27 **ABSTRACT**

28 Airborne particles and vapours, like many other environmental samples including water, soils, and  
29 sediments, contain complex mixtures of hydrocarbons, often deriving from crude oil either before  
30 or after fractionation into fuels, lubricants and feedstocks. Comprehensive 2D Gas  
31 Chromatography- Time-of-Flight Mass Spectrometry (GC×GC-ToFMS), offers a very powerful  
32 technique separating and identifying many compounds in complicated hydrocarbon mixtures.  
33 However, quantification and identification of individual constituents at high ionization energies  
34 would require hundreds of expensive (when available) standards for calibration. Although the  
35 precise chemical structure of hydrocarbons does matter for their environmental impact and fate,  
36 strong similarities can be expected for compounds having very similar chemical structure and  
37 carbon number. There is, therefore, a clear benefit in an analytical technique which is specific  
38 enough to separate different classes of compounds, and to distinguish homologous series, whilst  
39 avoiding the need to handle each isomer individually. Varying EI (electron impact) ionization mass  
40 spectrometry significantly enhances the identification of individual isomers and homologous  
41 compound groups, which we refer to as 'isomer sets'. Advances are reported in mapping and  
42 quantifying isomer sets of hydrocarbons ( $\geq C_{12}$ ) in diesel fuel, lubricating oil and diesel exhaust  
43 emissions. Using this analysis we report mass closures of *ca.* 90% and 75% for diesel fuel and  
44 lubricating oil, and identify 85% and 75% of the total ion current for gas and particulate phase  
45 diesel exhaust emissions.

46

47

48

49 **1. INTRODUCTION**

50 Crude oil contains a highly complex mixture of chemical constituents, mainly hydrocarbons (C<sub>4</sub>-C<sub>55</sub>)  
51 (Riazi, 2005). There are many reports of crude oil entering the environment through spillage, or  
52 deliberate release (Gertler et al., 2010). Most crude oil is treated and fractionated in order to  
53 produce fuels and lubricants for use in transport and combustion applications, and as feedstocks for  
54 the chemical industry (Riazi, 2005). All of these uses have a potential to contaminate the  
55 environment. Understanding fates, pathways, and effects of contamination requires chemical  
56 analysis and detailed interpretation of resulting data. Much of the chemical complexity of oil  
57 derives from the large numbers of straight and branched chain and cyclic hydrocarbon isomers for a  
58 given carbon number (Goldstein et al., 2007). Hence, analytical methods are required that can  
59 discriminate structurally similar sets of isomers in complex media.

60

61

62 Application of conventional gas chromatographic methods to oils and oil-derived samples was for  
63 many years severely limited by the poor separation capability of one-dimensional chromatography,  
64 due to the near-continuous range of physicochemical properties of hydrocarbons. Thus, typically  
65 90% of the hydrocarbon content of the sample is present in the unresolved complex mixture (UCM),  
66 creating a large hump in the chromatogram (Fraser et al., 1998; Schauer et al., 1999). The advent  
67 of two-dimensional gas chromatography, which provides enhanced separating capability due to the  
68 orthogonal separation by two capillary columns of different stationary phases, has transformed the  
69 problem by resolving the UCM into many thousands of individual compound peaks. The two  
70 columns are connected in series by a modulator which is employed to provide focusing of the  
71 primary column eluent (Liu et al., 1991; Phillips et al., 1995). Large amounts of data are produced

72 due to the large number of compounds separated. The information which is most useful  
73 scientifically in order to compare the main compositional attributes of samples is often more  
74 detailed than that provided by bulk Total Hydrocarbon measurements or fractionation into a few  
75 volatility classes, but less detailed than specific identification of many compounds. Use of a flame  
76 ionisation detector has the advantage of allowing generic quantification of any part of the  
77 chromatogram in terms of the carbon mass contained within it, but identification of specific  
78 chemical constituents with this detector can only be achieved on the basis of retention times which,  
79 in a very complex two-dimensional chromatogram and set-up-dependent chromatogram, are  
80 laborious to assign objectively. Mass spectrometric detection, especially when employing both low  
81 and high ionisation energies adds a third analytical dimension with the ability to overcome the  
82 problem of compound identification (Alam et al., 2016a), but has not generally been applied to  
83 generic quantification of compound groups within complex samples. In this study, we show that  
84 time-of-flight mass spectrometric detection can be used not only to identify and quantify individual  
85 chemical constituents within the chromatogram, but can also be used to quantify generic groups of  
86 compounds.

