**Abstract.** The Arosa site is well known in the ozone community for its continuous total ozone column observations recorded since 1926. Originally based on Dobson sun spectrophotometers, the site has been gradually complemented by three automatic Brewer instruments, in operation since 1998. To secure the long term ozone monitoring in this Alpine region and to benefit from synergies with the World Radiation Center, the feasibility of moving this activity to the nearby site at Davos (aerial distance of 13 km) has been explored. Concerns about a possible rupture of the 90 years long record has motivated a careful comparison of the two sites since great attention to the data continuity and quality has always been central to the operations of the observatory at Arosa. To this end, one element of the Arosa Brewer triad has been set up at the Davos site since November 2011 to realize a campaign of parallel measurements and to study the deviations between the three Brewer instruments. The analysis of the coincident measurements shows that the differences between Arosa and Davos remain within the range of the long term stability of the Brewer instruments. A non-significant seasonal cycle is observed, which could possibly be induced by a stray light bias and the altitude difference between the two sites. These differences are shown to be lower than the short term variability of the time series and the overall uncertainty from individual Brewer instruments and therefore are not statistically significant. It is therefore concluded that the world's longest time series of the total ozone column obtained at Arosa site could be safely extended and continued with measurements taken from instruments located at the nearby Davos site without introducing a bias in this unique record.

## 1 Introduction

Since the 1920s, good quality ozone column measurements have been obtained by the sun spectrophotometry technique initially developed by Prof. G. Dobson (*Basher*, 1982; *Komhyr et al.*, 1989). At that time, he created the first ozone network of the so-called Dobson instruments distributed at four sites in Europe, one of them being Arosa (*Dobson*, 1968). The good quality of the Arosa measurements was the result of a very involved scientist (Prof. W. P. Götz) carefully maintaining the observations in this high altitude and low-pollution environment. This motivated Prof. G. Dobson to permanently leave an instrument for continuous operation at the LichtKlimatisches Observatorium (LKO) Arosa. The LKO had been founded a few years earlier at the initiative of a medical corporation with the initial purpose of understanding why Alpine atmosphere proved to be beneficial

for patients suffering from tuberculosis disease (*Stahelin et al.*, 2016). The long term continuation of the ozone column monitoring at LKO has continued in the 1960s under the responsibility of Prof. H.-U. Dütsch and later on, from the 1980s, under the responsibility of Prof. J. Stahelin associated to the Federal Office of Meteorology and Climatology (MeteoSwiss) to assure the technical support and the development of the LKO. The Arosa ozone column measurements record is well known  
5 in the ozone community as the longest continuous series worldwide starting in 1926 (*Dütsch*, 1984; *Stahelin et al.*, 1998; *Scarnato et al.*, 2009, 2010).

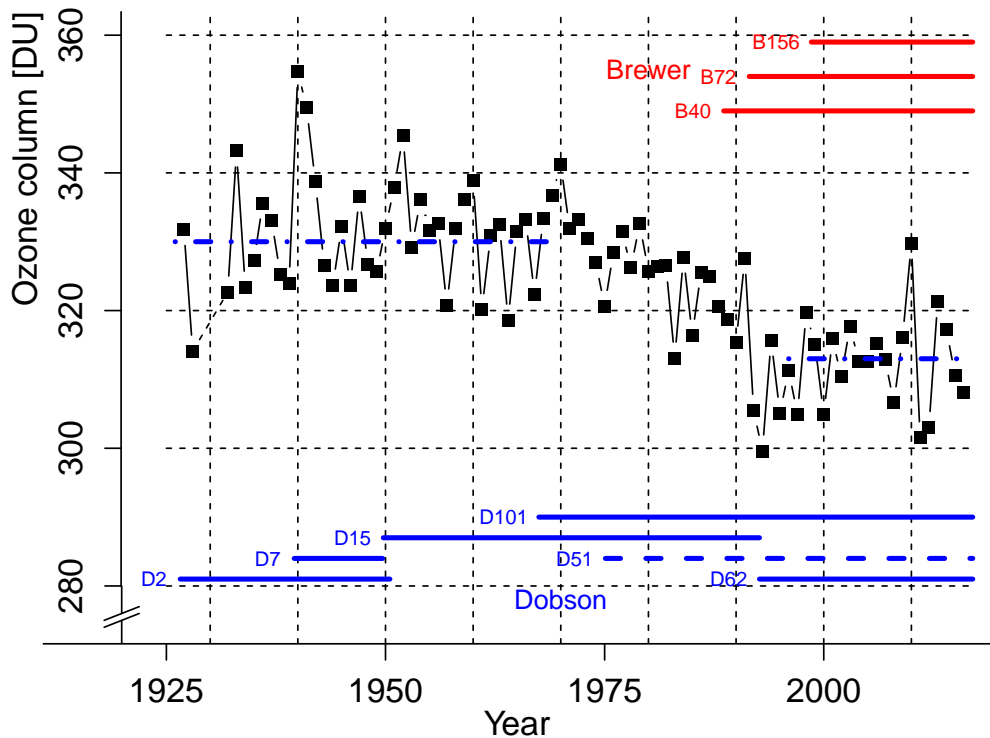

The ozone column time series was initially composed of measurements from a suite of manual and automatic Dobson sun spectrophotometers with various contiguous or overlapping operation periods as illustrated in the lower part of Figure 1 (blue segments). On a regular basis since 1957, the ozone column series has been complemented by ozone profile measurements  
10 based on the Umkehr technique (*Petropavlovskikh et al.*, 2009). From 1994 onwards, three Dobson instruments have been in operation at Arosa, with two instruments focused on ozone column and one on Umkehr profile measurements. In Figure 1, the annual mean ozone column composite time series is illustrated. The depletion of stratospheric ozone, first observed in the polar regions (*Solomon*, 1999; *Farman et al.*, 1985), has had a signature at mid-latitudes of ~5% decrease in the total ozone column clearly evident in Arosa between 1970 and 1990 in Figure 1 (blue broken lines). The effects of the Montreal protocol  
15 and its successive amendments appear as a leveling of the ozone column over the last past decade (*Pawson et al.*, 2014). This first stage of the ozone layer recovery is clear. However the expected increase does not appear unambiguously and statistically significant in the LKO series.

Developed in Canada, the new generation Brewer sun spectrophotometers have been introduced in the market in the 1980s (*Kerr et al.*, 1981; *Kerr and McElroy*, 1995). These fully automatic Brewer instruments have been gradually introduced at the  
20 LKO over the time period 1988 to 1998 to constitute a triad as illustrated at the top of Figure 1 (red segments) (*Stübi et al.*, 2017).

The Physikalisches Meteorologisches Observatorium (PMOD) located in the adjacent Davos valley was founded in 1907 and played a similar role as the LKO. Today, PMOD is well known for its activities in the domain of radiation measurements and worldwide calibration services and has acquired the status of the World Radiation Center (WRC) for the World Meteorological  
25 Organization (WMO).

