14 **Abstract**

15 Observations of multiwavelength Mie-Raman lidar taken during the SHADOW field
16 campaign are used to analyze a smoke/dust episode over West Africa on 24-27 December 2015.
17 For the case considered, the dust layer extended from the ground up to approximately 2000 m
18 while the elevated smoke layer occurred in the 2500 m – 4000 m range. The profiles of lidar
19 measured backscattering, extinction coefficients and depolarization ratios are compared with the
20 vertical distribution of aerosol parameters provided by the Modern-Era Retrospective analysis
21 for Research and Applications, Version 2 (MERRA-2). The MERRA-2 model simulated the
22 correct location of the near-surface dust and elevated smoke layers. The values of modeled and
23 observed **extinctions** at both 355 nm and 532 nm are also rather close. Good coherence between
24 measured and modeled extinction profiles provides an opportunity to test how well the model
25 reproduces backscattering of dust particles at different wavelengths. The comparison shows good
26 agreement of modeled and measured backscattering coefficients at 355 nm, meaning that the
27 modeled dust lidar ratio of 65 sr in the near-surface layer is close to the observed **value** at 532
28 nm however, the simulated lidar ratio is lower than measurements (about **40 sr and 50 sr**
29 respectively). The reason for this disagreement could be that the assumed imaginary part of the
30 refractive index for dust (0.0025 at 532 nm) is too low, or that the particle size distribution in the
31 model is too much weighted toward fine mode dust. The model predicts significant concentration

1 of dust particles inside the smoke layer. This is supported by a **high** depolarization ratio of 15%
2 observed in the center of this layer. The backscattering Ångström exponent at 355/532 nm as
3 well as both lidar ratios have a minimum in the center of the elevated layer, which can also be
4 explained by the presence of dust.

5

6

7 **1. Introduction**

8 Atmospheric aerosols are an important factor influencing the Earth's radiative budget,
9 though its impact is still highly uncertain due largely to the complicated mechanisms of aerosol –
10 cloud interaction. In particular, the processes in the aerosol – cloud ecosystem are strongly
11 influenced by the height distribution of different aerosol components, thus the knowledge of
12 these height distributions is essential to decrease the uncertainty of aerosol radiative forcing
13 estimates. Lidar is a recognized instrument for vertical profiling of aerosol properties, and the
14 possibility to invert lidar observations at several wavelengths to aerosol microphysical properties
15 has been extensively studied both theoretically and experimentally over the two past decades
16 (e.g. Müller et al., 1999; 2016; Veselovskii et al., 2002; Böckman et al., 2005). These studies
17 revealed the importance of using Raman or HSRL (high spectral resolution lidar) systems, which
18 allow independent measurements of aerosol extinction and backscattering coefficients to be
19 made. At present, the most practical configuration of Raman (HSRL) lidar is based on a **triple**
20 Nd:YAG laser. Such a lidar provides the so called $3\beta+2\alpha$ set of observations, including three
21 backscattering (355 nm, 532 nm, 1064 nm) and two extinction (355 nm, 532 nm) coefficients.

22 However the problem of inversion of $3\beta+2\alpha$ observations is **underdetermined**. As a result,
23 instead of a unique solution, a family of solutions should be considered, leading to an increase in
24 retrieval uncertainties. Still the estimation of volume density (V) and effective radius (r_{eff}) with
25 uncertainty below 30% is possible, especially when the fine mode in the particle size distribution
26 (PSD) is predominant (e.g. Veselovskii et al., 2004; Müller et al., 2005; 2016; Pérez-Ramírez et
27 al., 2013,). The refractive index (RI) can be also estimated from the measurements, although the
28 uncertainty of such estimation is significant: for the real part (m_R) of RI the uncertainty is
29 normally about ± 0.05 and for the imaginary part (m_I) it is about 50% when $m_I > 0.01$.
30 (Veselovskii et al., 2004; Müller et al., 2016). Proposed improvements of inversion schemes
31 were considered in recent publications (Chemyakin et al., 2014; Kolgotin et al., 2016), still these

1 improvements  don't resolve the fundamental issue: the information content of $3\beta+2\alpha$
2 observations is insufficient to support exact solution of the problem and additional information
3 should be used in retrievals to improve the accuracy of the retrieved products (Veselovskii et al.,
4 2005; Burton et al., 2016; Kahnert and Andersson, 2017; Alexandrov and  Mishchenko 7).

5 We should recall also that in the inversion schemes considered, the refractive index is
6 normally assumed to be spectrally and size independent, which is generally not the case in the
7 atmosphere. Moreover, the volume density and effective radius obtained from $3\beta+2\alpha$
8 observations are attributed to the whole size distribution, which is of limited practical use,
9 because of the importance of characterizing the particle properties separately for the fine and
10 coarse modes. Considering these issues makes the inverse problem even more underdetermined,
11 emphasizing the need for additional input information.

12 One opportunity to get this additional information is  combining the lidar observations
13 with aerosol transport models (Kahnert and Andersson, 2017). Models provide the vertical
14 distribution of mass mixing ratios of chemical aerosol components, which can be used as “initial
15 guess” in the inversion scheme. MERRA-2 offers a unique opportunity to provide such an
16 “initial guesses” of the vertical structure of aerosol chemical composition. MERRA-2 is
17 produced with NASA’s global Earth system model, GEOS-5 (Goddard Earth Observing System
18 version 5) (Gelaro et al 2017) and includes an online coupling with the Goddard Chemistry,
19 Aerosol, Radiation and Transport model (GOCART), which allows for assimilation of aerosol
20 optical depth (AOD) from space borne and surface instruments such as MODIS, AVHRR,
21 MISR, and AERONET (Randles et al. 2017). The fundamental data that MERRA-2 provides are
22 vertical profiles of the mass mixing ratios of five aerosol components: dust, sea salt, black and
23 organic carbon, and sulfate aerosols. The main optical parameters related to lidar measurements,
24 such as aerosol extinction and backscattering coefficients can be calculated basing on these data.
25 The principal question arising, however, is how well the reanalysis reproduces independent
26 observations, and thus can provide a realistic initial guess for a lidar inversion scheme. Buchard
27 et al. (2017) and Randles et al (2017) extensively validated MERRA-2 with independent surface
28 and aircraft observations of particulate matter (PM_{2.5}) and AOD, as well as space-based
29 observations of absorption aerosol optical depth and aerosol index, finding generally good
30 agreement between the observations and MERRA-2.