87

88 Motor vehicles are a major source of organic carbon in the atmosphere, and the majority of the fine  
89 particulate matter (PM) emitted is carbonaceous, directly emitted as primary organic aerosol (POA)  
90 or formed as secondary organic aerosol (SOA) (Jimenez et al., 2009). A substantial fraction of the  
91 POA in vehicle emissions has been shown to be semi-volatile under atmospheric conditions  
92 (Robinson et al., 2007; May et al., 2013), and is mainly comprised of aliphatic species in the carbon  
93 number range between  $C_{12}$ – $C_{35}$ , with effective saturation concentrations ( $C^*$ ) between 0.1 and  $10^3$   
94  $\mu\text{g m}^{-3}$  (Robinson et al., 2007; Weitkamp et al., 2007). The semi volatile organic compound

95 (SVOC) composition of lubricating oil has been reported to be dominated by branched, cyclic and  
96 straight alkanes ( $\geq 80\%$ ), with the largest contribution from cycloalkanes ( $\geq 27\%$ ) (Sakurai et al.,  
97 2003; Worton et al., 2014).

98

99 Previous research has used a limited range of tracer compounds, or homologous series, for the  
100 quantification of emissions, considering representative species that can be distinguished from the  
101 bulk of the mass, typically involving analysis of the n-alkanes, polycyclic aromatic hydrocarbons  
102 (PAH), hopanes, and steranes (Schauer et al., 1999; 2002) each of which represent only a small  
103 fraction of the total mass or number of compounds emitted and might lead to underestimation of the  
104 importance of lubricating oil as a source of SOA (Brandenberger et al., 2005; Fujita et al., 2007).

105 Rogge et al. (1993) investigated the sources of fine organic aerosol from non-catalyst and catalyst  
106 equipped vehicles using one-dimensional GC/MS, but could only resolve 10-15% of the organics,  
107 including n-alkanes and PAH. Although some studies have utilized soft ionization to analyse diesel  
108 fuel at a molecular level, (Briker et al., 2001); Eschner et al., 2010; Amirav et al., 2008) very few  
109 studies have analysed lubricating oil at a molecular level that includes the analysis of SVOCs  
110 (Worton et al., 2015; Reddy et al., 2012). In order to address the problems of coelution of  
111 constituents of the UCM, Worton et al. (2014) and Isaacman et al. (2012) utilized gas  
112 chromatography coupled with vacuum ultraviolet ionization mass spectrometry (GC/VUV-MS) to  
113 study the constitutional isomers present in lubricating oil and diesel fuel, respectively, and in a  
114 standard crude oil from the Gulf of Mexico (Worton et al., 2015). More recently, Goodman-Rendall  
115 et al. (2016) used GC/MS with cold electron impact (EI) ionization, resolving detailed molecular  
116 components of diesel fuel. Their results showed that the most important factors in determining SOA  
117 yields were carbon number, the presence (or absence) of a ring moiety and the degree of

118 substitution; and precise information of branching and degrees of unsaturation was of secondary  
119 importance. Dunmore et al. (2015) have shown that diesel-related hydrocarbons are responsible for  
120 60 % of the winter primary hydrocarbon hydroxyl radical reactivity and possibly up to 50 % of the  
121 ozone production potential in London. Detailed chemical characterization of diesel emissions would  
122 therefore not only resolve factors in determining the contribution to SOA yields, but also to shed  
123 light on specific precursors with large photochemical ozone creation potentials and OH reactivity,  
124 as well as the identification of compounds that are harmful for human health and the environment.

125

126

127 As well as identifying individual compounds, using GC×GC allows compounds of similar chemical  
128 structure to be classified into distinct groups in ordered chromatograms based on their volatility and  
129 their polarity, providing information that aids identification and assessment of environmental fate.  
130 Dunmore et al. (2015) recently grouped low molecular weight ( $\leq C_{12}$ ) hydrocarbons in atmospheric  
131 samples by carbon number and functionality using GC×GC. They reported the grouping of  $C_6$ – $C_{13}$   
132 aliphatics and  $C_2$ – $C_4$  substituted monoaromatics, combining the area of all the peaks contained  
133 within their selected areas.

134

135 In our study, two dimensional Gas Chromatography Time-of-Flight-Mass Spectrometry  
136 (GC×GC-ToF-MS) (Adahchour et al., 2008; Alam et al., 2013; Alam et al., 2016b) was combined  
137 with an innovative quantification methodology based on total ion current (TIC) signal response to  
138 provide identification and quantification for the compound classes within typical diesel fuel, engine  
139 lubricant and engine emissions (gas and particulate phases), providing a near complete mass  
140 closure for diesel fuel and engine lubricant and analyses of diesel engine exhaust composition.