The question of pooling the PMOD/WRC and LKO resources has regularly been raised, for profiting from synergies between the two institutions and improving efficiency. The main objection to a change of site for the ozone column monitoring has always been focused on the importance of the long LKO measurements series, which should neither be discontinued nor disrupted. To assure the quality of these important historical Dobson and Brewer series in Switzerland on the long term, a new  
30 analysis of the situation was conducted at MeteoSwiss that led to a two phase multi-year project.

In the first phase, the Dobson instrument was automated resulting in a significant increase of the number of measurements as well as improved data quality. The description of the automated version of the Dobson instrument will be the subject of a separate publication. In parallel to these technical developments, a campaign of parallel Brewer measurements at the two sites Arosa and Davos was initiated to objectively determine any influences of the environment (e.g. altitude, surrounding  
35 topography, etc.) and location on the measured ozone column. The results of this campaign are presented in this study. In the

**Figure 1.** Time series of the annual mean ozone column above Arosa, Switzerland. The different instruments in operation are illustrated by blue segments for the Dobson and red segments for the Brewer instruments. Dobson  $D_{051}$  is mostly dedicated to Umkehr measurements. The broken blues lines are the mean ozone column before 1970 and after 1997, respectively.

second phase, a similar campaign of parallel measurements with automated Dobson instruments is running since January 2016. However, the middle term stability and the calibration status after the major upgrade of these instruments have to be assessed before publishing these results and a 2–3 years comparison campaign is also necessary.

The 13 years of the Arosa Brewer triad covering the previous period 1998–2011 were carefully analyzed to quantify the reproducibility and the long term stability of these Brewer measurements. The results of this latter analysis are described in *Stübi et al. (2017)* and reference to this publication will appear in the present analysis since it is based on a similar approach. The combined information from the two studies would provide the objective scientific evidence on which to base a decision on relocating the Dobson and Brewer instruments from Arosa to Davos.

In section 2, the two measurement sites are briefly presented with emphasis on the environmental factors with a potential to produce systematic effects. In section 3, the instruments and the data sets are described and the analysis of the 2010–2016 measurements period with Brewer  $B_{072}$  instrument located first at Arosa (until end of 2011) and then at Davos is presented. The discussion of the results is found in section 4, followed by the conclusions in section 5.

## 2 Sites Characteristics

Arosa is an alpine resort ( $\sim 2,500$  permanent inhabitants) in the Swiss Alps at a mean altitude of 1800 m a.s.l. surrounded by a mountain circus with summits reaching 3000 m a.s.l. The LKO measurement site (46.779 N, 9.675 E) is on the terrace of a building at 1850 m a.s.l. where the two triads of sun spectrophotometers (Dobson and Brewer) were collocated until the beginning of the campaign in November 2011. The area is isolated from major industrial pollution sources since Arosa is connected to the Rhine valley by a  $\sim 30$  km long narrow valley and a altitude difference of  $\sim 1000$  m preventing the inflow of polluted air masses. There is an average of  $\sim 300$  sunny days per year allowing at least 4 direct sun observations with the most favorable clear sky conditions in the morning hours.

Davos is a small city ( $\sim 12,500$  permanent inhabitants) in the adjacent valley south-east of Arosa at a mean altitude of 1550 m a.s.l. The industrial activity is more developed at Davos than at Arosa but is still limited. The measurement site (46.813 N, 9.844 E) is located in front of the PMOD/WRC building at 1590 m. PMOD/WRC sits above a well pronounced inversion layer which effectively prevents local pollution from the valley to reach the Observatory.

Figure 2 illustrates the horizon as seen from the LKO site (blue shaded area) calculated from a model of the Swiss topography at 25m horizontal resolution. The horizon seen from the PMOD/WRC site is illustrated by the red line. The blue lines correspond to the course of the sun at the beginning of each month from January to June. The two horizons present similarities with differences only at the extreme East and West for the Summer months. However, this longer sun exposure of Arosa is not important as the observations are limited to air mass values  $\mu \leq 4$  in order to reduce the effect of the stray light interference in the single monochromator Brewer instruments (see next section).

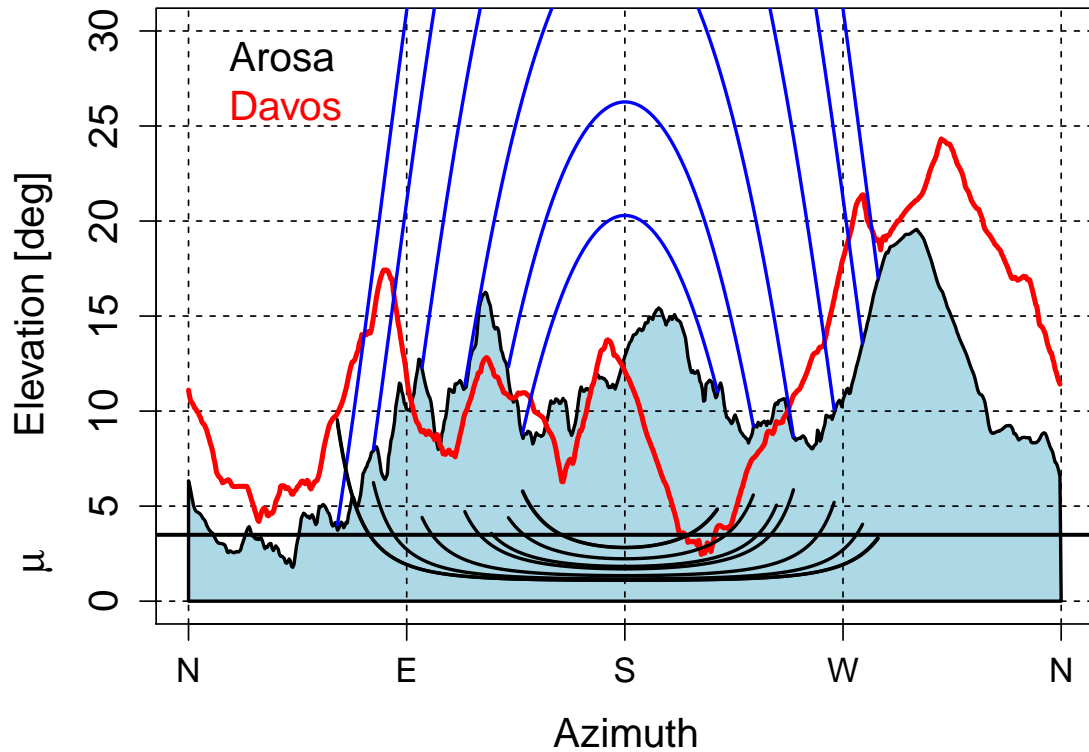

At the bottom of Figure 2, the six black lines correspond to the daily cycle of the  $\mu$  values for the illustrated sun courses and the horizontal line to the limit  $\mu = 4$ . The extra sun duration time for the Arosa site and  $\mu$  values below this limit only occur during the late afternoon hours in Summer. However, in the alpine environment clouds are frequently present at that time of the day and the presence of trees at the North–West direction of LKO site prevent measuring until the sun reaches the horizon. Similarly to Arosa, the number of days appropriate for direct sun measurements at Davos is  $\sim 300$  per year. Finally, the horizontal distance between Arosa and Davos sites is  $\sim 13$  km and the altitude difference is  $\sim 260$  m.

