relative to the measured irradiance and manufacturer-specified lamp output at 10 VDC.

NO and NO_2 were produced via the reaction $N_2O + O(^1D) \rightarrow 2NO$, followed by the reaction $NO + O_3 \rightarrow NO_2$. N_2O (99.5%) was introduced from a compressed gas cylinder at flow rates ranging from 0 to 648 $cm^3\ min^{-1}$, corresponding to mixing ratios of 0% to 5.6% at the carrier gas flow rates that were used. Using N_2O as the NO_x precursor has the following advantages over the simple addition of NO to the carrier gas. First, due to continuous production of $O(^1D)$ from O_3 photolysis inside the reactor (along with minor consumption of N_2O), the spatial distribution of NO and NO_2 is more homogenous.

Atmospheric Measurement Techniques Discussions

Second, attainable steady-state mixing ratios of NO from N_2O + $O(^1D)$ reactions (ppb levels) are orders of magnitude higher than simple NO injection (sub-ppt levels) as inferred from photochemical model simulations described below in Sect. 2.3.Third, photolysis of N_2O at 185 nm (if used) provides an additional source of $O(^1D)$ from the reaction $N_2O + h\nu \rightarrow N_2 + O(^1D)$. We assume background [NO] $<$ 0.05 ppb in the reactor based on separate [NO] measurements and calculate additional NO formed from N_2O + $O(^1D)$ reactions using the model described in Sect. 2.3.

NO_3 radicals, which are produced as a byproduct of NO_2 + O_3 or HNO_3 + OH reactions, can potentially convolute interpretation of results if the relative oxidation rates of isoprene/α-pinene by OH and NO_3 are comparable. For results presented in Sects. 3.2 and 3.3, calculated OH, O_3 and NO_3 exposures combined with published OH, O_3 and NO_3 rate constants (Atkinson, 1986, 1991) suggest that the relative contribution of NO_3 to isoprene and α-pinene oxidation ranges from approximately 0 to 4% and 0 to 40%, respectively, as a function of [N_2O]. Thus, reaction rates of α-pinene with OH, O_3 and NO_3 may be comparable under a subset of experimental conditions. Potential implications are discussed in more detail in Sect. 3.3.

2.2 Chemical ionization mass spectrometer (CIMS) measurements

Mass spectra of isoprene and α-pinene gas-phase oxidation products were obtained with an Aerodyne high-resolution time-of-flight mass spectrometer (Bertram et al., 2011) coupled to an atmospheric pressure interface with a nitrate ion chemical ionization source (NO_3^--HRToF-CIMS, hereafter abbreviated as "NO_3^--CIMS") (Eisele and Tanner, 1993; Ehn et al., 2012). Nitrate (NO_3^-) and its higher order clusters (e.g. HNO_3NO_3) generated from x-ray ionization of HNO_3 were used as the reagent due to the selectivity to highly oxidized organic compounds, including species that contribute to SOA formation (Ehn et al., 2014; Krechmer et al., 2015). Isoprene and α-pinene oxidation products were detected as adducts with NO_3^- or $HNO_3NO_3^-$. CIMS data were analyzed using the Tofware software package (Tofwerk AG, Aerodyne Research, Inc.) implemented in IGOR Pro 6 (Wavemetrics, Inc.). The output of the PAM oxidation flow reactor was sampled at 10.5 $Lmin^{-1}$ through a 2' length of 0.75" OD stainless steel tubing inserted directly into the rear feedthrough plate of the reactor.

2.3 Photochemical modeling

We used a photochemical model Li et al. (2015); Peng et al. (2015) implemented in MATLAB (Mathworks) to calculate concentrations of radical/oxidant species produced in the reactor. Model input parameters included pressure, temperature, [H_2O], [O_3], [N_2O], I_{254}, mean residence time, and the input mixing ratios of isoprene and α-pinene. Differential equations used to describe the radical/oxidant chemistry were integrated at 5 millisecond time steps. The following reactions and associated kinetic rate constants (Sander et al., 2000, 2006) were implemented to describe NO_x chemistry in the reactor:

Calculated OH exposures (product of mean OH concentration and residence time) ranged from 1.7×10^{10} to 2.1×10^{12} molec cm^{-3} sec or approximately 3 hours to 16 days of equivalent atmospheric exposure at [OH] = 1.5×10^6 cm^{-3} (Mao et al., 2009). Steady-state [NO] and [HO_2] ranged from 0 to 13.5 ppb and 0.01 to 2.1 ppb, respectively, depending on [N_2O], [H_2O], [O_3] and I_{254}. We assumed $\pm$25% uncertainty in the calculated OH exposure and $\pm$60% uncertainty in other model outputs (Peng et al., 2015). For ratios of model outputs with independent $\pm$60% uncertainties (e.g. NO:HO_2), propagated uncertainties of $\pm$85% were assumed. Addition of N_2O at the highest mixing ratios that were used suppressed [OH] because N_2O competes with H_2O as a sink for $O(^1D)$. Potential consequences of OH suppression are discussed where applicable in Sects. 3.2 and 3.3.

3 Results and Discussion

3.1 Optimal reactor operating conditions for $O(^1D)$ + N_2O + reactions

To investigate optimal operating conditions for NO_x generation, we implemented the model described in Sect. 2.3 over I_{254}, $[O_3]$, and $[H_2O]$ values ranging from 3.2×10^{13} to 6.4×10^{15} ph cm^{-2} sec^{-1}, 0.5 to 50 ppm, and 0.07 to 2.3% at 22°C, respectively, as a function of $[N_2O]$ = 0 to 5%. These values span the nominal range of operating conditions that can be achieved with the PAM reactor. To facilitate independent evaluation of the effects of $[O_3]$ and I_{254} on [NO], we restricted our analysis to conditions that use only 254 nm photolysis. Using both 185 and 254 nm photolysis provides additional sources of $O(^1D)$ and OH from N_2O and H_2O photolysis at 185 nm, respectively, at the expense of independent control of $[O_3]$ and I_{254}.

Figure 1 shows the modeled steady-state [NO] in the reactor as a function of $[N_2O]$ = 0 to 5%, assuming a mean residence time of 80 sec, $[H_2O]$ = 1%, and $[O_3]$ = 5 ppm. In addition, Figs. S1 - S3 in the Supplement show modeled NO:HO_2 and OH:NO_3 ratios as a function of input $[N_2O]$, with I_{254}, $[O_3]$, and $[H_2O]$ each varied individually while other input conditions are fixed. The following observations that are evident from Figs. 1 and S1 - S3 were used to constrain the optimal oxidant conditions. First, at fixed $[O_3]$, $[H_2O]$, and $[N_2O]$, increasing I_{254} increases $[O(^1D]$ and consequently [NO]. Second, at fixed I_{254}, $[H_2O]$, and $[N_2O]$, decreasing $[O_3]$ increases [OH]:$[NO_3]$ by decreasing NO_2 formation from NO + O_3 reactions, and consequently NO_3 formation from NO_2 + O_3 reactions. At lower $[N_2O]$, increasing $[O_3]$ increases [NO] because greater NO production from higher $[O(^1D)]$ offsets greater NO loss from reaction with O_3. On the other hand, at higher $[N_2O]$, greater O_3 loss from reaction with NO_2 offsets greater NO production from higher $[N_2O]$. Third, at fixed I_{254}, $[O_3]$, and $[N_2O]$, increasing $[H_2O]$ increases [OH]:$[NO_3]$ by increasing OH production from H_2O + $O(^1D)$ reactions. The relative importance of these operating conditions is situationally dependent on the relative OH, O_3, and NO_3 rate constants of the target species and photochemical age. To demonstrate proof of principle, we present NO_3^--CIMS spectra of isoprene and α-pinene oxidation products in the following sections.

3.2 NO_3^--CIMS spectra of isoprene oxidation products

Figure 2 shows NO_3^--CIMS mass spectra of products generated from the oxidation of isoprene (C_5H_8) that cluster with NO_3^- ions to form NO_3^--species adducts. Ion signals are plotted as a function of mass-to-charge ratio (m/Q). NO_3 adduct formation is a relatively low-energy process that does not result in fragmentation of the analyte (Eisele and Tanner, 1993; Kurtén et al., 2011). Thus, the measured ion signals are directly related to the chemical formula of individual species that are generated in the reactor. Ion signals corresponding to isoprene oxidation products shown in Fig. 2 were colored based on classification in ion groups containing 4-5 carbon atoms with zero ($C_{4-5}H_{4-12}O_{3-8}$), one ($C_5H_{7-11}O_{3-8}NO_3$), and two ($C_5H_{10}O_{2-4}(NO_3)_2$) nitrogen atoms, where we assumed that nitrogen atoms were associated with nitrate functional groups and not heterocyclic compounds. We also assume that nitrate functional groups are formed from RO_2 + NO reactions (Sect. 2.1).