1 For global validation of the aerosol vertical distribution, the modeled profiles of
2 attenuated backscatter were compared to spaceborne Cloud–Aerosol Lidar with Orthogonal
3 Polarization (CALIOP) observations (Winker et al., 2009), and a good consistency between
4 simulations and observations was reported (Nowottnick et al., 2015, Buchard et al., 2017).
5 However, the utility of CALIOP observations for accurate evaluation of aerosol vertical
6 distributions is limited as only elastic backscatter is analyzed and the signal to noise ratio of
7 space borne measurements is low. More opportunities for model validation are provided by
8 ground based multiwavelength Raman or HSRL systems. Such lidars by their nature have limited
9 spatial coverage but are better suited for characterization of the vertical distribution of particle
10 properties at a chosen location.

11 In our paper, we consider Raman lidar observations taken during a smoke/dust episode
12 over West Africa in December 2015 during the SHADOW campaign (Veselovskii et al., 2016),
13 and compare the vertical profiles of particle parameters with MERRA-2. The simultaneous
14 presence of dust and smoke layers in the atmosphere provides an opportunity to test the ability of
15 the model to reproduce the vertical structure of aerosol properties over the observation site.

16

17 **2. Measurement setup and data analysis**

18 **2.1 Observation site**

19 The observation site is located at the Institute for Research and Development (IRD)
20 Center, Mbour, Senegal (14⁰N, 17⁰W). Information about the SHADOW (study of SaHAran
21 Dust Over West Africa) campaign and instruments at the IRD site can be found in the recent
22 publication by Veselovskii et al. (2016). During the SHADOW campaign data from three lidar
23 instruments were available:

24 • Cimel CE-370 micropulse lidar (www.cimel.fr) operated 24 hours per day at 532 nm
25 allowing real-time monitoring of aerosol and cloud layers.

26 • Doppler lidar Windcube WLS 100 (www.leosphere.com) provided continuous
27 monitoring of the wind field in the range from 100 m to 5 km with 50 m range resolution.

28 • Multiwavelength Mie - Raman polarization lidar LILAS (Lille Lidar AtmosphereS),
29 allowed simultaneous detection of elastic and Raman backscatter signals and thus provides
30 $3\beta+2\alpha$ observations along with depolarization ratio at 532 nm.

1 LILAS measurements were performed from inside a laboratory building through a
 2 window at an angle of 47 deg with respect to the horizon. Acquiring Raman backscatter at 408
 3 nm also permits profiling of the water vapor mixing ratio (WVMR) (Whiteman et al., 1992). For
 4 calibration of the water vapor channel, radiosonde launches from Dakar (about 70 km away from
 5 Mbour) were used. The large separation between the lidar and radiosonde locations prevented an
 6 accurate calibration, so the WVMR data were used mainly to monitor the relative change of the
 7 water vapor content. The temporal resolution of the measurements was approximately 3 minutes.
 8 The backscattering coefficients and depolarization ratio were calculated with range resolution 7.5
 9 m (with corresponding height resolution of 5.5 m). Resolution of extinction coefficient
 10 measurements varied with height from 50 m (at 1000 m) to 125 m (at 7000 m).

11 Particle extinction (α) and backscattering (β) coefficients at 355 nm and 532 nm are
 12 calculated from elastic and Raman backscatter signals, as described in Ansmann et al. (1992).
 13 Backscattering coefficients at 1064 nm were calculated by the Klett method (Klett, 1981).

14 In the data analysis both volume (δ^v) and particle (δ) depolarization ratios are considered.
 15 These ratios are defined as

$$16 \quad \delta^v = \frac{\beta_{\perp}^p + \beta_{\perp}^m}{\beta_{\parallel}^p + \beta_{\parallel}^m} = C \frac{P_{\perp}}{P_{\parallel}} \quad (1)$$

$$17 \quad \delta = \frac{\beta_{\perp}^p}{\beta_{\parallel}^p} \quad (2)$$

18 Here P is the power of the elastic backscatter signal. Superscripts “p” and “m” indicate particle
 19 and molecule backscattering, while subscripts “ \perp ” and “ \parallel ” indicate cross- and co-polarized
 20 components, C is the calibration constant. Particle depolarization is calculated as suggested by
 21 (Freudenthaler et al., 2009):

$$22 \quad \delta = \frac{(1 + \delta^m) \delta^v R - (1 + \delta^v) \delta^m}{(1 + \delta^m) R - (1 + \delta^v)} \quad (3)$$

23 here δ^m is the molecular depolarization ratio and R is the aerosol scattering ratio:

$$24 \quad R = \frac{\beta^p + \beta^m}{\beta^m} \quad (4)$$

1 For further convenience we will use notations $\beta = \beta_{\text{H}}^p + \beta_{\text{I}}^p$, and $\alpha = \alpha^p$. To characterize the
2 spectral dependence of β and α , the backscattering and extinction Ångström exponents (BAE and
3 EAE) for wavelengths λ_1 and λ_2 are calculated as:

$$4 \quad A^\beta = -\frac{\ln\left(\frac{\beta_{\lambda_1}}{\beta_{\lambda_2}}\right)}{\ln\left(\frac{\lambda_2}{\lambda_1}\right)}, \quad A^\alpha = -\frac{\ln\left(\frac{\alpha_{\lambda_1}}{\alpha_{\lambda_2}}\right)}{\ln\left(\frac{\lambda_2}{\lambda_1}\right)} \quad (5)$$

5

6 **2.2 MERRA-2 aerosol reanalysis**

7 The MERRA-2 simulations of aerosol properties over the observation site were made
8 using the GOCART model (Chin et al. 2002) integrated within GEOS-5. The model includes
9 representations of dust, sea salt, black and organic carbon, and sulfate aerosols. The aerosol
10 components are assumed to be externally mixed. The optical properties of these aerosol
11 components are summarized in Appendix 1. Sulfate and carbonaceous aerosols are both assumed
12 to be in the fine mode. Sea salt and dust are both represented by five size bins spanning 0.1 – 10
13 microns radius for dust and 0.03 – 10 microns dry radius for sea salt, allowing for simulation of
14 both the fine and coarse fractions of each. A more complete description of how GOCART is
15 implemented in GEOS-5 is provided in Colarco et al. (2010), which also includes a detailed
16 evaluation of the model with respect to MODIS, MISR, and AERONET aerosol optical depth
17 observations.