In summary, the basic characteristics of the sites can be considered to be very similar which should, a priori, limit the site-specific differences in the ozone column.

## 3 Instruments and analysis

For the comparison of the Arosa and Davos sites, the Mark II single monochromator Brewer  $B_{072}$  from the Arosa triad was moved to Davos and parallel measurements started on November 22<sup>nd</sup>, 2011. Besides a five week interruption at the beginning of 2013 (01.02.2013 – 04.03.2013) due to technical problems, the operation has continued as intended.

Three "maintenance/calibration" campaigns with the European Brewer Calibration Center (RBCC-E) traveling reference instrument have taken place during that period to assure the good working conditions of the different instruments. The first one happened in July 2012 and the second in July 2014 at LKO. Brewer  $B_{072}$  was transported back to Arosa for this purpose

**Figure 2.** Calculated horizon from the Arosa (blue shaded) and Davos (red line) sites. The blue lines refer to the course of the sun at the beginning of the month from January to June. The black lines are the corresponding air mass  $\mu$  daily cycle for the different sun elevation curves.

for a short period in 2012 and a longer in 2014 (see illustration in Figure 3). In the third campaign in 2016, the instrument  $B_{072}$  was calibrated in Davos and the instruments  $B_{040}$  and  $B_{156}$  subsequently in Arosa. To get a long term perspective of the changes of the instruments' extra terrestrial constant (ETC) and the ozone absorption coefficient, we refer to Figure 2 of *Stübi et al. (2017)*. In table 1, the recent changes of these parameters are reported. It can be seen that besides the change of the ETC for Brewer  $B_{072}$  in 2014, only minor corrections have been necessary to keep the instruments in agreement with the traveling reference instrument (*Redondas et al., 2015; Redondas and Rodriguez-Franco, 2015*). The change of  $B_{072}$  ETC resulted from the improvement of the UV focusing, which significantly changed the response of the instrument (*Redondas and Rodriguez-Franco, 2015*). The other changes are related to the update of the temperature coefficients (in 2014 for  $B_{156}$  and in 2016 for  $B_{040}$ ) and the dead time (in 2012 for  $B_{040}$ , in 2014 for  $B_{072}$  and in 2016 for  $B_{156}$ ).

10 Details on the Arosa Brewer instruments are given in *Stübi et al. (2017)* therefore only a summary is presented here. The instruments were operated according to the standard acquisition and processing programs. The instrument constants were adjusted during the calibration campaigns and in between them, the data were reprocessed according to the time series of

**Table 1.** ETC and ozone absorption coefficient of the Arosa triad Brewer instruments from the last three calibration campaigns.

Parameter	Validity period	B <sub>040</sub>	B <sub>072</sub>	B <sub>156</sub>
ETC	2010–2012	2985	3168	1750
	2012–2014	2980	3180	1765
	2014–2016	2970	3223	1750
	2016–	2950	3215	1740
O <sub>3</sub> abs. coeff	2010–2012	0.3335	0.3397	0.3326
	2012–2014	0.3335	0.3386	0.3402
	2014–2016	0.3335	0.3377	0.3390
	2016–	0.3357	0.3377	0.3405

the internal lamps tests results. Only the direct sun observation were considered in this analysis and they were subject to an automatic and visual data screening on a daily basis, taking advantage of the presence of multiple collocated instruments at LKO, of ancillary surface radiation measurements and of cloud observations. Individual direct sun observations for each Brewer has to satisfy the standard deviation criteria ( $\sigma_{O_3} \leq 2.5$  DU) and only data with air mass factor  $\mu \leq 4.0$  were used in the present analysis.

For the comparison of Brewer total ozone data, coincident criteria were defined as time difference  $\delta t \leq 5$  minutes and air mass difference  $\delta\mu \leq 0.05$ . Since the measurement program of all three Brewer instruments was driven by the same set of commands according to the solar zenith angle (SZA), 90% of the coincidences were within  $\delta t \sim \pm 100$  seconds and  $\delta\mu \sim \pm 0.016$ .

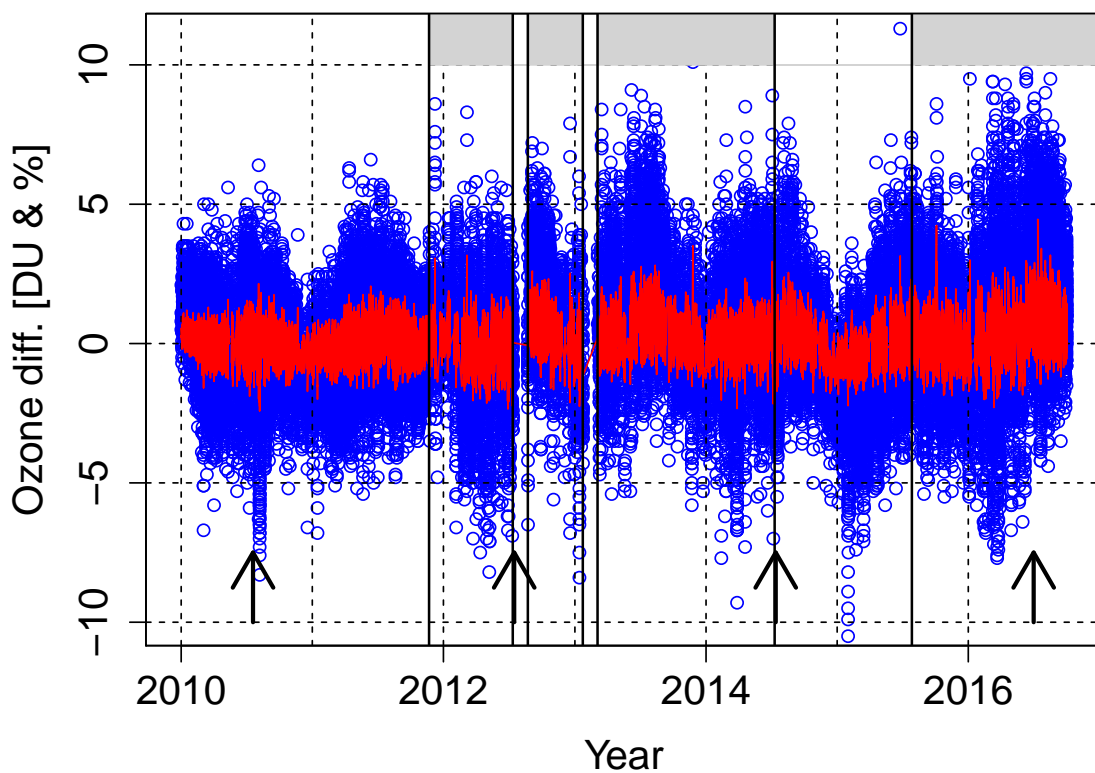

Figure 3 presents the differences of the coincident measurements of the Brewer instruments B<sub>040</sub> and B<sub>072</sub> over the time period 2010–2016 in Dobson units (blue) and reported to the midday ozone column in [%] (red). This figure does not allow distinguishing any substantial break in the series resulting from the transfer of the Brewer B<sub>072</sub> instrument to Davos. During the time period 2010–2012 when the three instruments were collocated at Arosa, only a limited number of differences exceeded  $\pm 5$  DU while this number increased when the instruments were apart. A slight seasonal cycle can also be noticed in this figure.

