Abstract. Lightning data as observed by the European Cooperation for Lightning Detection network EUCLID are used in combination with radar data to retrieve the temporal and spatial behaviour of lightning outliers, i.e. discharges located on a wrong place, over a 5-year period from 2011 to 2016. Cloud-to-ground stroke and intracloud pulse data are superimposed on corresponding 5-min radar precipitation fields in two topographically different areas, being Belgium and Austria, in order to extract lightning outliers based on the distance between each lightning event and the nearest precipitation. It is shown that the percentage of outliers is sensitive to changes in the network and to the location algorithm itself. The total percentage of outliers for both regions varies over the years between 0.8% and 1.7% for a distance to the nearest precipitation of 2 km, with an average of approximately 1.2% in Belgium and Austria. Outside the European summer thunderstorm season the percentage of outliers tends to increase somewhat. The majority of all the outliers are low peak current events with absolute values falling between 0 to 10 kA. More specifically, positive cloud-to-ground strokes are more likely to be classified as outliers compared to all other type of discharges. Furthermore, it turns out that the number of sensors participating in locating a lightning discharge is different for outliers versus correctly located events, with outliers having the least amount of sensors participating. In addition, it is shown that in most cases the semi-major axis assigned to a lightning discharge as a confidence indicator in the location accuracy is smaller for correctly located events compared to the semi-major axis of outliers.

25 **1 Introduction**

Present-day lightning location systems (LLS) are the result of continuous development over the years with improved location accuracy, peak current estimation and type classification for each observed lightning event. However, despite the great progress made to determine those properties amongst others, occasionally some events remain poorly determined by the LLS. For instance, the uncertainty of the measurements related to a low peak current discharge tends to be larger than it is for a high peak current event. In addition, it is still common practice to categorize positive cloud-to-ground (CG) strokes with estimated peak currents smaller than 5 or 10 kA as IC pulses since those are more likely to be of intracloud (IC) nature (Cummins et al., 1998; Wacker and Orville, 1999a, b; Jerauld et al., 2005, Orville et al., 2002; Cummins et al., 2006; Biagi et al., 2007). However, not all the properties are of equal importance for the different users of lightning data. Depending on the customers' application of the LLS data, different performance features are more important, while others are less important, e.g. power utilities normally do not care about the IC detection efficiency (DE) of an LLS, whereas the quality of the CG data is of utmost importance. On the other hand, aviation control and meteorological services which often trigger warning messages based on LLS data favor a good DE of CG as well as IC events coupled to a minimum of events located on a completely wrong position. It is therefore a necessity to gain a thorough knowledge of the LLS at hand.

During recent years the performance of LLS got more and more attention (Nag et al., 2015). A direct method to determine the quality of a network, and therefore the values assigned to each lightning event, is by comparing the data against so-called ground-truth observations. Those observations provide valuable information on the DE, location accuracy (LA) and in some cases even the peak current estimates retrieved from an LLS. This is done for instance by examining direct lightning strikes to instrumented towers (Diendorfer et al., 2000a, 2000b; Pavanello et al., 2009; Romero et al., 2011; Schulz et al., 2012; Schulz et al., 2013; Cramer and Cummins, 2014; Azadifar et al., 2016), through the use of rocket triggered lightning (Jerauld et al., 2005; Nag et al., 2011; Chen et al., 2012; Mallick et al., 2014a, 2014b, 2014c), and/or by recording lightning strikes with high-speed video and E-field measurements in open field (Biagi et al., 2007; Chen et al., 2012; Poelman et al., 2013a, Schulz et al., 2016). Although best practice to retrieve robust information on a networks' performance, the

aforementioned methods are quite labor intensive in order to acquire a large enough dataset for a statistically reliable output. Other methods exist, such as intercomparing different LLS within regions of overlapping coverage (Said et al., 2010; Pohjola and Mäkelä, 2013; Poelman et al., 2013b). However, the main disadvantage of those studies is the assumption of one network as being “ground-truth”. In reality this is hardly the case for any existing LLS, except maybe for the short-baseline lightning mapping arrays (Rison et al., 1999; Thomas et al., 2004; van der Velde et al., 2013; Defer et al., 2015). In this paper lightning data are combined with radar precipitation observations to analyze the temporal and spatial behavior of lightning outliers in two topographically different regions in Europe. Lightning outliers are sometimes also referred to in the literature as fake or ghost strokes and can be the result of signal interferences from power lines, radio frequencies or other site-specific disturbances or are simply misplaced events by the location algorithm. The results presented here are obtained by combining lightning observations from the European Cooperation for Lightning Detection network EUCLID with radar precipitation data in Belgium and Austria, as described in Section 2. The results of the analysis are presented in Section 3 and summarized in Section 4.