141

## 142 **2. EXPERIMENTAL**

### 143 **2.1 Sampling**

144 Gas and particulate phase diesel exhaust emissions were collected from a light-duty diesel engine.  
145 This 2.2 L, 4-cylinder, in-line compression ignition engine was equipped with a common rail direct  
146 injection system and a variable-nozzle-turbine (VNT) turbocharger. Samples were collected with no  
147 diesel oxidation catalyst (DOC) and diesel particulate filter (DPF). The diesel engine emissions  
148 were diluted (1:50) with cleaned compressed air using an in-house exhaust dilution system. Samples  
149 were collected at steady state engine operating conditions at a low engine load of 3.0 bar mean  
150 effective pressure (BMEP) and a speed of 1800 revolutions per minute (RPM). The temperature at  
151 the sampling point was  $25 \pm 5$  °C and samples were collected for 30 min at a flow rate of 1.8 L  
152  $\text{min}^{-1}$ . Adsorption tubes were used to collect gas phase constituents directly from the diluted diesel  
153 engine exhaust, downstream of a polypropylene backed PTFE 47 mm filter (Whatman, Maidstone,  
154 UK), which was used to collect constituents in the particulate phase. Further details of the engine  
155 exhaust sampling system are given elsewhere (Alam et al. 2016c).

156

157 Diesel fuel, engine lubricating oil, and gas-and-particulate diesel exhaust emission samples were  
158 analysed using GC×GC-ToF-MS. Briefly, 1  $\mu\text{L}$  of diesel fuel (EN 590-ultra low sulfur diesel, Shell,  
159 UK) was diluted (1:1000) in dichloromethane (DCM) and injected onto a stainless steel thermal  
160 adsorption tube, packed with 1 cm quartz wool, 300 mg Carbograph 2TD 40/60 (Markes  
161 International, Llantrisant, UK), for analysis on the thermal desorber (TD) coupled to the  
162 GC×GC-ToF-MS. The EN 590 ultra-low sulphur diesel fuel is representative of the standardized  
163 ultra-low sulphur content fuel ( $<10$   $\text{mg kg}^{-1}$  or ppm) that is widely used in the UK and Europe

164 (European Parliament and the Council of the European Union, 2009). 1  $\mu$ L of engine lubricant  
165 (fully synthetic, 5W30, Castrol, UK) was diluted (1:1000) in DCM and directly injected into the gas  
166 chromatographic column, as the high molecular weight constituents found in the lubricating oils  
167 would not efficiently desorb into the GC column from the adsorption tubes.

168

169

## 170 **2.2 Instrumentation**

171 Adsorption tubes were desorbed using TD (Unity 2, Markes International, Llantrisant, UK) and  
172 samples were subsequently analysed using a gas chromatograph (GC, 7890B, Agilent Technologies,  
173 Wilmington, USA) equipped with a Zoex ZX2 cryogenic modulator (Houston, USA). The primary  
174 column (first separation dimension) was equipped with a SGE DBX5, non-polar capillary column  
175 (30 m, 0.25 mm ID, 0.25  $\mu$ m – 5% phenyl polysilphenylene-siloxane). The secondary, more polar  
176 column (second separation dimension) was equipped with a SGE DBX50 (4.0 m, 0.1 mm ID, 0.1  
177  $\mu$ m – 50% phenyl polysilphenylene-siloxane), situated in a secondary internal oven. The GC $\times$ GC  
178 was interfaced with a BenchTOF-Select, time-of-flight mass spectrometer (ToF-MS, Markes  
179 International, Llantrisant, UK), with a scan speed of 50 Hz and a mass resolution of >1200 full  
180 width at half maximum (fwhm) at 70 eV and >800 fwhm at 14eV over 100 – 1000 m/z. The  
181 mass/charge range was 30 to 525 m/z, and quantification was conducted on nominal unit mass  
182 resolution. Electron impact ionisation energies on this ToFMS can be tuned between 10 eV and 70  
183 eV, the former retaining the molecular ion, while the latter causes extensive fragmentation, but  
184 allows comparison with standard library spectra (Alam et al. 2016a). Data were processed by using  
185 GC Image v2.5 (Zoex Corporation, Houston, USA).

186

### 187 **2.3 Standards & Chromatography Methodology**

188 Nine deuterated internal standards namely, dodecane-d<sub>26</sub>, pentadecane-d<sub>32</sub>, eicosane-d<sub>42</sub>,  
189 pentacosane-d<sub>52</sub>, triacontane-d<sub>62</sub>, biphenyl-d<sub>10</sub>, *n*-butylbenzene-d<sub>14</sub>, *n*-nonylbenzene-2,3,4,5,6-d<sub>5</sub>  
190 (Chiron AS, Norway) and *p*-terphenyl-d<sub>14</sub> (Sigma Aldrich, UK) were utilised for quantification.  
191 Natural standards included 24 *n*-alkanes (C<sub>11</sub> – C<sub>34</sub>), phytane and pristane (Sigma Aldrich, UK), 16  
192 *n*-alkylcyclohexanes (C<sub>11</sub> – C<sub>25</sub> and C<sub>26</sub>), 5 *n*-alkylbenzenes (C<sub>4</sub>, C<sub>6</sub>, C<sub>8</sub>, C<sub>10</sub> and C<sub>12</sub>), *cis*- and  
193 *trans*-decalin, tetralin, 4 alkyltetralins (methyl-, di-, tri- and tetra-), 4 *n*-alkyl naphthalenes (C<sub>1</sub>, C<sub>2</sub>,  
194 C<sub>4</sub> and C<sub>6</sub>) (Chiron AS, Norway) and 16 USEPA polycyclic aromatic hydrocarbons (Thames Restek  
195 UK Ltd). These standards were chosen in order to cover as much of the overall chromatogram as  
196 possible. The chromatography methodology (*i.e.* GC oven temperatures, temperature ramp rates *etc.*)  
197 of the analysis of the adsorption tubes, lubricating oil and gas/particulate phase samples is discussed  
198 in Section S1 in the Supplementary Information.