The parameters of the distribution of the differences series are given in table 2. The total number of coincident measurements were of the order of  $\sim 50'000$ , about half for collocation and half for distant locations as shown in the last column of table 2. The medians of the distributions showed a shift of the order of 0.25 % when Brewer B<sub>072</sub> was located at Davos accompanied by a widening of the inter-quantiles Q<sub>75%</sub>-Q<sub>25%</sub> (Q<sub>97.5%</sub>-Q<sub>2.5%</sub>) of 0.2% (0.8%). The differences between two Mark II and between a Mark II and a Mark III was  $\sim 0.2\%$ , which could be a sign of stray light effect if these features present a seasonal component. The overall changes reported in table 2 correspond to differences of the order of one Dobson unit. To reveal such small differences, the instruments must to be very well maintained and calibrated, as provided during the campaigns.

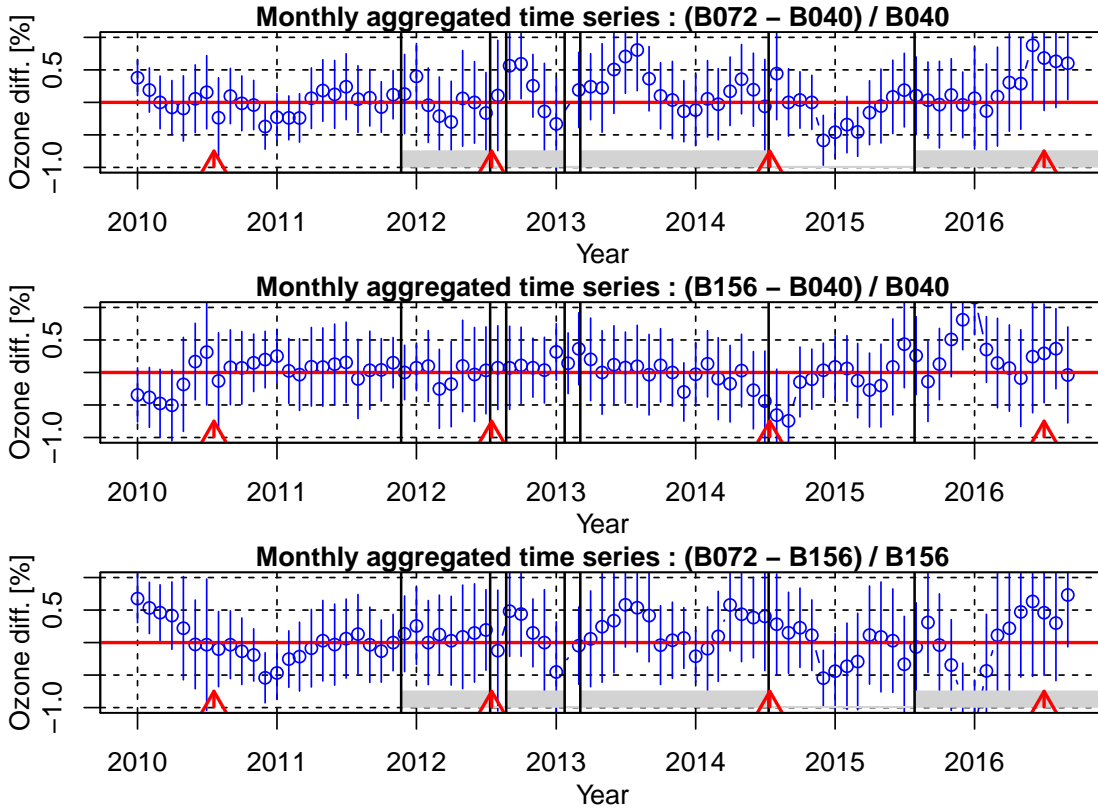

In order to gain a clearer picture of the temporal evolution of the coincident data, the time series were aggregated to monthly median values. The resulting difference time series for the three pairs of Brewer instruments are shown in Figure 4 together

**Table 2.** Quantiles of the distributions of the differences expressed in [%] between pairs of Brewer instruments collocated at Arosa (period LKO) or with B<sub>072</sub> at PMOD/WRC (period PMOD).

Brewer pair	Period	Q <sub>2.5%</sub>	Q <sub>25%</sub>	Median	Q <sub>75%</sub>	Q <sub>97.5%</sub>	Q <sub>75%</sub> -Q <sub>25%</sub>	Q <sub>97.5%</sub> -Q <sub>2.5%</sub>	Sample

**Figure 3.** Time series of the differences between coincident measurements of the Brewer instruments B<sub>040</sub> and B<sub>072</sub> over the period 2010–2016. Blue: difference in DU units. Red: difference in [%]. The arrows indicate the calibration campaigns and the gray shaded areas denote the periods when Brewer B<sub>072</sub> was operating in Davos.

**Figure 4.** Time series of the monthly median differences of coincident ozone column measurements by pairs of Brewer instruments. The gray zones underline the periods when the Brewer B<sub>072</sub> instrument were located at Davos. The blue bars correspond to one standard deviation.

with the  $2\sigma$  error bars. The monthly median differences between the collocated B<sub>040</sub> and B<sub>156</sub> instruments (middle panel) were mostly within the  $\pm 0.5\%$  limits. On the lower and upper panels, the median variations were larger, touching or crossing the  $\pm 0.5\%$  limits more frequently and exhibiting larger variability.

To further characterize the data presented above, the time series were decomposed into a systematic and a random component on a daily basis following the method in *Stübi et al. (2017)*. The first term is a measure of the long-term stability while the second term is linked to the short term variability. The pair of collocated Brewer instruments at LKO (B<sub>040</sub> and B<sub>156</sub>) were considered as the reference. The diurnal variation of the ozone column was modeled as a fourth order polynomial function of the time difference to 12 UTC fitted on all the measurements of the two reference Brewer instruments satisfying the quality and coincident criteria. A further constraint to avoid outliers and spurious coincidences was the requirement to have at least 5 coincident measurements for each Brewer instruments in the course of the day. Each Brewer was then characterized by an offset  $\delta_{B_{nnn}}$  and a standard deviation  $\sigma_{B_{nnn}}$  calculated as :

$$\delta_{B_{nnn}} = \text{median} \left( \sum_{i=1}^n [\{O_{3_{B_{nnn}}}\}_i - \{O_{3_{poly}}\}_i] \right) \quad (1)$$

$$\sigma_{B_{nnn}} = \sqrt{\sum_{i=1}^n \left( \left[ \{O_{3_{B_{nnn}}}\}_i - \{O_{3_{poly}}\}_i - E[\{O_{3_{B_{nnn}}}\}_i - \{O_{3_{poly}}\}_i] \right]^2 \right) / (n-1)} \quad (2)$$

$\{O_{3_{B_{nnn}}}\}_i$  being the measured data, respectively  $\{O_{3_{poly}}\}_i$  being the model data and  $E[x]$  the mean value operator. As the ozone column varies smoothly on the time scale of a few hours, the value interpolated at noon was considered the ozone column representative for that day.