2 Data and Methodology

2.1 Lightning location data

The European Cooperation for Lightning Detection network EUCLID has been operational since 2001 and processes as of January 2017 in real-time data of 164 sensors to provide European wide lightning observations of high and nearly homogeneous quality (Schulz et al., 2016; Poelman et al., 2016). All of the sensors operate over the same low-frequency (LF) range and provide amongst others timing and angle information. The individual raw sensor data are sent in real-time to a single processor, calculating the electrical activity at any given moment. The locations of the EUCLID sensors are displayed in Fig. 1. The network has been tested continuously over the years against ground-truth data from direct lightning current measurements at the Gaisberg Tower in Austria (Schulz et al., 2016), Peisserberg Tower in Germany (Heidler and Schulz, 2016) and Säntis Tower in Switzerland (Romero et al., 2011; Azadifar et al., 2016) and data from E-field and video recordings in Austria, France and Belgium

(Schulz et al., 2016). The latest comprehensive performance analysis of the EUCLID network based on those measurements revealed that the flash and stroke DE for negative CG discharges in different regions of the EUCLID network are greater than 93% and 84%, respectively, while for positive events those are greater than 87% and 84 %, respectively (Schulz et al., 2016). To retrieve the latter values, only those strokes are used in the analysis that match certain quality criteria such as χ^2 , a measure for the agreement between the different sensor measurements, and the semi-major axis of the confidence ellipse, and received a correct stroke classification as CG by the central processor. Those strict criteria, as well as temporary sensor outages during the measurements campaign, can impact the DE estimates given in Schulz et al. (2016). In addition, Schulz et al. (2016) showed that the LA dropped steadily over the years down to the present LA in the range of 100 m within the majority of the network. Note that in Schulz et al. (2016) ground truth observations are collected in Austria and Belgium, the same regions of the EUCLID network which are studied in this paper.

During the time period under consideration, significant changes of the EUCLID network regarding DE and LA were made (Schulz et al., 2016). Those are related to new sensor technology, timing error corrections and a new location algorithm which can influence the outlier behavior. One would think sensor upgrades have always a positive influence on a networks performance. While this is generally true in the long run, the upgrades can cause temporary problems in the beginning since those sensors are awaiting calibration. This is especially true for some sensors in Italy in 2014. From the day of the setup till the sensors were calibrated those sensors were configured to provide timing information only. However, timing only sensors often increase the number of outliers if those are used in solutions determined by two or three sensors only.

Figure 2a plots the annual distribution of the total stroke count over the years 2011 until 2016, as observed within the red boxes in Fig. 1. As expected, the CG distribution experiences a natural annual variability in Belgium as well as in Austria. With regard to the IC detections, one notices a sharp increase in 2015 and 2016. This increase is not climatological in nature, but is attributed to the increased amount of LS700x sensors in EUCLID and its capability to detect IC pulses in the low-frequency domain. The distribution of the total monthly stroke count is shown in Fig. 2b. A peak in activity is

observed in June and July for Belgium and Austria, respectively. For both regions about 95% of all the observed lightning activity occurs between May and September.

2.2 Weather radar data

Weather radar data of the Royal Meteorological Institute of Belgium (RMIB) and of Austro Control in Austria are used in this study. Fig. 1 shows the locations (white stars) and coverage (dashed lines) of the individual radars, as well as the limit of the composite as the outer contour of all the radars (solid lines). The use of radar composites is preferred over the individual radar observations since individual radar observations can be hampered by shielding effects. This is true especially in mountainous regions such as the Alps in Austria, limiting the detection range where the radar data is still considered of sufficient quality. Additionally, since the height of the radar beam above ground increases with increasing distance from the radar, precipitation can be underestimated or even undetected at far range by overshooting when precipitation is produced below the height of the lowest radar beam. Therefore, to eliminate the latter effect, the two geographical areas in this study are limited to the red boxes as indicated in Fig. 1.