199

200

### 201 **2.4 Grouping of Chromatographically Resolved Compounds**

202 Structurally similar compounds possess similar physicochemical properties. This facilitates  
203 identification when separating a mixture according to these physical and chemical properties. Diesel  
204 fuels, diesel emissions and lubricating oils have been shown to consist of a limited number of  
205 compound classes, but an enormous number of individual components within a class.

206

207 In this study we use GC×GC coupled to variable ionisation ToF-MS to map and quantify isomer  
208 sets previously unresolved in the UCM. Conventional electron ionisation at 70 eV imparts a large  
209 amount of excess energy causing extensive fragmentation, with a tendency to generate similar mass

210 spectra. Thus for example the isomeric alkanes all exhibit the same  $m/z$  43, 57, 71, 85, 99 patterns,  
211 thus obscuring the match with the NIST library and making identification from the mass spectrum  
212 very difficult. To address this issue, a lower ionization energy (10-14eV) was also employed in our  
213 study so that the organic compounds are ionized with minimal excess internal energy and thus less  
214 fragmentation, hence retaining the distinct identity of the molecule with a much larger fraction of  
215 the molecular ion (Alam et al., 2016a). Running samples on the GC×GC with both low and high  
216 ionization energy mass spectrometry results in a wealth of data for identification of compounds;  
217 where 14 and 70eV mass spectra can be compared for a given species owing to the identical  
218 retention times of the repeat runs. At low ionization energy the molecular ion is enhanced, at the  
219 same time as retaining some fragmentation, while at high ionization energy the mass fragmentation  
220 patterns of a species can be compared directly to mass spectral libraries. This allows easier  
221 identification of unknown compounds. Low EI spectra therefore give qualitative information, while  
222 high EI mass spectra allow for quantitative analyses to be performed.

223

224 Our recent work exploited soft ionisation (14 eV) to identify a large number of isomers,  
225 demonstrating the ability to separate and identify individual alkanes (normal, branched and cyclic)  
226 with specific carbon numbers, based on their volatility and polarity (Alam et al., 2016a). In this  
227 study we expand our previous qualitative analysis and separate the alkane series (as well as other  
228 homologous series) into isomer sets containing the same carbon number. Individual alkanes that  
229 were identified as having different molecular ions (i.e. different carbon number) to the  $n$ -alkane  
230 within the area of the chromatogram were included in their appropriate adjacent (usually  $n\pm 1$ ) area;  
231 for example, some dimethyl isomers can be shifted by  $\sim 100$  delta-Kovats ( $\sim 1$  carbon number),  
232 whereas trimethyl- and tetramethyl isomers have been reported to be shifted by  $\sim 150$  and  $\sim 200$

233 delta-Kovats. This has been completed for all the homologous series reported in this study. The  
234 grouping of the alkanes according to their respective carbon numbers is shown in Figure 1, where  
235 the least polar compounds (fast eluting peaks in the second dimension) are the alkanes, increasing in  
236 carbon number as the retention time in the first dimension increases.

237

238 This methodology was expanded to more polar homologous series including monocyclic alkanes,  
239 bicyclic alkanes, tricyclic alkanes, tetralins/indanes, monocyclic aromatics, bicyclic aromatics and  
240 alkyl-biphenyls. Like the alkanes, a significant problem in creating the boundaries of groups is the  
241 overlapping of one carbon number group into another. Identifying each individual compound in this  
242 case (as with the alkanes above) would be resource and time intensive and so carefully constructed  
243 ‘Computer Language for Identification of Chemicals’ (CLIC) qualifiers were created and utilised in  
244 order to match peaks and their mass fragmentation patterns. A CLIC qualifier is an expression in a  
245 computer language that allows users of chromatographic software to build rules for selecting and  
246 filtering peaks using retention times and mass fragmentation patterns (Reichenbach et al., 2005).  
247 This was exploited to identify specific compounds belonging to a compound class and a polygon  
248 selection tool within the GC Image software was drawn around this section of the chromatogram  
249 (coloured polygons shown in Figure 1). Any overlap in the graphics was accounted for by forcing  
250 peaks to belong to one compound class over another via strict mass fragment and molecular ion  
251 selection tools. Examples of CLIC expressions utilised for identifying compound classes are  
252 included in the Supplementary Information (Section S2). An example of a selected ion  
253 chromatogram with a specific CLIC expression is shown in Figure 2, for C<sub>6</sub>-substituted monocyclic  
254 aromatics, with their corresponding 70eV and 12eV mass spectra. The characteristic 70eV mass  
255 fragments at m/z 92, 105, 119, 133 signify cleavage of the C-C bond next to the benzene ring. The