5 The offset  $\delta_{B_{nnn}}$  represented the shift of the polynomial function to fit each instrument separately. The standard deviation  $\sigma_{B_{nnn}}$  was a measure of the dispersion of the data around the smoothed daily variation represented by the polynomial function.

The fourth order polynomial as a model for the diurnal variation is not critical and alternative fit functions did not affect the results.

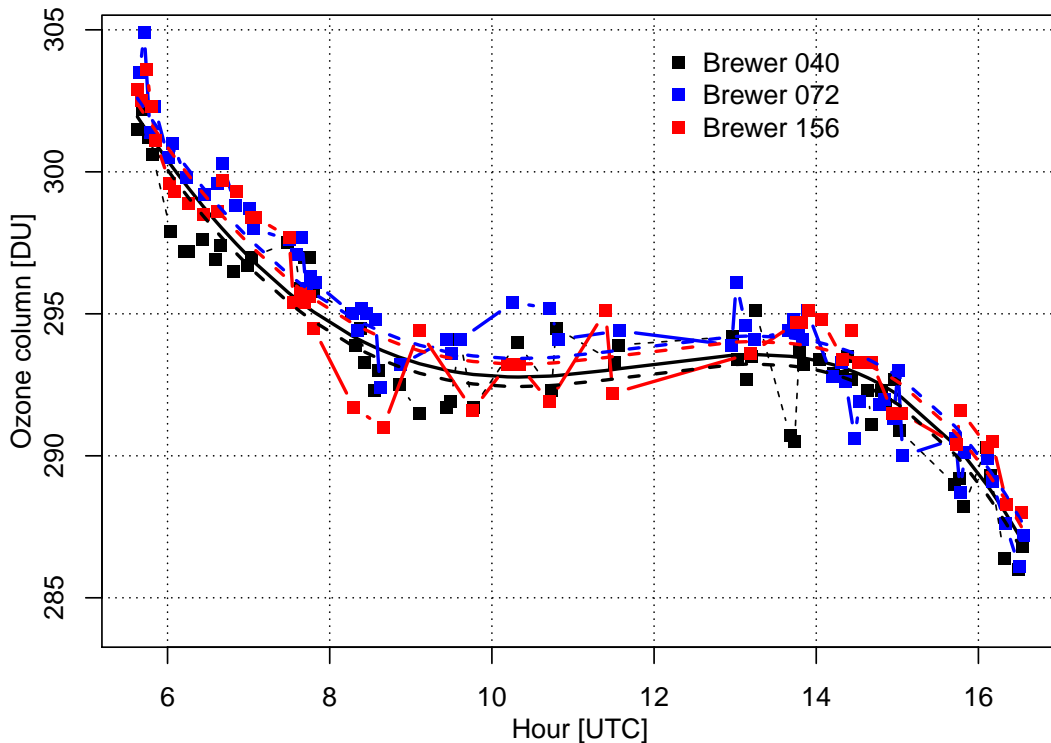

Figure 5 illustrates the procedure with the mean diurnal variation from the two reference instruments (black line) and the  
 10 three individually fitted lines (broken lines) displaced for this particular day by the offsets:  $\delta_{B_{040}} = -0.33$  DU,  $\delta_{B_{072}} = 0.65$  DU and  $\delta_{B_{156}} = 0.45$  DU. The standard deviations for the three Brewer instruments amounted to  $\sigma_{B_{040}} = 1.2$ ,  $\sigma_{B_{072}} = 1.1$  and  $\sigma_{B_{156}} = 1.1$  DU respectively.

The time series of the monthly median of  $\delta$  and  $\sigma$  terms divided by the ozone column at noon [%] for the three Brewer instruments are illustrated in Figure 6 for the period 2010–2016. The  $\delta$  variations for  $B_{040}$  and  $B_{156}$  instruments mirror each  
 15 other since they constituted the reference for the diurnal variation. They were below  $\pm 0.3\%$  for the entire period except at the end of 2015–beginning of 2016. The inter-quantiles ranges  $Q_{97.5\%}$ - $Q_{2.5\%}$  were only occasionally larger than  $0.5\%$  for these two instruments (error bars on Figure 6). The time series  $\delta_{B_{072}}$  exhibited larger variations with extremes reaching  $\pm 0.7\%$  for the median. Similarly, the error bars for  $B_{072}$  were larger as expected since this instrument is not part of the reference. These deviations of the  $\delta_{B_{072}}$  series presented a structured pattern which required further attention.

20 For the  $\sigma$  time series, the differences were much less pronounced reflecting the fact that  $\sigma$  were an intrinsic factor of each instrument. The range of  $\sigma$  for the  $B_{040}$  and  $B_{156}$  instruments was between  $\sim 0.2\%$  and  $\sim 0.5\%$  while for  $B_{072}$ , it was slightly larger by  $\sim 0.1\%$  but not significantly considering the  $Q_{97.5\%}$ - $Q_{2.5\%}$  inter-quantiles ranges. A distinct annual modulation in these  $\sigma$  series were present for the three instruments.

In Table 3, the parameters of the distributions of the  $\delta$  series are reported in the upper part and of the  $\sigma$  series in the lower  
 25 part. The  $\delta$  series medians for the reference instruments were very close to zero while a shift of the  $\delta_{B_{072}}$  distribution of  $\sim 0.2\%$  appeared when the instrument was located at Davos. The inter-quantile  $Q_{97.5\%}$ - $Q_{2.5\%}$  range of this last distribution was twice larger than the other single monochromator  $B_{040}$  when  $B_{072}$  instrument was collocated at Arosa and it widened to three times when it was located at Davos. While the two time periods should be indistinguishable for the  $B_{040}$  and  $B_{156}$  instruments, a variability of  $\pm 0.1$ - $0.2\%$  of the different quantiles were observed.

30 The three  $\sigma$  distribution parameters of the Brewer triad were very consistent with each other as seen in the lower part of table 3. The two reference Brewer instruments ( $B_{040}$  and  $B_{156}$ ) exhibited a similar median of  $\sim 0.35\%$ . The inter-quantile

**Figure 5.** Diurnal variability of the Brewer triad for July 12, 2011: ozone column vs. time [UTC]. The continuous black line is the model diurnal variation and the dashed lines correspond to the model adjusted to each Brewer data set. The black, blue and red colors correspond respectively to  $B_{040}$ ,  $B_{072}$  and  $B_{156}$  Brewer instruments.

range  $Q_{97.5\%}-Q_{2.5\%}$  was  $\sim 0.85\%$  for the reference instruments. For Brewer  $B_{072}$  instrument, the median was  $\sim 0.40\%$  and inter-quantile range  $Q_{97.5\%}-Q_{2.5\%}$  were, respectively 0.96% and 1.06% for the LKO and the PMOD/WRC periods.