The composite radar reflectivity threshold is set at 12 dBZ. Following the $Z = 200 * R^{1.6}$ relationship from Marshall and Palmer (1948), with Z being the reflectivity and R the rain rate, this threshold corresponds to a rain rate of 0.2 mm/h below which the rain rates are set to zero in this study. This low reflectivity threshold helps to detect convective clouds relevant for lightning generation even in weak cell cores from winter events or upper areas of thunderstorms at far ranges from the radar site.

125

2.2.1 Belgium

The radar composite used at RMIB consists out of three radars. RMIB owns and operates two of them; the radar at Wideumont in the southeast of Belgium and the radar in Jabbeke located near the west coast which became only operational since 2013. The third weather radar at the center of the composite is located at the airport in Zaventem near Brussels and is operated by Belgocontrol, in charge of the safety of civil aviation. All of the radars are C-band Doppler radars, performing a multiple elevation reflectivity scan every 5 minutes with a resolution of one degree in azimuth and 500 m in range for

Jabbeke and Zaventem and 250 m in range for Wideumont. The maximum range is 300 km for Jabbeke and 250 km for Zaventem and Wideumont. A Doppler filter for clutter elimination is used for the three
135 radars and an additional polarimetric fuzzy logic filter is used for Jabbeke. For each radar, a 2D
precipitation product is derived from the volume reflectivity data. The height of those individual
products corresponds to 1500 m above sea level. A composite is subsequently produced from these 2D
products taking for each pixel the maximum value of the radars covering this pixel. For more
information on the validation of the Belgian composite, the interested reader is referred to
140 Goudenhoofd and Delobbe (2016).

2.2.2 Austria

Austro Control, the Austrian civil air service provider is operating five C-band EEC polarized Doppler
weather radars in Austria, of which four of them are used in this study. Two of the radar sites are
145 located on the foothills of the Alps close to Vienna and Salzburg (Rauchenwart and Feldkirchen) and
the other two radar sites are situated in the west and south of Austria at mountain tops above 2000 m
close to Innsbruck and Klagenfurt (Patscherkofel and Zirbitzkogel). The underlying volume scan
contains 16 elevations ranging between -1.5° and 67° up to a range of 224 km. Doppler and statistical
clutter filters are applied before creating maximum surface projection of reflectivity which combines
150 strongest return from each elevation level. Resulting Austrian composite uses maximum reflectivity in
horizontal extent which is provided by one of the 4 radars to avoid shielding effects of the Alps.
Temporal and spatial resolution is 5 minutes and 1 km, respectively. For more details, the interesting
reader is referred to Kaltenboeck and Steinheimer (2015) and Kaltenboeck (2012a, 2012b). It is
important to note that the Austrian weather radar network was upgraded between 2011 and 2013, during
155 which the individual radar gains were modified. This adaptation of the gain could easily influence to
some degree the findings in this paper.

2.3 Methodology

To account for border effects of the radar observations as mentioned in Sect. 2.2, only lightning events within the red boxes as indicated in Fig. 1 are used. Those regions correspond approximately to the area where two or more radars participate in the radar image with sufficient distance from the border. Subsequently, CG strokes and IC pulses with timestamps, that fall within the start and end time of the radar scan, are superimposed on the corresponding 5-min radar precipitation fields. In order to have overall homogeneous coverage of the weather radar data, only the time steps were used for which all the radars within the composites were in operation. An event is then categorized as an outlier when no precipitation within a certain distance has been observed. The distance at which an event is classified as outlier is somewhat chosen arbitrary. Different runs are performed applying a distance Δr of 2, 5, and 10 km. An example of this method is visualized in Fig. 3. All the lightning events are superimposed as black dots, whereas the retrieved outliers are in red for clarity. Note that this method is supposed to give a lower limit of the percentage of outliers because some of the outliers will, by chance, be placed in a region with radar reflectivity larger than 12 dBZ. In the remainder of the paper, explanation of the results is based on the findings for a search radius Δr of 2 km, unless otherwise stated explicitly.