To generate spectra shown in Fig. 2, the reactor was operated at I_{254} = 6.4×10^{13} and 3.2×10^{15} ph cm^{-2} sec^{-1}, $[H_2O]$ = 1%, and $[N_2O]$ = 0 and 3%. As shown in Figs. S4 and S5, corresponding OH exposures ranged from $(1.7 – 2.0)\times10^{10}$ (Fig. 2a and b) and $(0.52 – 2.1)\times10^{12}$ molec cm^{-3} sec (Fig. 2c and d), respectively. At low OH exposure, the OH suppression at "high

Atmos. Meas. Tech. Discuss., doi:10.5194/amt-2016-394, 2017
Manuscript under review for journal Atmos. Meas. Tech.
Published: 6 January 2017

Atmospheric Measurement Techniques Discussions

NO_x" relative to "low NO_x" was comparatively minor (15%), whereas at high OH exposure, the OH suppression at "high NO_x" relative to 'low NO_x" was larger (75%). At the "high-NO_x" OH exposure of 5.2×10^{11} molec cm^{-3} sec, isoprene can react with OH up to 52 times in the reactor. This presumably exceeds the number of OH reactions (followed by RO_2 + NO reactions) that are necessary to fragment or condense oxidation products to the point where they are no longer detected with NO_3^--CIMS. Thus, it is unlikely that OH suppression at "high OH" and "high NO_x" significantly affected the NO_3^--CIMS spectra shown in Fig. 2.

3.2.1 NO_3^--CIMS spectral features observed at "low NO_x" conditions

$C_{4-5}H_{4-12}O_{3-8}$ ions comprised 93% and 97% of the signals at low and high OH exposure, respectively (inset pie charts in Figs. 2a and Fig. 2c). The $C_5H_{7-11}O_{3-8}NO_3$ signals that were observed here may be due to background NO_x in the reactor (Sect. 2.1). The signal at m/Q = 230, $C_5H_{12}O_6$ (NO_3^- omitted for brevity here and elsewhere), was the largest signal detected at both low and high OH exposures at "low-NO_x" conditions. This species is likely a second-generation oxidation product that contains two hydroxyl (OH) and two peroxide (OOH) functional groups (Krechmer et al., 2015; St Clair et al., 2016) and is typically associated with isoprene SOA formation and growth under "low-NO_x" conditions. (Liu et al., 2016) Signals in Figs. 2c-d are approximately 10 times higher than in Figs. 2a-b because additional OH exposure produces higher yields of multi-generation oxidation products that are detected with NO_3^--CIMS.

Previously-identified multi-generation isoprene oxidation products such as $C_5H_{10}O_5$, $C_5H_{12}O_5$, and $C_5H_{10}O_6$ (Surratt et al., 2006; Krechmer et al., 2015; St Clair et al., 2016) were also detected at significant intensity under low-NO_x conditions. When the OH exposure was increased by a factor of 100 from 2.0×10^{10} to 2.1×10^{12} molec cm^{-3} sec, the signal at $C_5H_{12}O_6$ increased by a factor of 10 and the signal at m/Q = 246, $C_5H_{12}O_7$, increased by a factor of 5. At high OH exposure, $C_5H_{12}O_7$ was the second-largest peak in the spectrum. These highly oxygenated isoprene oxidation products are likely also important in SOA formation processes. We note that $C_5H_{10}O_7$ is a proposed third-generation, tri-hydroperoxy carbonyl product of isoprene + OH in the absence of NO_x (Peeters et al., 2014).

We hypothesize two reasons for the prominence of $C_5H_{10}O_7$, $C_5H_{12}O_7$, and $C_5H_{10}O_8$ in our spectra. First, NO_3^- is more selective to highly oxidized species than other reagent ions (Surratt et al., 2006; Liu et al., 2016). Second, higher OH exposures were achieved in the reactor than in environmental chambers. For example, the spectra shown in Figs. 2a and 2b were obtained at integrated OH exposures of 1.7×10^{10} and 2.1×10^{12} molec cm^{-3} sec, respectively, compared to an OH exposure of 8.6×10^9 molec cm^{-3} sec in the environmental chamber NO_3^--CIMS measurements conducted by Krechmer et al. (2015).