The stray light refer to interfering radiation source out of the desired band measured by a specific instrument. The origin could be either internal to the instrument due to multiple reflexions or external from the scattered light in the atmosphere entering the field of view of the instrument. Stray light affects predominantly the measurements of the shortest wavelengths of the Brewer and Dobson instruments at large ozone slant columns ( $SC = \text{ozone column} \times \text{air mass} = O_3 \times \mu$ ) which produces a low bias of the measured ozone column (Scarnato *et al.*, 2009; Petropavlovskikh *et al.*, 2011; Christodoulakis *et al.*, 2015). This effect concerns particularly Dobson and single monochromator Brewer instruments located at high latitude and it varies from instrument to instrument (Karppinen *et al.*, 2015). To reduce these interferences in this study, the observations were limited to air mass values  $\mu \leq 4$  which corresponds to a SC of  $\sim 1200$  DU for the typical  $\sim 300$  DU ozone column of Arosa. To analyze further the stray light potential influence, the seasonality of the SC distribution averaged over the period 2011-2017 were calculated as illustrated in Figure 7. From April to October the SC was below 800 for 90% of the data which

**Table 3.** Quantiles of the distribution of the parameters  $\delta$  and  $\sigma$  of the three Brewer instruments express in [%]. Under the "Period" column, LKO means that the  $B_{072}$  instrument was collocated at Arosa, respectively PMOD/WRC correspond to having  $B_{072}$  at Davos and "All" for the whole period. The sample sizes were 705 days for the Arosa period and 801 days for the Davos period.

Parameter	Period	Q <sub>2.5%</sub>	Q <sub>25%</sub>	Median	Q <sub>75%</sub>	Q <sub>97.5%</sub>	Q <sub>75%</sub> -Q <sub>25%</sub>	Q <sub>97.5%</sub> -Q <sub>2.5%</sub>
$\delta B_{040}$	LKO	-0.31	-0.09	0.01	0.10	0.35	0.19	0.66
	PMOD	-0.50	-0.16	-0.04	0.06	0.26	0.22	0.76

$\sigma B_{156}$	All	0.18	0.30	0.37	0.45	0.61	0.75	0.89
$\sigma B_{072}$	LKO	0.19	0.31	0.39	0.48	0.77	0.79	0.96
	PMOD	0.21	0.35	0.44	0.55	0.85	0.90	1.06

were essentially free of the stray light effect as is the case for most of the Brewer instruments. Contrarily, measurements in December and January showed SC values above 800 which may potentially have induced a low ozone column bias for the two single monochromator instruments  $B_{040}$  and  $B_{072}$ . To evaluate the importance of this effect on the results of the present analysis, the  $\delta$  time series was grouped in three classes of SC according to the median of the monthly SC distributions illustrated in Figure 7 by the red lines. Figure 8 shows the results as boxplots. In the upper panel corresponding to the Arosa period with three collocated instruments, only Brewer  $B_{072}$  showed a significant SC dependence. Brewer  $B_{040}$  had a better stray light rejection and presented no SC dependence. In the lower panel corresponding to the Davos period, the three  $B_{072}$  box-plots showed the similar SC induced pattern moreover slightly shifted upwards. A  $\sim -0.2$  DU low ozone bias was therefore expected for  $B_{072}$  during the period November to February.

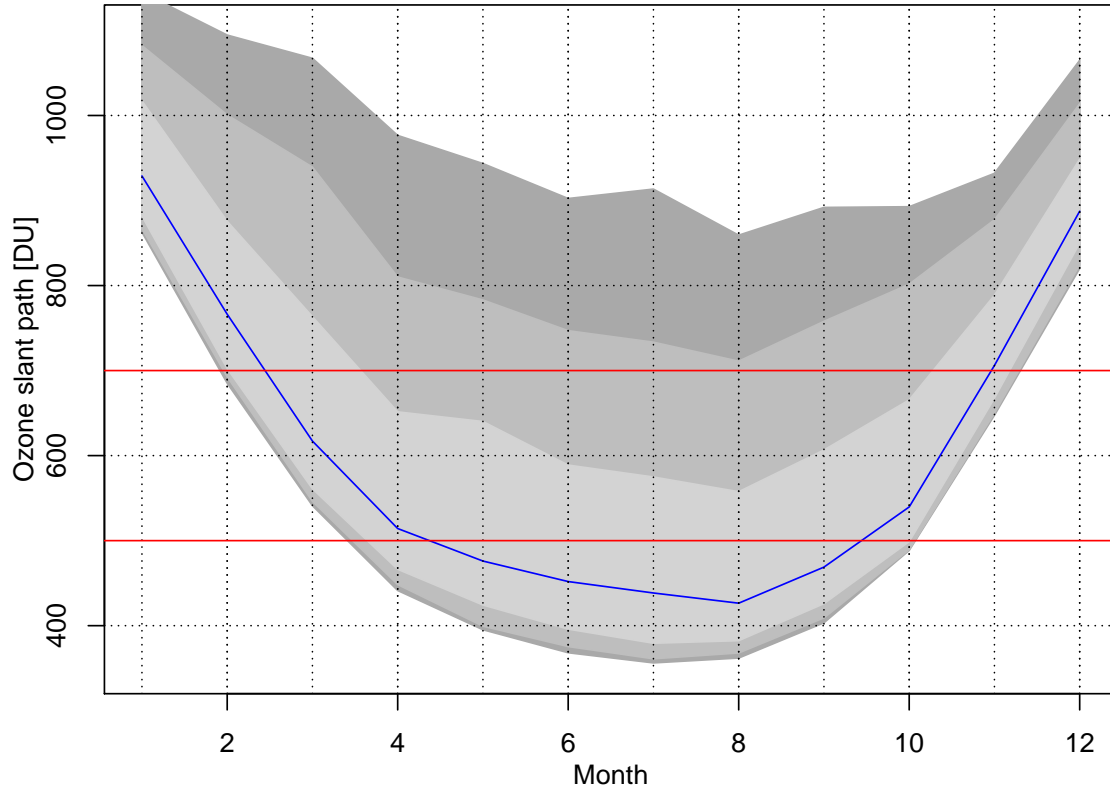

The seasonal variation can be better analyzed on aggregated  $\delta$  time series in monthly medians as illustrated in Figure 9. The upper panel is for the months with the three Brewer instruments collocated at Arosa and the lower panel for the Davos period. The errors bars are the inter-quantiles ranges  $Q_{97.5\%}-Q_{2.5\%}$ . No seasonal cycle can be distinguished on the  $\delta_{B_{040}}$  and  $\delta_{B_{156}}$  monthly median series neither on the upper panel nor on the lower panel. The Brewer  $B_{072}$  aggregated  $\delta_{B_{072}}$  series present a discernible seasonal component at both locations even if it is not significant at the 95% level except for December of the Arosa period. The expected low ozone bias for the Brewer  $B_{072}$  discussed above appears in Figure 9 when the SC is large in the November to March period.

The altitude difference between Arosa and Davos of 260 m introduces a difference of total column ozone above the two sites. Unfortunately, without actual measurements, it is impossible to characterize the ozone column above Davos from the surface to

**Figure 6.** Time series of the monthly median offset  $\delta$  (upper panel) and median standard deviations  $\sigma$  (lower panel) over the time period 2010–2016. The black, blue and red color lines correspond respectively to Brewer  $B_{040}$ ,  $B_{072}$  and  $B_{156}$  instruments. The error bars corresponding to the inter-quantiles  $Q_{97.5\%}$ - $Q_{2.5\%}$  ranges are displayed every third month for clarity. The gray areas show the time periods when the Brewer  $B_{072}$  instrument was located at Davos.