3 Results

The overall annual percentage of outliers for CG strokes and IC pulses relative to the total number of events, as a function of Δr between the event location and the nearest precipitation, is plotted in Fig. 4 for Belgium and Austria. There are several similarities and differences between the two areas. For example, the total percentage of outliers is of the same order of magnitude for both regions and varies between 0.8% and 1.7% throughout the years for an adopted Δr of 2 km. It is clear that choosing a larger Δr decreases the percentage of outliers, and vice versa, while maintaining the same annual trend. The percentage of the total outliers averaged over six years in Belgium and Austria is approximately 1.2%. In Belgium on average 0.5% of the outliers are of type CG and this value increases up to 0.9% in case of IC, whereas in Austria the level of CG outliers is only slightly higher than that of IC outliers, i.e. 0.8% for CG with respect to 0.5% in case of IC. Shorter baselines in Austria compared to Belgium

185 could be a reason for this discrepancy. The significant higher number of outliers in Belgium in 2011 compared to Austria can be attributed to a timing only sensor located close to Belgium (Den Haag) and another sensor in the Netherlands which was moved and afterwards operated for a longer time period with deactivated angle information (Roermond). From our experience, sensors providing only time information often cause additional outliers. For the vast majority of the sensors which provide angle and
190 time information those measurements have to be consistent since coherence between the latter two reduces the number of outliers. The level of outliers from 2012-2014 is roughly the same for both areas. The lowest level of CG outliers is found in 2016 in both areas. In addition, it is worth mentioning that in Belgium and Austria the majority of the CG outliers are single stroke flashes, while only a minority of the CG outliers belong to a flash with multiplicity larger than one. One could say that assuming a stable
195 radar network, the variation in the percentage of outliers over the years reflects the status of the lightning location network in a certain area. Hence, continuous monitoring of the outliers has the possibility to pick up potential problems in the network, which can be relevant for future automatic forecast applications.

The left panels in Figure 5 display the 6-year mean annual total lightning event (CG strokes + IC
200 pulses) density on a $10 \times 10 \text{ km}^2$ grid in Belgium and Austria. For Belgium, densities vary between 0.8 and 11 events $\text{km}^{-2}\text{yr}^{-1}$ with a median value of 3.4 events $\text{km}^{-2}\text{yr}^{-1}$ at $10\text{km} \times 10\text{km}$ resolution. Overall the densities in Austria are somewhat higher compared to Belgium resulting in a median value of 4.4 events $\text{km}^{-2}\text{yr}^{-1}$. The highest total lightning densities are found towards the southeast of Austria with a maximum of 22 events $\text{km}^{-2}\text{yr}^{-1}$. Fig. 5c and 5d reveal the spatial distribution of the percentage of total
205 outliers as observed in between 2011 and 2016. In Belgium, values range from 0.2% to 3.3%. The distribution of outliers within Belgium is rather uniform with here and there somewhat higher percentage values. The latter are mainly caused by IC outliers, since those contribute the most to the overall outlier percentage in each grid cell. In Austria, grid cell percentages range from 0.1% up to 33%. The majority of the grid cells have low outlier percentage values, except in the southwest corner. This is
210 exactly the place where the Alps disturb the radar observations leading to an increase in outliers with the employed method. From Fig. 5a and 5b we conclude that there is no real correlation between the total lightning event density and the spatial distribution of outliers.

Fig. 6 illustrates the monthly variation of the percentage of outliers. An obvious decrease is observed in the percentage of outliers during May-Sept, compared to the other months of the year. This feature could be related to the fact that more sensor upgrades occur during winter or because precipitation of winter thunderstorms is more difficult to detect with the weather radars. In addition, the 3D structure of lightning flashes in winter compared to summer is somewhat different (Lopez et al., 2017), which could increase the difficulty to locate those in winter accurately. Regarding the sensor upgrades, those often result in disabled angle information because systematic angle errors, i.e. site errors, are at first unknown and the correction takes a while because lightning data is necessary. Consequently, upgraded sensors start operation with disabled angle information during winter months. With respect to the observation of precipitation, during summer most of the storms are associated with large amounts of precipitation in vertically extended clouds, meaning that those storms are always very well detected by the radars. In contrast, winter storms are generally associated with less intense precipitation cells and with smaller vertical extensions. In some cases winter storms are not detected by the radars at long range. In that case, lightning produced by such undetected winter storms are wrongly classified as outliers. Vice versa, an incorrect classification may also occur when a wrong detection appears by chance in a precipitation area detected by the radar. In this case, a wrong lightning detection is classified as a correct detection. Since radars generally detect less precipitation in winter than in summer (e.g. Hazenberg et al., 2011) such misclassification occurs less in winter than in summer, which means that the classification method will produce more outliers in winter. Thus, the reduced efficiency of precipitation detected by the weather radars in winter is an additional possible source of the observed increase of outlier classifications in winter. Note that Poelman et al. (2016) showed that on average peak current estimates of winter lightning are higher than in summer. One would therefore expect that on average in winter more sensors participate in a lightning event compared to summer, resulting in a good location accuracy. Nevertheless, the absolute number of outliers during winter is much smaller compared to summer, as can be deduced from Fig. 3b. Thus, the increase in percentage of outliers may not be too important for the majority of applications.