18 **Optical properties of the aerosols** are primarily based on Mie calculations using the
19 particle properties as in Colarco et al. (2010) and Chin et al. (2002), with spectral refractive
20 indices from the Optical Properties of Aerosols and Clouds (OPAC, Hess et al. 1998) database.
21 However, for dust, non-spherical optical properties derived from an offline database are used
22 (Colarco et al. 2014). For sea salt, sulfate, and the hydrophilic portion of carbonaceous aerosol,
23 hygroscopic growth is considered following Chin et al. (2002), with growth factors from OPAC
24 **and Gerber** (1985). The refractive index for organic carbon is based on the 100% brown carbon
25 case from Hammer et al. (2016) and it is implemented as described in Colarco et al. (2017).

26 **Sources** of aerosols in the model include wind-speed based emissions of dust and sea salt,
27 fossil fuel combustion, biomass burning, biofuel consumption, biogenic particulate organic
28 matter, and oxidation of di-methyl sulfide (DMS) and SO₂, which includes volcanic sources.

1 Aerosol sinks include convective scavenging, dry deposition, and wet removal, where aerosol
2 hygroscopic growth is considered in the calculation of particle fall velocity and deposition
3 velocity. The model resolution is $0.5^\circ \times 0.625^\circ$ latitude by longitude with 72 hybrid-eta layers
4 from the surface to 0.01 hPa. Additional details of the simulation can be found in Randles et al.
5 (2017) and Buchard et al. (2017).

6 In MERRA-2, aerosol and meteorological observations are jointly assimilated within
7 GEOS-5. Aerosols are assimilated by means of analysis splitting and the local displacement
8 ensemble (LDE) methodology (Buchard et al. 2015, 2016). The system assimilated MODIS,
9 AVHRR, MISR, and AERONET 550 nm AOD. AERONET measurements are interpolated to
10 550 nm using the Angström relationship and the closest available channels, generally 500 and
11 675 nm. The assimilation determines an AOD increment, which corrects the model AOD in a
12 way that minimizes the differences between the model and observations. The AOD increment
13 both corrects for misplaced aerosol plumes, and scales the aerosol mass mixing ratio to match the
14 observations. The 2D AOD increment does not contain enough information to correct either the
15 vertical distribution of aerosols or the aerosol composition. Thus, the model determines the
16 aerosol speciation, optical properties, and vertical distributions, while the AOD increments
17 modulate the aerosol mass. Thus, the assimilated aerosol distributions and physical and optical
18 properties arise from the forecast model assumptions and the formulation of the aerosol data
19 assimilation algorithm.

20

21 3. Results of the measurements

22 The smoke layers from forest fires near the equator were regularly observed over the
23 instrumentation site during the wintertime measurement sessions made in December 2015 –
24 January 2016. In our study we will focus on a strong smoke episode that occurred on 24-27
25 December 2015. The back trajectories for the air mass over Mbour on 25 December 2015 at
26 04:00 UTC are shown in [fig. 1](#)   [together with map of fires on 20 December 2015](https://worldview.earthdata.nasa.gov)
27 [\(<https://worldview.earthdata.nasa.gov>\)](https://worldview.earthdata.nasa.gov).

28 The air masses below 1500 m (red and blue lines) are transported over the desert and are
29 strongly loaded by dust, while air masses at 3000 m (green line) arrive from the South and pass
30 over the regions of forest fires, and thus can transport smoke particles. The Cimel MPL operated
31 continuously through the period of 24-27 December and thus monitored the arrival and evolution

1 of the smoke layer, as shown in [fig. 1](#). An elevated smoke layer appears on 24 December around
2 00:00 UTC. The [layer](#) becomes thicker during the day but remains confined to the height interval
3 of 2.5 km– 4.0 km and stays well separated from the dust layer, which extends from the ground
4 to approximately 2.0 km. Such structure of the layers is preserved throughout 25 December, as
5 well.

6 Cirrus clouds appear at 08:00 UTC on 24 December at a height of 8 km, soon after the
7 smoke layer arrival ([fig. 2](#)) and persist throughout the smoke episode. After 12:00 UTC on 24
8 December the clouds start descending and by [7](#) UTC on 25 December the cloud base is below
9 6 km ([fig. 2](#)). On 26 December strong precipitation of ice particles occurs ([fig. 2c](#)) and finally, on
10 27 December the cloud is located at the top of the smoke-dust layer ([fig. 2d](#)).

11 Multiwavelength Raman lidar observations are available for the 23-25 December period
12 only. The height – temporal evolution of the backscattering coefficient β_{532} , depolarization
13 ratio δ_{532} and water vapor mixing ratio w measured by Raman lidar on the nights 23-24 and 24-
14 25 December 2015 are shown in [fig. 3](#). Due to the geometrical overlap factor the extinction data
15 can be processed starting from approximately 750 m, thus plots of all parameters start at this
16 height. The depolarization ratios of pure dust observed during SHADOW are in the 30-35%
17 range ([Veselovskii et al., 2016](#)), the depolarization ratio of smoke at 532 nm normally is
18 below 10% (e.g. Tesche et al., 2011, Burton et al., 2015). Hence depolarization measurements
19 provide a convenient way to separate the aerosols into dust and smoke components. On the
20 of 23-24 December the dust layer extends up to 2500 m, but high depolarization ratio (>30%),
21 which is usually associated with pure dust, is observed only below 1000 m, meaning that in 1000
22 m – 2500 m range the dust is probably mixed with smoke. The optical depth of the elevated
23 smoke layer is rather small on 23-24 December (0.1 at 5:00 UTC), but on 24-25 December it
24 increases up to 0.25 making possible the calculation of extinction coefficients from the Raman
25 lidar signals. For analyzing the vertical distribution of smoke and dust particle parameters, we
26 focus on the nighttime measurements of 24-25 December 2015.