3.2.2 NO_3^--CIMS spectral features observed at "high NO_x" conditions

Following addition of N_2O at ~3% mixing ratio, the NO_3^--CIMS spectra changed significantly at low and high OH exposures (Figs. 2b and d). The signals of $C_{4-5}H_{4-12}O_{3-8}$ oxidation products decreased, and the signals of $C_5H_{7-11}O_{3-8}NO_3$ and $C_5H_{10}O_{2-4}(NO_3)_2$ oxidation products increased. At low OH exposure, $C_5H_{7-11}O_{3-8}NO_3$ and $C_5H_{10}O_{2-4}(NO_3)_2$ signals constituted 24% and 8% of the NO_3^--CIMS signals, respectively (Fig. 2b). The largest signal in this spectrum was m/Q = 259, $C_5H_{11}O_4NO_3$. This compound is likely a second-generation oxidation product that contains two hydroxyl functional groups

Atmospheric Measurement Techniques Discussions

and one nitrate functional group (Xiong et al., 2015). A series of additional $C_5H_{9,11}O_{3-8}NO_3$ ions is also detected. The signal observed at m/Q = 288, $C_5H_{10}O_2(NO_3)_2$, is likely a second-generation oxidation product that contains two hydroxyl and two nitrate functional groups (Xiong et al., 2015). Other ion signals potentially associated with dinitrate species included m/Q = 304, $C_5H_{10}O_3(NO_3)_2$, and m/Q = 320, $C_5H_{10}O_4(NO_3)_2$. Related signals were detected at m/Q = 351 and 367, which we assume represent $(HNO_3NO_3^-)C_5H_{10}O_2(NO_3)_2$ and $(HNO_3NO_3^-)C_5H_{10}O_3(NO_3)_2$ because we are not aware of other feasible $(NO_3^-)C_5$ adducts at these mass-to-charge ratios.

At high OH exposure, the same $C_5H_{7-11}O_{3-8}NO_3$ and $C_5H_{10}O_{2-4}(NO_3)_2$ species observed at low OH exposure were detected, but at higher concentrations and at higher dinitrate:nitrate. This is presumably due to higher NO:HO_2 achieved at higher I_{254} and fixed $[N_2O]$ (Figs. 1, S1, S4-S5). $C_5H_{7-11}O_{3-8}NO_3$ and $C_5H_{10}O_{2-4}(NO_3)_2$ signals made up 30% and 56%, respectively, of the NO_3^--CIMS spectrum shown in Fig. 2d, where $C_5H_{10}O_2(NO_3)_2$ was the largest signal that is detected.

3.3 NO_3^--CIMS spectra of α-pinene oxidation products

Figure 3 shows NO_3^--CIMS mass spectra of products generated from the oxidation of α-pinene ($C_{10}H_{16}$). Ion signals corresponding to α-pinene oxidation products were colored based on classification in $C_5H_{6-8}O_{5-7}$, $C_{6-9}H_{8-14}O_{6-12}$, $C_{10}H_{14-18}O_{5-14}$, and $C_{19-20}H_{28-32}O_{9-18}$ ion groups containing zero nitrogen atoms; $C_5H_7O_{3-8}NO_3$, $C_{6-9}H_{9-15}O_{5-10}NO_3$, and $C_{10}H_{15-17}O_{4-15}NO_3$ ion groups containing one nitrogen atom; and a $C_{10}H_{16-18}O_{0-7}(NO_3)_2$ ion group containing two nitrogen atoms. As was the case with isoprene oxidation products, we assumed nitrogen atoms present in α-pinene oxidation products were associated with nitrate functional groups formed from RO_2 + NO reactions.

To generate spectra shown in Fig. 3, the reactor was operated at $I_{254} = 2.8\times10^{15}$ ph $cm^{-2}sec^{-1}$, $[H_2O]$ = 0.07%, and $[N_2O]$ = 0 and 3.2%. In this experiment, lower $[H_2O]$ was used to minimize [OH] and facilitate closer comparison with spectra from previous NO_3^--CIMS studies of α-pinene + O_3 oxidation products generated at "low-NO_x" conditions (Ehn et al., 2012, 2014). As shown in Fig. S6, corresponding OH and O_3 exposures ranged from (0.19 – 1.8)$\times10^{11}$ molec cm^{-3} sec and (7.2-9.5)$\times10^{16}$ molec cm^{-3} sec for the low- and high-NO_x conditions, respectively.