256 12eV mass spectra, however, produce poor characteristic fragment ions, but a prominent molecular  
257 ion (162) and  $m/z$  92 signifying the overall mass of the molecule and the benzene ring ( $\text{Ph-CH}_2^+$ ),  
258 respectively. In effect, the polygons mark out sets of isomeric compounds having the same  
259 empirical formula and shared structural elements; the sets appear to intersect each other in the  
260 two-dimensional chromatogram space, but compounds in the intersecting regions are assigned  
261 uniquely to a class using a third, mass spectrometric, data dimension (i.e. mass fragmentation  
262 patterns). The resulting isomer sets are more chemically and environmentally meaningful than the  
263 raw polarity/volatility assignment from the chromatography. This approach was completed  
264 independently for diesel fuel, lubricating oil, and gas/particulate phase exhaust emissions to ensure  
265 the applicability of polygon boundaries and reproducibility of retention times and mass fragments.  
266 Results indicated that isomers within the constructed polygon boundaries possessed identical  
267 retention times and interpretable mass spectra for all differing samples. Retention times were  
268 reproducible in both chromatographic dimensions in separate runs. The isomer sets (polygons) can  
269 be linked together in a large template that can also be linked to the internal standards. This allows  
270 easy alignment of the template (all isomer sets) in the event of slight shifts in retention times, due to  
271 column changes or instrumental maintenance.

## 272

### 273 **2.5 Quantification of compounds with no authentic standards**

274 The authentic standard mixture contains 74 standard compounds including 9 internal standards (see  
275 Section 2.3). These standards were chosen in order to cover as much of the overall chromatogram as  
276 possible and are used for obtaining a calibration for quantifying groups of isomers with the same  
277 molecular ion and functionality. For example; the response for  $\text{C}_{11}$  (undecane,  $m/z$  156) was used to  
278 quantify all  $\text{C}_{11}$  alkane isomers which were positively identified in the analysed samples (and have

279 the same molecular mass and retention times in all sample runs). Using retention times for C<sub>11</sub>  
280 alkane isomers as well as mass spectra, only those C<sub>11</sub> isomer peaks were selected that were  
281 observed using the SIC for m/z 156 (or the respective CLIC expressions). Isomer sets were  
282 comprehensively identified in the analysed samples using mass fragmentation at 70eV and  
283 molecular masses at lower ionisation energies (10-15eV). The total ion current within each polygon  
284 was integrated and the isomer set abundance was estimated using the response ratio of the closest  
285 structurally-related deuterated standard to the corresponding compound class natural standard with  
286 the same carbon number (usually within the polygon). This methodology has an uncertainty of  
287 approximately 24% and is discussed in detail in the Supplementary Information (Section S3).

288

### 289 **3. RESULTS AND DISCUSSION**

#### 290 **3.1 Analysis of Diesel Fuel**

291 The chromatography of the diesel fuel analysed by TD-GC×GC-ToF-MS is shown in Figure 1.  
292 Compounds identified within the diesel fuel included: *n*-alkanes, branched alkanes (mono-, di-, tri-,  
293 tetra- and penta-methyl), *n*-alkyl cycloalkanes, branched monocyclic alkanes, C<sub>1</sub>-C<sub>12</sub> substituted  
294 bicyclic alkanes, C<sub>1</sub>-C<sub>4</sub> substituted tetralins and indanes, C<sub>3</sub>-C<sub>12</sub> substituted monocyclic aromatics,  
295 C<sub>1</sub>-C<sub>3</sub> substituted biphenyls/acenaphthenes, C<sub>1</sub>-C<sub>4</sub> substituted bicyclic aromatics, C<sub>1</sub>-C<sub>2</sub> substituted  
296 fluorenes (FLU), C<sub>1</sub>-C<sub>2</sub> substituted phenanthrene/anthracenes (PHE/ANT) and unsubstituted PAH.  
297 Representative mass spectra at 12eV and 70eV ionization are presented in the Supplementary  
298 Information (Section S4). These compounds accounted for 93% of the total response (excluding the  
299 siloxanes which derive from contaminants *i.e.* column bleed) and was equivalent to 90 % of the  
300 mass injected. Therefore, out of the 8026 (± 24) ng that was injected into the GC×GC (mass  
301 calculated by weighing and diluting a known volume of diesel fuel, while the uncertainty represents

302 the combined uncertainties of the processes involved in this estimation) a mass of approximately  
303 7200 ( $\pm$  1728) ng was accounted for. We suspect that a significant amount of the mass that was  
304 unaccounted may be  $<C_{10}$  and/or any unresolved peaks that we were unable to measure and/or  
305 identify using our technique. The percentage contribution of each compound class identified to the  
306 total mass accounted for is shown in Table 1.