27 [Fig. 4](#) shows horizontal wind direction and speed measured by the wind lidar on 24-25
28 December. The range corrected signal of the wind lidar can be evaluated starting from 100 m
29 height, and the corresponding height – temporal image is shown in [fig. 5](#). The wind speed was
30 measured in the dust layer (< 1500 m) for the whole period, however inside the smoke layer the
31 backscatter signal is lower, so the measurements were possible only in the period of 16:00-22:00

1 UTC on 24 December. During 24-25 December 2015, the wind in the low troposphere (<1500
2 m) is mainly dominated by the easterly Harmattan continental trades. Deceleration and
3 acceleration of the lower part of the Harmattan (<1000 m) are observed, respectively in the
4 beginning of the afternoon and during the night. The vertical profile of the wind speed
5 demonstrates the presence of a Low Level Jet (LLJ) where the maximum wind speed (Jet speed)
6 is located at a height of 350 m (LLJ height) at 1:00 UTC. LLJs are known to contribute to
7 regional horizontal aerosol transport and to increase vertical mixing. Indeed, the LLJ occurrence
8 at 1:00 UTC increases the aerosol loading by transporting desert dust. The corresponding
9 increase of backscattering due to the LLJ at 1:00 UTC on 25 December can also be seen in [fig. 5](#)
10 [Vertical](#) profiles of temperature T , potential temperature Θ , wind direction and speed
11 together with relative humidity RH and water vapor mixing ratio (WVMR) from radiosonde
12 launched from Dakar at 00:00 UTC on 25 December 2015 are shown in [fig. 6](#). The profile of
13 wind speed and wind direction obtained from the sonde confirms that the LLJ observed with
14 lidar at Mbour is not a local phenomenon, because it is also observed at Dakar. The vertical
15 profile of potential temperature suggests that the Nocturnal Boundary Layer (NBL) top
16 corresponds to the LLJ height. Above 3000 m, the lidar and sonde depict southerly winds which
17 transport the smoke plume. [Water](#) vapor mixing ratio increases above 2500 m; as a result the RH
18 in the smoke layer reaches 75% while in the dust layer RH is below 30%.

19 To quantify the vertical distribution of particle parameters, [fig. 7](#) shows profiles of
20 backscattering (β_{355} , β_{532} , β_{1064}) and extinction (α_{355} , α_{532}) coefficients derived from Raman lidar
21 measurements for three temporal intervals on the night of 24-25 December: 19:00-23:00 UTC,
22 1:00-4:00 UTC and 4:00-7:00 UTC. The particle depolarization ratios δ_{532} for the same intervals
23 together with the water vapor mixing ratio w are shown in [fig. 8](#), while extinction and
24 backscattering Ångström exponents $A_{355/532}^{\alpha}$, $A_{355/532}^{\beta}$, $A_{532/1064}^{\beta}$ are given by [fig. 9](#). For the first
25 temporal interval ([fig. 7a](#)) dust and smoke layers are well separated. Extinction coefficients α_{355}
26 and α_{532} differ in the smoke layer ($\alpha_{355} > \alpha_{532}$), but inside the near-surface dust layer (below 1750
27 m) the extinction values are nearly the same. The depolarization ratio is $\delta_{532} = 35 \pm 5\%$ at 750 m
28 and it gradually decreases with height to $27 \pm 4\%$ at 1750 m. Above that height δ_{532} decreases
29 quickly, indicating an increase in the contribution of smoke particles. For the second and third
30 temporal intervals the dust and smoke layers appear to mix leading to layering in the

1 backscattering coefficient in the 1000 m – 2000 m range. The EAE in this range is increased up
2 to 0.5 (fig.9c) indicating that these layers may contain significant amounts of smoke.

3 The EAE of pure dust observed during SHADOW is slightly negative $A_{355/532}^{\alpha} \approx -0.1$
4 (Veselovskii et al., 2016). In (fig.9a) the EAE below 1500 m is about 0.2 ± 0.2 , so the dust likely
5 contains some amount of smoke. Values of EAE close to zero are observed in (fig.9b) below
6 1000, where the depolarization ratio increases up to $35 \pm 5\%$. Inside the dust layer $\beta_{355} < \beta_{532}$, so
7 the corresponding backscattering Ångström exponent is negative. The negative values of $A_{355/532}^{\beta}$
8 have been already reported by Veselovskii et al., (2016), where negative BAE was attributed to
9 an increase of the imaginary part of the complex refractive index at 355 nm compared to 532 nm.
10 In the center of the elevated layer at 3100 m $\delta_{532} = 14 \pm 3\%$, while at the top of this layer δ_{532}
11 decreases to $6 \pm 1.5\%$ (fig.8a), indicating a possible presence of dust particles in the center of
12 elevated layer. The loading of elevated layer with dust particles is supported also by the profiles
13 of $A_{355/532}^{\beta}$: for all three temporal intervals $A_{355/532}^{\beta}$ demonstrates the dip in the center of elevated
14 layer, while $A_{355/532}^{\alpha}$ and $A_{532/1064}^{\beta}$ do not decrease (fig.9c) 0- 4000 m range. As mentioned, for pure
15 dust $A_{355/532}^{\beta}$ is negative, so presence of dust in the center of smoke layer should decrease the
16 backscattering Ångström exponent. The presence of dust in the smoke layer is not surprising,
17 because upwelling airflows in forest fires region can lift a significant amount of dust together
18 with biomass burning products.

19 Profiles of lidar ratios at 355 nm and 532 nm, for the same temporal intervals as in (fig.7)
20 are shown in (fig.10). Lidar ratios in the dust layer at 532 nm and 355 nm for 19:00-23:00 UTC
21 period are $LR_{532} = 55 \pm 8$ sr and $LR_{355} = 70 \pm 10$ sr, respectively. At the top of the elevated layer,
22 where the smoke particles are predominant, the lidar ratios for the same period are higher:
23 $LR_{532} = 65 \pm 10$ sr and $LR_{355} = 75 \pm 11$ sr. Due to the presence of dust in the center of the elevated
24 layer, the height dependence of lidar ratios shows a decrease, with a minimum at approximately
25 3000 m for all three temporal intervals. The decrease is more pronounced at 532 nm, because the
26 difference between smoke and dust lidar ratios is larger at this wavelength. The lidar ratios below
27 2000 m at 01:00-04:00 and 04:00-07:00 UTC become strongly oscillating because of high
28 gradients of backscattering and extinction coefficients at low altitudes and are not shown due to
29 high uncertainties.