To first order, at OH and O_3 exposures of 2.1×10^{10} and 7.4×10^{15} molec cm^{-3} sec that are attained at $[N_2O]$ = 3.2%, α-pinene should react once with each oxidant in the gas phase. Thus, at the highest $[N_2O]$ values used, yields of second-generation (or later) α-pinene + OH oxidation products detected with the NO_3^--CIMS were minimized relative to α-pinene + O_3 first-generation oxidation products, as desired (Jokinen et al., 2015). However, a potential consequence of using $O(^1D)$ + N_2O reactions to study the NO_x-dependence of chemical systems similar to those examined by Ehn et al. (2012, 2014) is that RO_2 may be produced from α-pinene + NO_3 reactions in addition to α-pinene + O_3 or α-pinene + OH reactions (Sect. 2.1 and Fig. S6).

3.3.1 NO_3^--CIMS mass spectral features observed at "low NO_x" conditions

Of the signal detected at "low-NO_x" conditions (Fig. 3a), $C_5H_{6-8}O_{5-7}$, $C_{6-9}H_{8-14}O_{6-12}$, $C_{10}H_{14-18}O_{5-14}$, and $C_{19-20}H_{28-32}O_{9-18}$ ion groups comprised 6%, 23%, 54%, and 5%, respectively. The C_{10} monomers and C_{19-20} dimers compounds that were observed are often associated with atmospheric new particle formation events (Ehn et al., 2014). The prominent $C_{10}H_{14,16}O_{7-9}$

Atmospheric Measurement Techniques Discussions

ion signals detected at m/Q = 308, 310, 324, 326, 340 and 342 in our measurements were dominant signals in previous laboratory and field experiments influenced by the ozonolysis of α-pinene emissions (Ehn et al., 2010, 2012, 2014; Jokinen et al., 2015). Other ion signals that were observed correspond to C_{5-9} species that were generated following carbon-carbon bond cleavage of the C_{10} carbon backbone (Ehn et al., 2012). The remaining ~13% of the signal was classified into$C_5H_7O_{6-11}NO_3$, $C_{6-9}H_{9-15}O_{5-10}NO_3$, and $C_{10}H_{15-17}O_{4-15}NO_3$ ion groups and may be due to background NO_x in the reactor (Sect. 2.1).

3.3.2 NO_3^--CIMS mass spectral features observed at "high NO_x" conditions

As was the case with NO_3^--CIMS spectra of isoprene oxidation products, the addition of N_2O to the reactor significantly changed the mass spectrum of α-pinene oxidation products (Fig. 3b). At [N_2O] = 3.2%, organic nitrates and dinitrates comprised 65% of the total ion signal (Fig. 3b inset). We observed reduction in $C_{6-9}H_{8-14}O_{6-12}$, $C_{10}H_{14-18}O_{5-14}$, and $C_{19-20}H_{28-32}O_{9-18}$ ion signals, along with increases in $C_5H_{6-8}O_{5-7}$, $C_5H_7O_{3-8}NO_3$, $C_{6-9}H_{9-15}O_{2-7}NO_3$, $C_{10}H_{15-17}O_{1-11}NO_3$ and $C_{10}H_{16-18}O_{0-7}(NO_3)_2$ signals. The C_{10} dinitrates may originate from two α-pinene + OH reactions followed by two RO_2 + NO reactions, but may also include contributions from one α-pinene + NO_3 reaction followed by one RO_2 + NO reaction. The largest ion signal in Fig. 3b was observed at m/Q = 240, $C_5H_6O_7$. The largest organic nitrate signals in this spectrum were at m/Q = 329, $C_8H_{13}O_6NO_3$, followed by $C_{10}H_{15}O_6NO_3$ (m/Q = 355), $C_{10}H_{16}O_3(NO_3)_2$ (m/Q = 354), and $C_{10}H_{15}O_5NO_3$ (m/Q = 339).