260 m above ground, but surface ozone observations at the two locations and a comparison with free tropospheric observations can be used to derive meaningful boundaries on the magnitude of this difference. At Arosa, surface ozone observations are conducted by the local authorities at the LKO site. At Davos, a surface ozone station is operated as part of the Federal air pollution monitoring network (NABEL). This station is nine hundred meters away from the PMOD/WRC site on a 35 m high tower in a forest. As discussed by *Chevalier et al. (2007)* for the central European region, ozone concentrations in the free troposphere increase with altitude fairly consistently irrespective of geographical location, however, this stratification can be modulated substantially by surface effects. Thus, surface ozone observations made at stations below 1200 m a.s.l were found to be as much as 40% lower than those observed by aircraft and ozone balloon sondes in the free troposphere. The deviations decreased with increasing altitude of the stations to less than 8% for stations above 2000 m a.s.l. The mean annual surface ozone concentrations observed at Arosa ( $42.3 \pm 8.2$  ppb) and Davos ( $42.0 \pm 7.1$ ) were found to be very similar despite the difference in altitude (see Figure 4 in *Chevalier et al. (2007)*). Both stations exhibit about 5 ppb lower ozone concentrations than expected

**Figure 7.** Seasonal cycle of the slant column over Arosa. The different bands from dark gray to light gray encompass the respective SC limits of  $Q_{97.5\%} - Q_{2.5\%}$ ,  $Q_{90\%} - Q_{10\%}$  and  $Q_{75\%} - Q_{25\%}$ . The blue line is for the monthly medians.

from free tropospheric profiles, with hourly variabilities of  $\sim 11$  ppb in Summer and  $\sim 8$  ppb in Winter. The seasonal variability was on the order of 15-20 ppb. This variability is likely due to changing weather and synoptic scale transport, with superimposed photochemical effects of local pollution.

Under the hypothesis of a constant ozone mixing ratio above the inversion layer mentioned in section 2, the partial ozone column can be estimated as:

$$\Delta \text{Column } O_3(t) = \int_{p_{Davos}(t)}^{p_{Arosa}(t)} O_3(t, p) * d \ln p = 0.79 * \{ \ln(p_{Davos}(t)) - \ln(p_{Arosa}(t)) \} * O_3(t) \quad [DU] \quad (3)$$

with the ozone  $O_3(t)$  [ppm] values measured at Davos NABEL surface station. The result of this simple calculation based on the hourly daytime measurements over the time period 2006-2014 is shown in Figure 10 and suggests an average contribution of the partial ozone column to the total ozone column above Davos of  $\sim 0.25\% \pm 0.15\%$ .

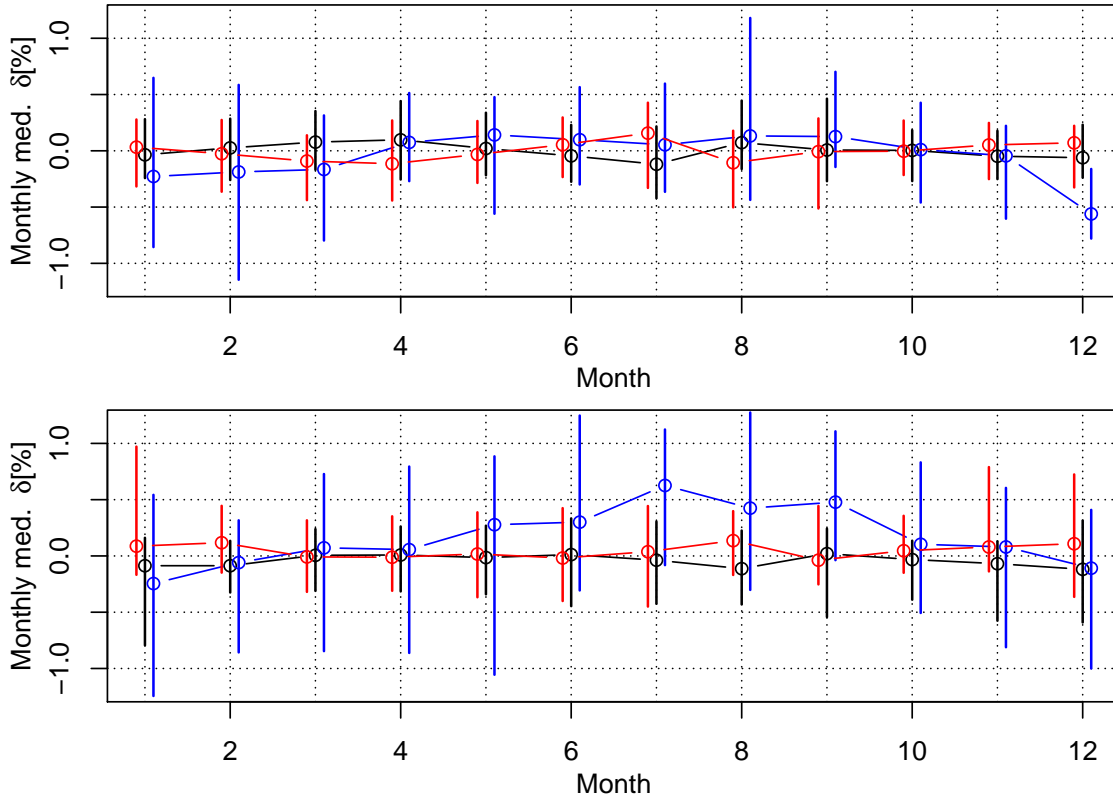

**Figure 8.** Boxplot of the  $\delta$  time series of the three Brewer instruments according to three classes for the median of the ozone slant column monthly distributions (red lines in Figure 7): median SC  $\leq 500$ ,  $500 < \text{median SC} \leq 700$  and  $700 < \text{median SC}$ . The upper panel is for the Arosa period, respectively the lower panel for the Davos period and from left to right, the distributions of respectively  $\delta_{B_{040}}$ ,  $\delta_{B_{072}}$  and  $\delta_{B_{156}}$ .

#### 4 Discussion

The Brewer sun spectrophotometers are very reliable instruments to measure the ozone column in a fully automated mode within 1% reproducibility. It is therefore well adapted to compare two different sites under the same measurement program. This allowed us to generate a large dataset of coincident measurements to evaluate the potential impact of the instrument location on the measurements during an extended period of time. This approach is in line with the Global Climate Observing System (GCOS) monitoring principles 1 and 2 (GCOS (2003)) which state that an assessment of impact should be made before the implementation of a change and a suitable period of overlap of the observing systems is required. It has been applied here to document a possible move of the Arosa based ozone column monitoring activities at the nearby Davos site.