1  Fig. 11, shows the dependence of the particle depolarization ratio δ_{532} on the extinction
2 Ångström exponent derived from data in  fig. 7. The depolarization ratio monotonically
3 decreases while EAE rises from 0 to 0.9.  The observed high values of the depolarization ratio
4 are attributed to big dust particles with EAE close to zero, while small smoke particles are
5 characterized by low depolarization (below 10%). If depolarization ratios of smoke δ^s and dust δ^d
6 are known, the contributions of smoke and dust particles to the total backscattering can be
7 separated $\beta = \beta^s + \beta^d$ (Sugimoto and Lee, 2006; Tesche et al., 2009; Miffre et al., 2012; David
8 et al., 2013, Burton et al., 2014). Assuming  that the depolarization ratios of dust and smoke particles
9 do not change with height the contributions β^d and β^s can be calculated as suggested by Tesche et
10 al. (2009):

$$11 \quad \beta^d = \beta \frac{(\delta - \delta^s)(1 + \delta^d)}{(\delta^d - \delta^s)(1 + \delta)} \quad \text{and} \quad \beta^s = \beta - \beta^d, \quad (6)$$

12 In our computations we used values $\delta^d = 35\%$ and $\delta^s = 7\%$.

13 The results of the decomposition of β_{532} for β_{532}^d and β_{532}^s components for the same three
14 temporal intervals as in  fig. 7 are shown in  fig. 12. This figure presents  total backscattering
15 coefficient β_{532} together  with particle depolarization ratio δ_{532} . The dust contribution to
16 backscattering is marked with magenta,  while individual backscattering $\beta_{532} - \beta_{532}^d$ is attributed to
17 the smoke and is marked with grey. For the height regions with low backscattering the
18 uncertainty of β_{532} is high, so the decomposition for these regions is not shown. The dust is
19 predominant below 1700 m for 19:00-23:00 UTC period, however even the elevated layer
20 contains a significant amount of dust: at 3100 m $\beta_{532}^d \approx 0.3\beta_{532}$. After 01:00 UTC the smoke
21 layers descend  and their contribution to backscattering becomes significant down to 1000
22 m height. We should recall that though lidars were widely used for the study of smoke layers
23 over Europe and United States (e.g. Amiridis et al., 2009; Nicolae et al., 2015; Burton et al.,
24 2015; Veselovskii et al.,  2015) contribution of dust to the smoke layers properties was
25 normally not considered. However, the contribution of dust may become important since dust
26 particles in Africa can be lifted during the forest fire and transported over large distances.

27

28 **4. Comparison of lidar measurements with MERRA-2**

1 MERRA-2 [profiles](#) vertical distribution of mass mixing ratios of five aerosol
2 components, so for each of these components the extinction, backscattering coefficients and
3 depolarization ratios can be calculated. [Vertical](#) profiles of extinction coefficient of dust, black
4 carbon (BC), organic carbon (OC), sea salt (SS) and sulfates (SU) together with total extinction
5 α_{532} are shown in [fig.13](#) for 03:00 UTC and 21:00 UTC on 24 December 2015. At 03:00 UTC
6 the aerosol is localized below 3000 m. Dust extinction is predominant, but contribution of OC to
7 the total extinction coefficient rises with height reaching maxima at 2250 m. The presence of a
8 significant amount of OC agrees with the low values of depolarization ratio above 1500 m for
9 this temporal interval in [fig.3](#)

10 At 21:00 UTC an elevated layer with a maximum of extinction at 3150 m is observed
11 [\(fig.13b\)](#). In this layer OC and dust provide similar contributions to extinction (about 40% at
12 3150 m height). From the results shown in [fig.12a](#) we can estimate the contribution of dust to
13 α_{532} in the center of elevated layer as 30% (by assuming the dust lidar ratio $LR_{532}=55$ sr), so the
14 measured and simulated dust contributions are in good agreement. Below 1750 m the dust is the
15 main contributor to the extinction coefficient providing 88% of α_{532} at 1000 m [\(fig.13a\)](#). The
16 observed dust contribution to α_{532} at the same height is about 90% [\(fig.12a\)](#), which again shows
17 good agreement between the model and measurements. Total contribution of BC and SU to
18 extinction is below 20% in the elevated smoke layer, and in the near-surface dust layer their
19 contribution is negligible. The extinction coefficients can be recalculated to the backscattering
20 using model lidar ratios of the aerosol components. Fig.13c shows the profiles of backscattering
21 coefficients at 532 nm computed for the same temporal interval as in Fig.13b. The simulation of
22 the backscattering coefficient is more challenging than that of extinction, because backscatter
23 depends more strongly on the particle morphology and refractive index. A detailed comparison
24 of measured and modeled profiles of backscattering coefficients will be performed later in this
25 section.

26 As mentioned, the comparison of model and observed values is more straightforward for
27 extinction coefficients. Fig.14 shows the time-series of extinction profiles at 355 [nm](#) and 532 nm
28 modeled for the night of 24-25 December 2015 at 18:00, 21:00, 00:00, 03:00, 06:00 UTC. The
29 profiles are shifted relative to each other on 0.1 km^{-1} . The corresponding profiles of extinction
30 coefficients measured by Raman lidar are shown in [fig.15](#). [fig.15](#) convenience of comparison,
31 [fig.16](#) presents measured and modeled α_{355} profiles from [fig.14](#) and [fig.15](#) now plotted together.

1 The model reproduces well the location of the elevated smoke layer, as well as the top of the
2 near-surface dust layer. However, the model does not resolve the oscillations of extinction
3 profile below 2000 m at 03:00 and 06:00 UTC on 25 January.