Fig. 7 plots the outlier percentages related to each individual group, e.g. percentage of negative IC is related to the total number of negative IC. Proportionally, the degree of occurrence of positive and

negative outliers is of the same level, except for 2011, and follows the annual variation as in Fig. 4. Positive CG strokes exhibit the highest percentage of outliers in Belgium and Austria. This could be related to the fact that positive CG strokes are often accompanied with significant IC activity complicating the transmitted electromagnetic fields (Fuquay, 1982; Saba et al., 2009). It is therefore
245 harder to detect and locate correctly such strokes, resulting in a higher percentage of outliers. Furthermore, the percentage of negative CG outliers is roughly half of that of the positive CG outliers for the years 2011-2014. The opposite is found in case of IC pulses, where the percentage of negative IC outliers is higher compared to the positive counterpart. However, the difference between positive and negative CG outliers and/or IC pulses decreases in 2015 and 2016. Thus, the percentage of outliers is
250 more or less unrelated to the polarity of the event. In 2016, it is obvious that the outlier percentages of the individual types are more or less in line with each other. This could also be a result of the improved performance of the latest adopted location algorithm.

In Fig. 8, the percentage of outliers for peak current intervals up to ± 20 kA is plotted, calculated with respect to the total amount of discharges within each peak current interval. It is seen that the distribution
255 corresponds well between Belgium and Austria. Because positive CG strokes with peak currents below 5 kA are categorized as IC, no data for positive CG below 5 kA exists. First of all, the majority of the outliers for positive CG and IC discharges are found in between [5, 10] kA and [0, 5] kA, respectively, with a decline towards the larger peak current intervals. This is not surprising since the higher the peak current, the more sensors participate on average in locating the event. This is also true for negative IC
260 outliers, whereas negative CG outliers have the highest percentage in the [-10, -5] kA range. Except for the [-5, 0] kA interval, the percentages are similar between negative IC and CG outliers. This is not the case for the positive IC and CG outliers. In addition to what is plotted in Fig. 8, it is found that the percentage of CG outliers with absolute peak currents above 20 kA is a factor of about three lower compared to the total percentage of outliers found within $|0-20|$ kA, and a factor of 15 lower in case of
265 IC. The larger drop in case of IC results from the lower amount of IC events with absolute peak currents larger than 20 kA compared to CG events.

Fig. 9 reveals the cumulative distribution of the number of sensors participating in a solution as a function of event type. First of all, one notices that in case of CG strokes more sensors participate in a

solution compared to IC events. This is attributed to the fact that in the LF range the amplitude of even
270 the largest IC pulses is significantly lower compared to that of CG return strokes (Weidman et al.,
1981). The amplitude difference between CG strokes and IC pulses increases even further with
increasing propagation distance between the source and the lightning sensor (Cooray et al., 2000).
Hence, more sensors will detect the radiation from a single CG discharge compared to an IC pulse. The
resemblance in distribution between Belgium and Austria is not surprising since the lightning sensors in
275 EUCLID are quite homogeneously distributed across the network. In addition, more sensors participate
in the location of discharges that are correctly located, than is the case of CG as well as IC outlier
events. For instance, 85% of the IC outliers are located by 2 or 3 sensors, whereas this drops to 50% for
correctly located IC pulses. For CG strokes on the other hand, only 20% of the outliers are located with
more than 6 participating sensors, whereas this is the case for more than 60% for the CG strokes within
280 2 km of the nearest precipitation. We find that the median amount of sensors participating in a solution
for correctly located CG and IC is 8 and 3, respectively, and this drops to 3 and 2 sensors participating
in case of CG and IC outliers.