The alignment of the Arosa Brewer instruments with respect to the global network is assured by the regular maintenance and calibration campaigns which have demonstrated an agreement with the RBCC-E traveling reference to within  $\pm 1\%$  and

**Figure 9.** Seasonal cycle of the offset  $\delta$  for Brewer  $B_{040}$ ,  $B_{072}$  and  $B_{156}$  instruments in red, blue and green color, respectively. The upper panel corresponds to the Arosa period while the lower panel corresponds to the Davos period. The bars correspond to the inter-quantiles  $Q_{97.5\%}$ - $Q_{2.5\%}$ .

even closer to within  $\pm 0.5\%$  in the recent years. The present analysis was concentrated on the study of the relative difference between the measurements obtained from the traveling Brewer instrument  $B_{072}$  located either at Arosa or at Davos and the two other instruments of the Arosa Brewer triad ( $B_{040}$  &  $B_{156}$ ).

The large number of direct coincident measurements reported in table 2 and illustrated in Figure 3 showed that no significant differences were present at this stage. It was not possible to identify minor influences of the sites and a further step in the analysis was required. It consisted in a separation in two terms: the short term variability  $\sigma$  (random term) and the longer term stability  $\delta$  (systematic term). The same approach was already used in *Stübi et al. (2017)* to evaluate the quality of the Arosa Brewer triad measurements. The findings were a stability of the instruments of  $\sim 0.40\%$  over a time scale of a decade and a short term variability of  $\sim 0.3\%$ , in good agreement with a similar analysis of the world reference Brewer triad at Toronto (Fioletov et al., 2005; Kerr and al., 1998).

The results of this method are presented in table 3 and Figure 6. The three  $\sigma$  distributions present a seasonal variation of  $\sim 0.2\%$ . The larger air mass factors prevailing in Winter induced a larger difference of the measurement signals and the extra

**Figure 10.** Monthly mean percentage contribution of the partial ozone column integrated from the Davos to Arosa altitudes based on the NABEL surface ozone measurements to the total column. The bars correspond to two standard deviations.

terrestrial constant and potentially a better signal/noise ratio thus, reducing  $\sigma$ . In summer particularly, the sun radiation intensity at the ground level change by many orders of magnitude and therefore neutral density filters are used in the Brewer instrument to attenuate the signal by known factors to avoid the saturation of the photomultiplier. The transitions between the different neutral density filters may be a source of additional fluctuations enhancing the short term variability. The distribution of  $\sigma_{B_{072}}$

5 is slightly larger than the other two, independently of the sites.

Regarding the  $\delta$  parameter for the Arosa period, a larger  $\delta_{B_{072}}$  distribution was expected since it was not part of the reference built upon  $B_{040}$  and  $B_{156}$  instruments data. A factor  $\sqrt{3}$  could be expected based on assumption that instrumental uncertainty are the same for all instruments and not correlated. For the Davos period, a shift ( $\sim 0.2\%$ ) and a widening (factor  $\sim 1.4$ ) of the  $\delta_{B_{072}}$  distribution was observed.

10 Two additional factors were investigated that could potentially make a contribution to differences between measurements at the two investigated sites. First, the altitude difference created an additional partial column which is estimated of the order of  $\sim 0.25\%$  ( $\sim 0.8$  DU) based on simple assumptions. This partial column is of the same order of magnitude as the median of the  $\delta_{B_{072}}$  distribution for the Davos time period of  $B_{072}$  instrument. Secondly, the upper panel of Figure 9 shows a seasonal

curvature in the  $\delta_{B_{072}}$  distribution which had the signature of a stray light problem. The investigation confirmed (see Figure 8) a pronounced bias for Brewer  $B_{072}$  for the Winter months which could explain the mentioned curvature.

In summary, the present analysis did not show significant differences between coincident Brewer measurements at the two locations. The locations Davos and Arosa did not introduce discontinuities in the measurements of the ozone column measured by Brewer instruments. A small seasonal variation of the ozone column difference of  $\pm \sim 0.2\%$  was identified in the analysis which could not be distinguished from a stray light bias of the test  $B_{072}$  instrument. The altitude difference between the two sites generated a non-significant partial column based on surface ozone measurements embedded in the total uncertainties of the measurements .

Finally, the analysis of coincident data precluded the possibility of observing differences in the sampling of the daily cycle at the two sites, e.g. larger numbers of observations at low sun angles. The analysis of the horizons from Arosa and Davos sites was checked with the help of a high resolution model of the topography. A bias of the ozone column due to a different sampling of the diurnal cycle caused by the topography of the sites was excluded.

The above conclusions are based on the analysis of Brewer instruments data while the Arosa long term record is based on Dobson measurements. Therefore the question of the validity of these results could be raised. The analysis of the agreement between the two types of instruments was the subject of the publication by *Scarnato et al.* (2009). It was shown that the time series of the differences between coincident data presented a seasonal cycle which were reduced by a correction based on the SC and taking into account of the temperature of the ozone layer. Later on, *Redondas et al.* (2014) have shown that these differences were further reduced by the introduction of the ozone cross section recently published by the University of Bremen (*Gorshchev et al.*, 2014; *Serdyuchenko et al.*, 2014). The agreement between the Arosa Brewer and Dobson data were shown to agree to  $\leq 1\%$  which no significant seasonal difference.

## 5 Conclusions

The motivation for this work was the perspective of a continuation of the Arosa total ozone column series at the Davos site. The analysis of the campaign data between the two stations separated horizontally by 13 km and vertically by 260 m showed that the two sites agree to better than  $\sim 0.5\%$ , which represents the limit of the combined long term stability and the precision of Brewer instruments. The monthly median differences are of the order of  $\sim 0.2\%$ , superimposed with an additional seasonal cycle of the same order, none of these numbers being significant at the 95% confidence level. It remains speculative if the altitude difference could be the reason of the small but not significant difference on the ozone column. The quality of the Arosa data set and especially its continuity has always been a great concern in the maintenance and development of the LKO observatory. From this analysis, it can be concluded that the ozone column series initiated at Arosa in 1926 would not been disrupted by a change of site. Local factors potentially influencing the measurements are below the measurements variability and stay below the long term stability of the Brewer instruments and within the uncertainties associated to the calibration procedures of the Brewer network. The introduction of the more recent laboratory measured ozone cross-sections in the processing of Brewer data as well as of the ozone layer effective temperature in the Dobson ozone column calculation assure the safe transfer of the

conclusions presented above to the Arosa long term record based on Dobson instruments. The confirmation of these results with automated Dobson instruments is presently underway and the results will be reported after completion of this second parallel measurements campaign.

## **6 Data availability**

- 5 The data used for this analysis are available at the WOUDC for the Brewer  $B_{040}$  instrument. The complete data sets can be requested by direct contact with the corresponding author. In a near future, they all will be available at the EUBREWNET data center (see European Cooperation in Science and Technology: COST ES 1207: A European Brewer Network (EUBREWNET), <http://www.eubrewnet.org>).

*Author contributions.* R. Stübi has made the analysis of the data and written the first version of the manuscript. H. Schill was in charge of  
10 the quality control and the preparation of the data sets. L. Egli was responsible for the daily control of the Brewer  $B_{072}$  in Davos. J. Klausen, L. Vuilleumier, J. Gröbner, L. Egli and D. Ruffieux have revised the manuscript.