4 To quantify the difference between measured ($\alpha_{355}^{\text{meas}}$) and modeled ($\alpha_{355}^{\text{mod}}$) extinction
5 coefficients at 355 nm, [fig. 17](#) shows profiles of extinctions difference $\Delta\alpha_{355} = \alpha_{355}^{\text{meas}} - \alpha_{355}^{\text{mod}}$ for
6 results from [fig. 16](#). The difference is normally below 0.1 km^{-1} . The frequency distribution of
7 $\Delta\alpha_{355}$ for all five profiles is shown in [fig. 18](#). The mean value is -0.01 km^{-1} with standard
8 deviation of 0.042 km^{-1} . With typical values of extinction coefficient in elevated smoke layer and
9 near-surface dust layer being on the order of 0.2 km^{-1} , the relative difference of modeled and
10 measured extinction is estimated to be below 25% for the time period considered.

11 To analyze how well the model reproduces the temporal variations of aerosol optical
12 depth, [fig. 19](#) presents AODs at 355 nm on 23 – 24 December 2015 for two height intervals: 750
13 m – 2000 m and 2500 m – 4500 m. The first interval corresponds to the near-surface dust layer,
14 while the second interval corresponds to the elevated smoke layer. The AOD is calculated from
15 the Raman backscatter in the day time measurements could be processed only in the dust
16 layer, due to enhanced background noise. Thus day time measurements in the elevated smoke
17 layer are not plotted. The time of the appearance of the smoke layer is well represented in the
18 model results (about 00:00 UTC on 24 December), however the lidar derived AOD of this layer
19 increases rapidly from the first appearance of the layer, while in the model the rapid increase in
20 AOD growth starts approximately 5 hours later. The model predicts that the maximum value of
21 AOD in the smoke layer (0.27) is reached at 20:00–24:00 UTC interval, which reasonably agrees
22 with observations: mean value of measured AOD for this interval is 0.23 ± 0.02 . After midnight
23 the modeled AOD of the smoke layer decreases quickly, while lidar measured AOD stays about
24 0.25. The measured AOD of the near-surface layer agrees with the model. The observed AOD
25 exceeds the model values in the beginning (at 00:00 UTC on 24 December measured and
26 modeled AODs are 0.24 and 0.175, respectively), but after 10:00 UTC, the values are in better
27 agreement. Thus, we can conclude that the model reproduces the temporal variability of AOD in
28 the dust and smoke layers.

29 The agreement between modeled and observed extinction profiles provides an
30 opportunity to test how well the backscattering coefficients can be modeled. Simulation of
31 backscattering coefficients is especially challenging for dust for several reasons. First of all, we

1 are not confident in the accuracy of the presumed scattering phase function in the backward
 2 direction. Second, the backscattering coefficient strongly depends on the particle refractive
 3 index, in particular on the imaginary part, which may vary over a wide range depending on dust
 4 origin. The in situ ground measurements in West Africa, performed during the SAMUM field
 5 campaign, demonstrate that the mean value of m_I for dust episodes is about 0.003 at 532 nm and
 6 0.02 at 355 nm. However deviation from these mean values for every individual measurement
 7 can be significant (Müller et al., 2009; Kandler et al., 2011; Ansmann et al., 2011). The
 8 imaginary part of RI of dust in the model is assumed to be 0.007 at 355 nm, following previous
 9 OMI data analysis (Torres et al., 2007) and 0.0025 at 532 nm.
 10 Fig. 20 shows measured and modeled backscattering coefficients at 355 nm and 532 nm
 11 for the same five temporal intervals as in fig. 16. At 355 nm the modeled and measured values
 12 agree for both the smoke and dust layers. However at 532 nm the backscattering coefficients
 13 agree only inside elevated layer, while below 1750 m the modeled β_{532} significantly exceeds the
 14 measured values. As mentioned, the modeled lidar ratio LR_{532} for the mixture is close to 40 sr at
 15 1000 m, while the measured lidar ratio in the near surface dust layer is 55 ± 8 sr. The reason for
 16 this disagreement could be that the assumed imaginary part of the refractive index for dust
 17 (0.0025 at 532 nm) is too low. Recall however, that we cannot determine the imaginary part of
 18 the refractive index for dust by simply adjusting the modeled lidar ratio to the measured one,
 19 because the lidar ratio depends on several factors besides m_I , such as the particle size distribution
 20 and the aspect ratio of the ellipsoids used in the model. It is possible that the particle size
 21 distribution in the model is too much weighted toward fine mode dust.

22 The modeled and measured particle intensive parameters, such as extinction $A_{355-532}^\alpha$ and
 23 backscattering $A_{355-532}^\beta$ Ångström exponents together with the particle depolarization ratio δ_{532}
 24 are shown in fig. 21. The measurements are averaged over 19:00 – 23:00 UTC interval while
 25 modeled values are given for 21:00 UTC. The model reproduces well the observed vertical
 26 distribution of $A_{355-532}^\alpha$ both in the dust and the elevated layer. As follows from fig. 7a, inside the
 27 dust layer $\beta_{355} < \beta_{532}$, so the corresponding $A_{355-532}^\beta$ is negative with a minimum value of about -
 28 0.4. The model predicts values of $A_{355-532}^\beta$ as low as -1.4. The modeled BAE is sensitive to the
 29 choice of the imaginary part of RI at 355 nm and 532 nm and, as mentioned, the chosen
 30 $m_I(532)=0.0025$ may be too low for this episode. In the elevated layer the modeled $A_{355-532}^\beta$ is

1 close to the observed one. The modeled BAE has no minimum in the center of elevated layer,
2 because the modeled ratio of dust and OC aerosol concentrations shows only a small variation
3 throughout the elevated layer.

4 The model reproduces reasonably well the depolarization in the elevated layer, but inside
5 the dust layer the modeled δ_{532} is significantly lower than what is observed (22% compared to
6 35%). This problem is well known: the spheroidal model underestimates the depolarization ratio
7 when typical dust PSD and complex refractive index are used (Veselovskii et al., 2010; Wiegner
8 et al., 2009; Müller et al., 2013; Nowottnick et al., 2015).