3.4 Transition from RO_2+HO_2 to RO_2+NO-dominant regimes observed in isoprene and α-pinene oxidation products

Figures 4 and 5 shows normalized signals of the representative groups of isoprene and α-pinene oxidation products as a function of increasing NO:HO_2. For each group of compounds, signals obtained at a specific NO:HO_2 were normalized to the maximum observed signal. NO:HO_2 is correlated with the relative branching ratios of RO_2 + HO_2 and RO_2 + NO reactions that govern the distribution of oxidation products observed in Figs. 2 and 3. As is evident from Figs. 4 and 5, different ion families were characterized by different trends as a function of NO:HO_2. The normalized signals of C_{4-5} (isoprene), C_{6-10} (α-pinene) and C_{19-20} (α-pinene) species decreased monotonically with increasing NO:HO_2. In Fig. 5, the abundance of C_{19-20} dimers decreased significantly faster than the C_{6-10} species. Because dimers are products of RO_2 + RO_2 self-reactions, their yield is quadratic with respect to [RO_2] and therefore was more affected by competing RO_2 + NO reactions than species formed from RO_2 + HO_2 reactions.

The normalized signals of C_5 (isoprene) and C_{10} (α-pinene) organic nitrates reached their maximum values at NO:HO_2 $\approx$ 1 prior to decreasing. Maximum signals of C_{6-9} organic nitrates (α-pinene) were obtained at NO:HO_2 = 2.4, and maximum signals of C_5 (isoprene) and C_{10} (α-pinene) dinitrates were obtained at NO:HO_2 = 5.2 and 6.4. The formation of dinitrates was favored when RO_2 + NO >> RO_2 + HO_2, as expected, and regardless of whether RO_2 was formed from oxidation of α-pinene by OH, O_3 or NO_3. We hypothesize that NO:HO_2 >> 1 favored RO_2 + NO fragmentation reactions that led to formation of smaller, more volatile $C_5H_{6-8}O_{5-7}$ and $C_5H_7O_{3-8}NO_3$ α-pinene oxidation products (Atkinson, 2007; Chacon-Madrid and Donahue, 2011), whose signals continuously increased with increasing NO:HO_2, along with other products not detected with

Atmospheric Measurement Techniques Discussions

NO_3^--CIMS. This pathway apparently competed with NO_x-influenced auto-oxidation processes that led to formation of C_5 isoprene dinitrates, C_6-C_{10} α-pinene nitrates and C_{10} α-pinene dintrates.

Isoprene oxidation products such as $C_5H_9O_4NO_3$ and $C_5H_{11}O_4NO_3$ contain one peroxide and one nitrate functional group, and $C_5H_9O_5NO_3$ contains two peroxide and one nitrate functional group. The formation of these species, as well as C_{6-10} α-pinene-derived organic nitrates, was favored at NO:HO_2 $\approx$ 1-2 where the relative rates of RO_2 + NO and RO_2 + HO_2 reactions were similar. This correlation suggests that the C_{6-10} α-pinene organic nitrates detected with NO_3^--CIMS contained a combination of peroxide and nitrate functional groups, whereas C_5 (isoprene) and C_{10} (α-pinene) dinitrates contained fewer functional groups that were specifically formed from RO_2 + HO_2 reactions.

4 Atmospheric Implications

The use of $O(^1D)$ + N_2O reactions in oxidation flow reactors facilitates systematic control of NO:HO_2 over the range of "RO_2 + HO_2 dominant" to "RO_2 +NO dominant" conditions. Further, this is accomplished with the use of a single OH radical precursor (O_3) that has previously hindered characterization of NO_x-dependent chemistry in oxidation flow reactors. Our results suggest that this method can be used to identify molecular tracers for processes influenced by RO_2 + NO and/or RO_2 + NO_2 reactions. For example, $C_5H_{7-11}O_{3-8}NO_3$ compounds formed from the oxidation of isoprene were detected in air masses influenced by mixed isoprene and anthropogenic emissions (Lee et al., 2016). Similarly, $C_{10}H_{15}O_{5-8}NO_3$ compounds formed from the oxidation of α-pinene were detected in air masses influenced by α-pinene emissions that were subsequently oxidized by O_3 in the presence of NO (Yan et al., 2016).

This method will be used in future work to investigate the influence of NO_x on physicochemical properties of secondary organic aerosols such as hygroscopicity and refractive indices over an atmospherically relevant range of NO:HO_2. Care should be taken to use experimental conditions that minimize the relative contributions of unwanted NO_3-initiated oxidation chemistry, particularly when using species such as α-pinene that are highly reactive to NO_3. While potential formation of dinitrates from α-pinene + NO_3 reactions at high-NO conditions was not the primary goal of this experiment, we note that this chemical fingerprint has been observed in ambient measurements (Yan et al., 2016) and thus represents an additional application of $O(^1D)$ + N_2O reactions in future work. Additionally, studies that require multiple days of equivalent atmospheric OH oxidation at NO:HO_2 $>>1$ should consider implementing 185 nm photolysis of H_2O and N_2O to provide additional sources of $O(^1D)$ and OH that may decrease OH suppression due to competing $O(^1D)$ + H_2O and $O(^1D)$ + N_2O reactions.