307

308

309 Our results indicate that the majority of the diesel fuel consists of aliphatic compounds, with a low  
310 aromatic content ( $\sim$ 10%). Very few published studies exist elucidating the contribution of different  
311 constituents in diesel fuel (Isaacman et al., 2012; Welthagen et al., 2007; Gentner et al., 2012).  
312 Most studies focus on the characterisation of specific compounds within diesel fuels such as  
313 nitrogen containing species (Wang et al. 2004), cyclic compounds (Edam et al., 2005), or to identify  
314 strengths and weaknesses in analytical techniques (Frysiner et al., 1999). Recently, VUV  
315 ionization at 10 – 10.5 eV has been exploited to elucidate some of the structures within diesel fuel,  
316 by separating components using GC (Isaacman et al., 2012). The authors report their observed  
317 mass of diesel fuel as 73% aliphatic and 27% aromatic, broadly consistent with the results of this  
318 study. Up to 11% of the observed mass fraction of diesel fuel was attributed to bicyclic alkanes, a  
319 factor of 2 larger than observed in this study. Their observed mass fractions of cycloalkanes and  
320 benzene, however, are in excellent agreement. The contribution of branched alkanes (*i*-alkanes) and  
321 linear *n*-alkanes to the total mass of the alkanes was 39.1 and 23.1%, respectively. A significant  
322 proportion of the total mass observed was attributed to alkanes (62%), a factor of 1.5 larger than  
323 reported by Isaacman et al. (2012). However, the differences observed between diesel fuel  
324 analysed in this study and that reported by Isaacman et al. (2012) are attributable to different fuel

325 formulations and/or fuel source, as opposed to analytical methods. Although not shown here, a  
326 significant number of alkane isomers were identified for each carbon number using soft ionisation  
327 mass spectrometry, accounting for a total of ~200 alkanes across the C<sub>11</sub> – C<sub>30</sub> range. The ratio of  
328 *i*-alkanes to *n*-alkanes sharply decreases after C<sub>25</sub>, indicating a reduced amount of mass represented  
329 by branched isomers present in diesel fuel for >C<sub>25</sub> alkanes, which could be related to the  
330 formulation process, or reflect the composition of the feedstock.

331

### 332 **3.2 Analysis of diesel engine emissions (gas phase)**

333 A GC×GC contour plot of the gas phase diesel exhaust emissions is shown in the Supplementary  
334 Information (Figure S5). The observed chromatogram for the gas phase emissions looked extremely  
335 similar to that of the diesel fuel chromatogram (Figure 1), suggesting that the majority of  
336 compounds found in the gas phase emissions are of diesel fuel origin. All of the compounds found  
337 in the diesel fuel were observed in the gas phase emissions, albeit with a reduced number of  
338 *i*-alkanes >C<sub>20</sub>, which may signify efficient combustion of these high molecular weight compounds,  
339 or partitioning into the particulate phase. The measured constituents of the gas phase diesel exhaust  
340 emissions are shown in Table 1. Approximately 15 % of the total ion current (response, excluding  
341 siloxanes) was unaccounted for. Table 1 illustrates the percentage mass of each compound class  
342 identified, in the 85% of the response that was accounted for. As the total mass of the gas phase  
343 sample is unknown, a mass for the remaining 15% of the total response cannot be estimated, as the  
344 individual components that are unidentified will have different responses per unit mass. For  
345 example, 23.5% of the mass identified was attributed to C<sub>4</sub> – C<sub>12</sub> alkyl substituted monocyclic  
346 aromatics and accounted for 9.7% of the total ion current response; and 10.0% of the mass  
347 identified was bicyclic alkanes, representing 9.2% of the response.

348

349 Although the diesel fuel constituents present in the gas phase exhaust emissions broadly were  
350 compositionally consistent with the fuel, there were significant differences observed in their relative  
351 amounts. Of the total mass identified in the gas phase emissions, *n*-alkanes and *i*-alkanes  
352 represented 9.8% and 30.1%, respectively. These are factors of 2.4 and 1.3 lower than that for diesel  
353 fuel, respectively; which may be due to preferred combustion of these compounds (Burcat et al.,  
354 2012). Enhancements of monocyclic aromatics, monocyclic alkanes, bicyclic alkanes and bicyclic  
355 aromatics were observed in the emissions, possibly due to them being intermediate species formed  
356 during the combustion of larger molecules (Gentner et al., 2013), and unlikely to be a contribution  
357 from lubricating oil as very little mass was attributed to compounds with  $<C_{18}$  (see Section 3.3). A  
358 very limited number of oxygenates were also identified (*e.g.* ketones ( $m/z$  58, 72), carboxylic acids  
359 ( $m/z$  60)), most probably combustion products of diesel fuel, but representing a very small fraction  
360 of the total measured gas phase emissions ( $<1\%$ ). However, carboxylic acids are difficult to detect  
361 using GC/MS without prior derivatization and may therefore be underestimated. Gentner et al.  
362 (2013) suggest that compounds such as alkenes, aromatics and oxygenates comprise  $\sim 30\%$  of the  
363 total measured gas phase emissions, in agreement with this study; however, they suggest that these  
364 products are unlikely to contribute to primary organic aerosol (POA). We observe these aromatic  
365 compounds in the particulate phase also, indicating a contribution.