9 One of the MERRA-2 data products is the water vapor mixing ratio (WVMR), which
10 helps to identify atmospheric parcels, is critically important for determining atmospheric stability
11 and serves as the source of water for aerosol hygroscopic growth. [Fig. 22](#) shows five model
12 profiles of WVMR [together](#) with the results of Raman lidar measurements for the same temporal
13 intervals as in [fig. 14](#). The model reproduces rather well the WVMR profile inside the elevated
14 layer (2500 m – 4500 m) on 24 December, though on 25 December the modeled values in this
15 range are lower than the observations. In the near-surface dust layer, the deviation of modeled
16 values from the measurements is larger. Statistical analysis [of the](#) deviation of modeled values
17 from lidar measurements for all five profiles (the same as in [fig. 18](#)), shows that mean difference
18 is 0.04 g/kg with standard deviation of differences of 1.6 g/kg. Thus in the elevated layer, where
19 WVMR is approximately 8 g/kg, the agreement is quite good, however in the dust layer, which is
20 characterized by low water vapor content (below 4 g/kg), the difference may be up to 40%.

21

22 **5. Inversion of lidar measurements to particle microphysical properties**

23 In the previous section, as validation of the model output we compared the modeled
24 aerosol optical parameters, such as extinction, backscattering coefficients, and depolarization
25 ratio with the values derived from lidar measurements in a straightforward way. The comparison
26 of particle microphysical properties such as volume, effective radius and complex refractive
27 index, however, is not straightforward, since it needs inversion of the measurements and requires
28 additional assumptions. In the case of dust particles the inversion becomes especially
29 challenging, because:

- 30 - The size distribution of dust contains a strong coarse mode with particle radii
31 extending up to ~ 15 μm , and the estimation of properties for such big particles is

- 1 difficult since measurements are only performed in the wavelength range 0.355-1.064
2 μm ;
- 3 - The inversions have to consider the refractive index as spectrally independent. In fact,
4 the imaginary part of the dust RI is spectrally dependent with a strong enhancement at
5 355 nm compared to 532 nm;
 - 6 - The dust particles are not spherical so that the application of Mie formulas for the
7 forward modeling results in errors in computing the scattering phase function.

8 Regarding **shape** issue, one of the ways to mimic the scattering properties of dust
9 particles is to use the model of randomly oriented spheroids (Mishchenko et al., 1997; Dubovik
10 et al., 2006). The implementation of this model for inversion of dust lidar measurements is
11 described in Veselovskii et al., (2010, 2016), and Müller et al., (2013). This algorithm was used
12 also for inversion of our $3\beta+2\alpha$ observations. The range of particle radius in the inversion has
13 been set to a minimum and maximum of 0.075 and 15 μm , respectively. The real part of RI was
14 allowed to vary in the range 1.35 - 1.65, while the imaginary part varied in the range 0 - 0.02.
15 The refractive index was assumed to be spectrally independent. The effects of a possible spectral
16 dependence of the imaginary part of RI were considered in Veselovskii et al., (2016).

17 Profiles of the effective radius, volume density, and real part of the refractive index
18 retrieved from optical measurements in **fig.7a** are shown in **fig.23**. The inversion was performed
19 for two cases, with the assumption of all spherical particles (SVF=0) or all spheroids
20 (SVF=100%). A realistic solution (for the mixture of spherical and non-spherical particles),
21 should be closer to spheroids in the dust layer, while in the elevated layer it should be closer to
22 the results obtained with spheres. The model results provided by MERRA-2 are shown on the
23 same plot. The effective radius and volume density obtained in assumption of spherical particles
24 are always higher than the values obtained with spheroids. The modeled effective radius at 1000
25 m height is 1.1 μm , which is close to $r_{\text{eff}}=1.0\pm 0.3 \mu\text{m}$ obtained from lidar measurements using
26 the spheroids model. Lidar derived effective radius in the elevated layer at 3000 m is
27 approximately 0.4 μm and 0.5 μm when spheroids and spheres are used respectively, while the
28 modeled value is 0.3 μm . The reason for the lower value of modeled effective radius is the
29 contribution of black carbon, which is characterized by small size and relatively low hygroscopic
30 growth. Recall that in the inversion of lidar measurements, the smallest radius considered is

1 0.075 μm . Modeled values of the volume density agree well with lidar retrievals in both dust and
2 elevated layers.

3 The estimation of the real part of RI from lidar measurements is sensitive to the type of
4 kernel functions chosen for retrieval. In the regularization algorithm the treatment of dust
5 particles as spheres strongly underestimates m_R (Veselovskii et al., 2010), so results obtained
6 with spheres in the dust layer are not shown in fig.23c. At 1000 m the m_R retrieved with
7 spheroids is 1.52 ± 0.05 , which agrees well with the modeled value. Inside the elevated smoke
8 layer, where fine mode particles predominate, the application of spheroids overestimates m_R . The
9 lidar derived real part of RI at 3000 m is 1.43 ± 0.05 for spheres and 1.51 ± 0.05 for spheroids, so
10 we expect that the true value would lie within this. The simulated value of $m_R = 1.50$ in the
11 elevated layer is quite high, which is again the result of BC contribution.

12 The single scattering albedo (SSA) is one of the key parameters to be retrieved and
13 conclusions about the potential of the multiwavelength lidar method strongly rely on its ability to
14 profile SSA. Fig.24 shows SSA at 355 nm, 532 nm and 1064 nm. As mentioned, the spectral
15 dependence of m_I was not accounted for and the algorithm retrieves an average value of the
16 imaginary part over the interval of 355 nm – 1064 nm. In particular, for dust and OC the
17 imaginary part is underestimated at 355 nm and overestimated at 532 nm and 1064 nm. As a
18 result, in the dust layer the retrieved SSA exceeds the model values at 355 nm, while at 532 nm
19 and 1064 nm the situation is opposite. Still at a height of 1000 m, the difference between modeled
20 and lidar derived SSAs is below 0.04 for all wavelengths. In the elevated layer, where the
21 spectral dependence of m_I is less pronounced, the simulated and retrieved SSA agree well with a
22 corresponding difference of less than 0.02.