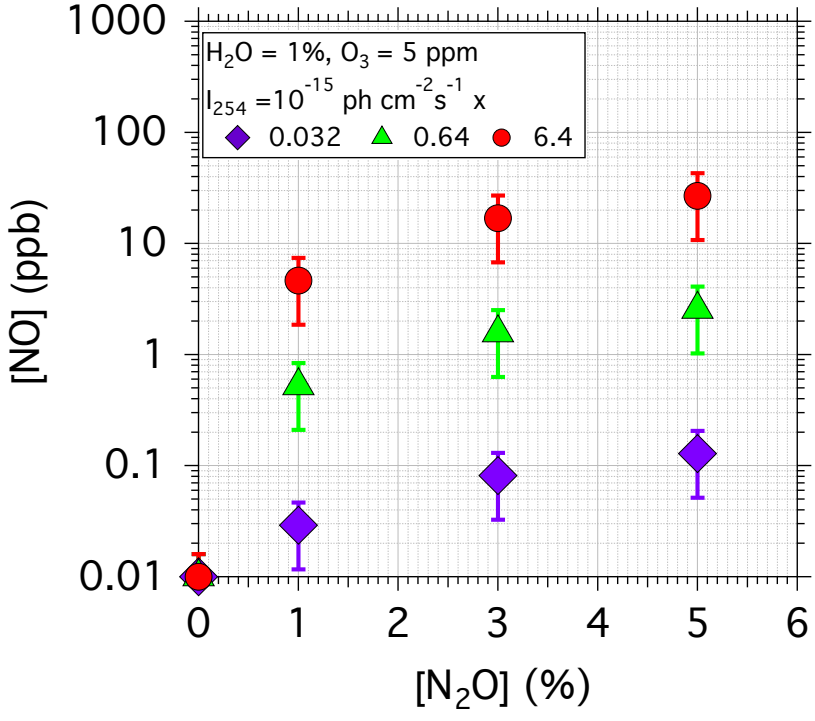

Figure 1. Modeled steady-state [NO] as a function of [N_2O] input to the PAM oxidation flow reactor at I_{254} = 0.032×10^{15}, 0.64×10^{15} and 6.4×10^{15} ph cm^{-2} sec, [H_2O] = 1%, [O_3] = 5 ppm, mean residence time = 80 sec. Error bars represent $\pm$ 60% uncertainty in modeled [NO] (Peng et al., 2015).