366

### 367 **3.3 Analysis of Lubricating Oil**

368 The isomer sets (polygons), identified in the lubricating oil chromatogram, are shown in Figure 3A.  
369 Molecular ions present in the mass spectra enabled the grouping of isomers by carbon number,  
370 while the presence of the characteristic mass fragments, presented in Table 1, were used to confirm

371 the identity of the type of hydrocarbon. The representative mass spectra for compounds presented in  
372 Table 1, for the lubricating oil is shown in the Supplementary Information, Section S6. Polygons  
373 were drawn around groups of compounds that possessed the same molecular ion for a given  
374 compound class, see Figure 3A and 3B. The lubricating oil was analysed using two independent  
375 temperature ramps of the GC×GC (methodologies outlined above); one to achieve the best possible  
376 comprehensive separation of compounds in the oil (Figure 3A) and the other using methodologies  
377 developed for analysis of the particulate phase components of engine exhaust (Figure 3B), to  
378 ascertain where the compounds identified in the oil are present in the particulate phase emissions  
379 filter. Figure 3B also illustrates the positioning of the SVOC measured in the gas phase, that are  
380 observed in the particulate phase filter as well as the positioning for the PAH. The grouping  
381 template that is illustrated in Figure 1 covers the SVOC range indicated in Figure 3B.

382

383

384 Using the signature mass fragment ions (Table 1) together with the calculated molecular mass,  
385 specific compounds with the same carbon number were isolated, see Figure S7-A and S7-B. For  
386 example, selecting the ion fragment  $m/z$  92 and 119 for monocyclic aromatics gives rise to the  
387 selected ion chromatogram illustrated in Figure S7-A. This can be achieved using 70eV mass  
388 spectrometry identifying a homologous series across a large carbon number range. However,  
389 selecting the molecular mass for a specific carbon number allows the identification of all isomer  
390 sets in a region of the chromatogram with that specific molecular mass, as shown in Figure S7-B for  
391  $C_{22}$  monocyclic aromatics ( $m/z$  302). A mass of 8511 ( $\pm 255$ ) ng of lubricating oil was injected into  
392 the GC×GC, of which 6356 ( $\pm 1525$ ) ng was quantified. This methodology was used to identify and  
393 quantify the following homologous series:  $C_{16}$ – $C_{33}$  straight and branched chain alkanes,  $C_{16}$ – $C_{33}$

394 monocyclic alkanes, C<sub>17</sub>–C<sub>33</sub> bicyclic alkanes, C<sub>17</sub>–C<sub>33</sub> tricyclic alkanes and C<sub>16</sub>–C<sub>33</sub> monocyclic  
395 aromatics. These compound groups represented approximately 91% of the total ion current  
396 (excluding siloxanes) and 75% of the mass fraction. Adamantanes, diamantanes, pentacyclic and  
397 hexacyclic alkanes, steroids, steranes, and hopanes represented 5% of the total ion current, while the  
398 remaining 4% remained unidentified. These compounds were not quantifiable using this  
399 methodology, as there were no standards available that corresponded to these sections of the  
400 chromatography and could not be estimated as they are not present in a homologous series.  
401 However, from previous literature, these compound classes are thought to represent a small fraction  
402 of the mass (Worton et al., 2015). Furthermore, we have not taken into account any  
403 non-organic/hydrocarbon species but according to these data, the fraction of any non-HCO material  
404 is likely to be small.

405  
406  
407 Worton et al. (2015) exploited VUV photoionization mass spectrometry to characterize  
408 comprehensively hydrocarbons in a standard reference crude oil sample. They reported a total mass  
409 closure of  $68 \pm 22\%$ , comprised of linear and branched alkanes (19%), 1-6 ring cycloalkanes (37%),  
410 monoaromatics (6.8%) and PAH (4.7%). The mass fractions observed for linear and branched  
411 alkanes in this study were 11% and 12%, respectively, which is in excellent agreement. There is  
412 also excellent agreement with the mass attributed to bicyclic (2-ring) and tricyclic (3-ring) alkanes  
413 however, for monocyclic alkanes the results presented here are a factor of 2 larger than Worton et  
414 al.(2015) and 2.5 larger than Reddy et al. (2012). Both previous studies analysed similar crude oil  
415 samples associated with the Deepwater Horizon disaster (McNutt et al., 2012), and would be  
416 expected to differ appreciably from a lubricating oil. Furthermore, no PAH were observed in the

417 lubricating oil in this study, in agreement with Zielinska et al. (2004) but in contrast to Worton et al.  
418 (2015). We attribute this difference to the varying crude oil origins and formulation processes  
419 involved in the production of synthetic oil.