23

24 6. Summary and conclusion

25 In our study we have considered a smoke/dust episode over West Africa to compare the
26 vertical profiles of particle parameters modeled by MERRA-2 and retrieved from Raman lidar
27 measurements. The Raman lidar provides profiles of backscattering and extinction coefficients at
28 355 nm and 532 nm with uncertainty below 10%, so comparison of these parameters with model
29 predictions can be considered as a type validation. In the case we selected, the simultaneous
30 presence of the dust and smoke layers resulted in significant height variation of particle

1 parameters, providing a good opportunity to test the models' capability to reproduce complicated
2 vertical structure.

3 Modeled and observed vertical profiles of α_{355} and α_{532} show good similarity: MERRA-2
4 provides the correct location of both the near-surface and elevated layers. The mean difference
5 between modeled and observed extinction coefficients for profiles considered is approximately
6 0.01 km^{-1} with standard deviation of 0.042 km^{-1} . Good coherence between measured and
7 modeled extinction provides an opportunity to test, how well the model reproduces particle
8 backscattering. One of the issues in such a comparison is the spectral dependence of the
9 imaginary part of the refractive index of dust. The m_I can change significantly for dust of
10 different origin and this variability may be accounted for in future model developments. Still
11 even for the current version, comparisons of modeled and measured β_{355} show good agreement in
12 the dust layer. At 532 nm however, the modeled backscattering coefficients in the dust layer
13 exceed the observed values. The modeled lidar ratio is about 40 sr, while the measured LR_{532} in
14 the dust layer is about 55 sr. This discrepancy may be an indication that m_I of dust during the
15 episode considered is higher than the value assumed in the model. Another possible explanation
16 is that the model particle size distribution is too much weighted toward fine mode dust. The
17 backscattering coefficients inside the smoke layer agree with modeled values for both 355 nm
18 and 532 nm wavelengths. The measured lidar ratios at the top of the elevated layer, where smoke
19 particles are predominant, are $LR_{355}=75\pm 11$ sr and $LR_{532}=70\pm 10$ sr, which is close to the
20 corresponding model values for organic carbon of 71 sr and 66 sr, respectively.

21 MERRA-2 predicts the existence of a significant amount of dust in the elevated smoke
22 layer, and the high values of observed depolarization ratio agree with this prediction. The
23 existence of minima of $A_{355/532}^{\beta}$ in the center of elevated layer, characterized by the highest δ_{532}
24 also supports this finding. Moreover, the lidar ratios at both 355 and 532 nm also have a minima
25 in the center of the layer because the lidar ratio of dust is lower than that of smoke. The
26 contributions of dust and smoke particles to the backscattering and extinction coefficient at 532
27 nm evaluated from particle depolarization ratio agree with the values provided by the model. We
28 should recall that in lidar studies of forest fire smoke variation of the depolarization ratio
29 throughout the smoke plume is usually related to the aging processes in the plume. However, we
30 should also consider the possibility that there may be mineral dust present in the plume, and
31 MERRA-2 modeling can be helpful for such an analysis.

1  Analysis of only one episode is not sufficient for broad conclusions regarding how well
2 the model reproduces the vertical distribution of particle properties. More measurements at
3 different locations are needed. However, the results presented here demonstrate the potential of
4 synergy between the model and lidar measurements. Analysis of different measurement sessions
5 along with the use of modeled particle parameters in lidar retrieval schemes are in our future
6 plans.

7

8 Acknowledgments: The authors are very grateful to IRD-Dakar (Institut de Recherche pour le
9 Développement) for their welcome and efficient support and also thank the labex CaPPA for
10 supporting this campaign. The CaPPA project (Chemical and Physical Properties of the
11 Atmosphere) is funded by the French National Research Agency (ANR) through the PIA
12 (Programme d'Investissement d'Avenir) under contract "ANR-11-LABX-0005-01" and by the
13 Regional Council "Nord-Pas de Calais" and the "European Funds for Regional Economic
14 Development (FEDER). Development of lidar retrieval algorithms was supported by Russian
15 Science Foundation, (project 16-17-10241).

2 **APENDIX**3 **Optical properties of aerosol components in MERRA-2 model.**

4 Table 1 summarizes the main characteristics of five aerosol components: dust, sea salt,
5 black carbon, organic, carbon and sulfates used in MERRA-2 model. For dust and sea salt five
6 size bins are considered. All values are given for the relative humidity $RH=0$. Thus OC, BC and
7 SU with the effective radii of $0.09 \mu\text{m}$, $0.04 \mu\text{m}$ and, $0.157 \mu\text{m}$ respectively are presented by the
8 fine fraction only, while dust and sea salt contribute to both fine and coarse fractions.

9 The dust particles are assumed to be hydrophobic, but other aerosol components may
10 present significant hygroscopic growth. To account for the effect of relative humidity, the growth
11 factor g , which is the ratio of particle radius at current RH to the dry particle radius, is
12 introduced. Fig.A1 shows dependence of the growth factor of different aerosol components on
13 relative humidity (RH). For sea salt the results are given for five size bins from Table 1. Each bin
14 has different growth factor: g increases with increase of particle radius. Relative humidity
15 modifies also the particle complex refractive index (CRI). Dependence of the real and the
16 imaginary part of particle components on relative humidity is shown in fig.A2. For dry sea salt
17 particles RI is supposed to be the same for all size bins. However in the process of hygroscopic
18 growth the RI of different bins behaves differently: both m_R and m_I decrease with bin number
19 (radius) increasing.

20

1

2 Table 1. Parameters of the aerosol components, such as minimal radius (r_{\min}), maximal radius
 3 (r_{\max}), effective radius (r_{eff}), real (m_{R}) and imaginary (m_{I}) part of the refractive index at 355 nm,
 4 532 nm, 1064 nm used in MERRA-2 model. For dust and sea salt five size bins are considered.
 5 All values are given for RH=0.

Component	r_{\min} , μm	r_{\max} μm	r_{eff} μm	$m_{\text{R}355}$	$m_{\text{R}532}$	$m_{\text{R}1064}$	$m_{\text{I}355}$	$m_{\text{I}532}$	$m_{\text{I}1064}$	
Dust	Bin 1	0.1	1.0	0.64	1.53	1.53	1.53	0.007	0.0026	0.0022