The central processor assigns to each lightning event a value of the semi-major axis (SMA) of the 50%
confidence ellipse. This value can be used as a quality indicator of the location accuracy, with smaller
285 values indicating a larger confidence in the assigned location of the event. The distribution of SMA for
all the events (CG + IC) is plotted in Fig. 10, separated into and normalized to outlier and correctly
located events. In addition, the total number of events per SMA interval for Belgium and Austria is
indicated. Note that events with an SMA larger than 7.5 km do not exist in the data since those events
are regarded as bad quality events and hence rejected by the location algorithm. First of all, it is striking
290 that the SMA distribution is almost equal for Belgium and Austria. The majority of OK events, i.e.
75%, have SMA values falling in the 0-1 km range, whereas this drops to 40% in case of outliers. The
average and median value of the SMA for OK events is 775 m and 200 m, respectively, and this
increases to 1.83 km and 1.48 km in case of outliers. Although not shown in this plot, it is found that the
average SMA for CG strokes is smaller by a factor of two compared to IC pulses. This is expected since
295 more sensors participate in a solution for CG strokes compared to IC pulses as discussed in Fig. 9.

Looking at Fig. 8 to 10 one could wonder whether the CG outliers could be simply considered as IC discharges misclassified by the network, since IC discharges have on average lower peak currents, hence lower number of contributing sensors and therefore smaller SMA. Although this can be partly true, still a considerable fraction of the CG outliers are found to have large peak currents. It is therefore
300 unlikely that all the CG outliers are in fact misclassified IC discharges.

Up to now, lightning discharges have been classified into either correctly located strokes or outliers based on their distance to the nearest precipitation. However, using an additional time criterion it is possible to further dissociate the outliers into isolated outliers in space and time from those that are just wrongly located from a group of correctly located events. Fig. 11 plots the distribution of the time
305 difference between the outliers and its closest (in time) correctly located event. Once more, the distribution is found to be similar in Belgium and Austria. The majority of the outliers occur within one second of a correctly located event. One could argue that these are simply bad located lightning events, whereas those that take place later than one second are so-called ghost outliers, i.e. outliers in time and space. Furthermore, from this plot it is found that the outliers behave quite independent of polarity and
310 classification in Belgium and Austria.

4 Summary

In this study all lightning events detected by the EUCLID network during 2011 and 2016 that fall within selected areas in and around Belgium and Austria are classified as outliers or correctly located events based on their distance Δr to the nearest precipitation. The latter two regions were chosen specifically
315 for their difference in topography and because high spatial and temporal resolution radar data were readily available. A similar approach can be performed in the future on a larger spatial scale based for instance on the radar composite imagery produced by the Eumetnet Operational Programme for the Exchange of Weather Radar Information (OPERA, Huuskonen et al. 2014) and related EUCLID domain.

320 The applied methodology makes use of radar data with an adopted lower reflectivity threshold of 12 dBZ. Hence, precipitation is required to discriminate between the outliers and well-located lightning events. Therefore lightning produced by “dry” thunderstorms or bolts from the blue will be

misclassified as outliers. However, these particular phenomena are extremely limited and would not influence to a large extent the results presented in this study. We believe that a methodology based on
325 satellite cloudiness products would not allow a proper identification of outliers since cloudiness in Belgium and Austria is mostly not associated with thunderstorms.

Categorizing the lightning events based on radar reflectivity data and comparing the results from different geographical regions is not a straightforward task. The reason is potential calibration issues in the different radar networks with maybe even different technology and local beam blockage problems
330 especially in the mountainous regions in Austria. A workaround, at least for the last problem, is to use composite radar data. Despite those difficulties the overall results in both regions agree quite well. The overall percentage of outliers for both regions varies annually between 0.8% and 1.7% for a distance Δr to the nearest precipitation of 2 km and drops further when a more relaxed Δr is chosen. These values are lower limits since it is possible that an outlier is located in an area with rain. The percentage of
335 outliers is quite small having in mind that a Δr of 2 km is already a quite strict criterion. Outside the European summer thunderstorm season the percentage of outliers tends to increase somewhat. Amongst some of the sources responsible for this increase is the fact that more sensor upgrades occur during winter or that the radar underestimates to some extent precipitation. In addition, the 3D structure of flashes is somewhat different in winter compared to summer, which could increase the difficulty to
340 locate those accurately. The majority of all the outliers are low peak current events with absolute values falling between 0 to 10 kA. More specifically, positive CG strokes are more likely to be classified as outliers compared to all other type of discharges. Furthermore, it turns out that the number of sensors participating in locating a lightning discharge is different for outliers versus correctly located events, with outliers having the least amount of sensors participating. In addition, it is found that in general the
345 SMA of non-outliers is much smaller compared to the SMA belonging to outliers.