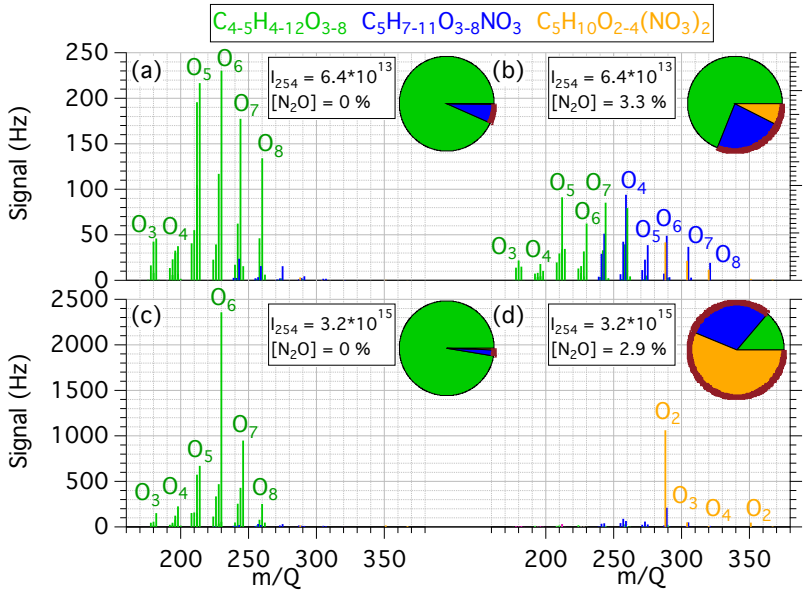

Figure 2. NO_3^--CIMS mass spectra of isoprene oxidation products generated at $[H_2O]$ = 1%, $[O_3]$ = 5 ppm, mean residence time = 80 sec: (a) I_{254} = 6.4×10^{13} ph cm^{-2} sec^{-1}, $[N_2O]$ = 0%; (b) I_{254} = 6.4×10^{13} ph cm^{-2} sec^{-1}, $[N_2O]$ = 3.2 %; (c) I_{254} = 3.2×10^{15} ph cm^{-2} sec^{-1}, $[N_2O]$ = 0 %; (d) I_{254} = 3.2×10^{15} ph cm^{-2} sec^{-1}, $[N_2O]$ = 2.9 %. Colors are based on classification in $C_{4-5}H_{4-12}O_{3-8}$, $C_5H_{7-11}O_{3-8}NO_3$, and $C_5H_{10}O_{2-4}(NO_3)_2$ ion groups, with fractional contributions indicated in inset pie charts (brown outline = organonitrate). "O_x" indicate number of oxygen atoms in labeled ions (not including oxygen atoms in nitrate functional groups).

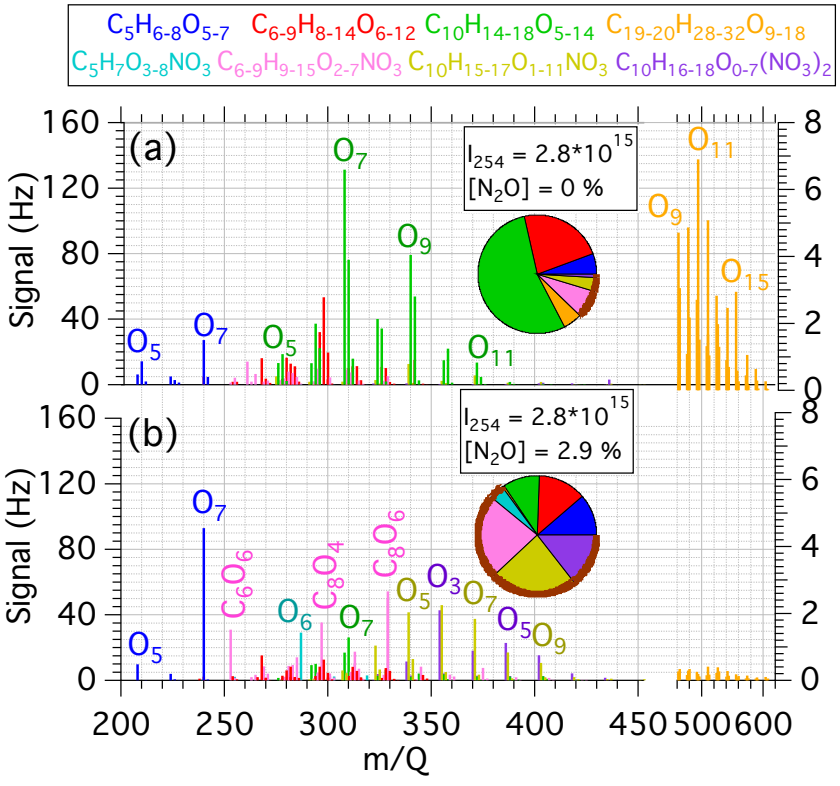

Figure 3. NO_3^--CIMS mass spectra of α-pinene oxidation products generated at $[H_2O]$ = 0.07%, $[O_3]$ = 5 ppm, mean residence time = 80 sec: (a) I_{254} = 2.8×10^{15} ph $cm^{-2}sec^{-1}$, $[N_2O]$ = 0 %; (b) I_{254} = 2.8×10^{15} ph $cm^{-2}sec^{-1}$, $[N_2O]$ = 3.2 %. Colors are based on classification in $C_5H_{6-8}O_{5-7}$, $C_{6-9}H_{8-14}O_{6-12}$, $C_{10}H_{14-18}O_{5-14}$, $C_{19-20}H_{28-32}O_{9-18}$, $C_5H_7O_{3-8}NO_3$, $C_{6-9}H_{9-15}O_{2-7}NO_3$, $C_{10}H_{15-17}O_{1-11}NO_3$, and $C_{10}H_{16-18}O_{0-7}(NO_3)_2$ ion groups. Fractional contributions of each species type indicated in inset pie charts (brown outline = organonitrate). "O_x" labels indicate number of oxygen atoms in corresponding signals (not including oxygen atoms in nitrate functional groups).