420

421 Previous work from this group identified a large number of isomeric species in base oil using 14eV  
422 EI ionization energy mass spectrometry (Alam et al., 2016a). Although we were able to identify a  
423 large number of compounds, there still existed a small amount of fragmentation at 14eV,  
424 particularly for alkyl-methyl-, alkyl-dimethyl-, and alkyl-trimethyl-cyclohexanes. In this study the  
425 fragmentation was significantly reduced for these compounds at 12eV (i.e. relative intensities of  $m/z$   
426 97, 111, 125 reduced by >50%) and completely eradicated (relative intensities of mass fragments  
427 reduced by >95%) at 10eV, leaving the  $m/z$  82 ion (for monocyclic alkanes) and the molecular ion.  
428 This demonstrates the significant differences observed in fragmentation over small changes in lower  
429 ionisation EI energies and may also account for slight discrepancies between studies (Worton et al.,  
430 2015; Isaacman et al., 2012; Alam et al., 2016b). Utilising these differences in fragmentation from  
431 using low ionization energies (10 – 15eV) may provide more information in regards to the structure  
432 of many isomeric compounds.

433

#### 434 **3.4 Analysis of Diesel Engine Emissions (Particulate Phase)**

435 90% of the total ion current of the particulate phase filter was identified and attributed to a wide  
436 range of classes. Of the total mass identified, 47 ( $\pm 11$ )% was straight and branched chain alkanes,  
437 20 ( $\pm 4.8$ )% monocyclic alkanes, 7.5 ( $\pm 1.8$ )% bicyclic alkanes, <3 ( $\pm 0.7$ )% tricyclic alkanes, 6  
438 ( $\pm 1.4$ )% monocyclic aromatics, 7 ( $\pm 1.7$ )% oxygenates, <1 ( $\pm 0.2$ )% furanones, 4 ( $\pm 1.0$ )% PAH and  
439 2 ( $\pm 0.5$ )% fatty acid methyl esters (FAMES). Figure 4 illustrates the percentage mass contribution

440 of homologous series (including isomers) identified as a function of carbon number. Peak  
441 concentrations of alkanes (cyclic and straight/branched chain) were observed between  $C_{24} - C_{27}$   
442 consistent with the lubricating oil, while a small peak in concentration was also observed in the  $C_{15}$   
443  $- C_{20}$  range, consistent with the fuel and gas phase emissions. Oxygenated compounds were found  
444 to be present in the  $C_{11} - C_{22}$  range, suggesting that these compounds are combustion products. The  
445 concentration of monocyclic aromatics was steady throughout the carbon number distribution ( $C_{15} -$   
446  $C_{32}$ ), with a small peak at  $C_{25} - C_{27}$ . The presence of PAH in the particulate phase suggests their  
447 formation via diesel fuel combustion or unburnt fuel, owing to their absence in the lubricating oil.  
448 There are numerous studies reporting the absence of PAH in unused lubricating oil and presence in  
449 used oil, which suggests the absorption of blow-by exhaust containing fuel combustion associated  
450 PAH (Fujita et al., 2006). FAMES were identified by their characteristic fragmentation at 70eV EI  
451 ionization and with their characteristic ion ( $m/z$  174) at low EI ionization (12 eV).

452

453

454 There have been few studies investigating the contribution of lubricating oil and fuel to the emitted  
455 diesel POA, suggesting 20 to 80% influence from lubricating oil (Worton et al., 2014;  
456 Brandenberger et al., 2005; Kleeman et al., 2008; Sonntag et al., 2012). Most recently, it has been  
457 suggested that  $\geq 80\%$  of the SVOC composition is dominated by branched cycloalkanes with one or  
458 more rings and one or more branched alkyl side chain (Worton et al., 2014). This is significantly  
459 larger than that reported in this study ( $\geq 30\%$ ), where the majority of the emissions are dominated  
460 by straight and branched chain alkanes (47%) over a volatility range that also suggests a significant  
461 contribution from the diesel fuel ( $C_{11} - C_{20}$ , see Figure 4). The diesel fuel and lubricating oil  
462 contained respectively 62% and 47.5% straight and branched chain alkanes (summed), suggesting a

463 larger possible contribution of diesel fuel to the vapour phase engine emissions (which is dominated  
464 by straight and branched chain alkanes). The contribution of unburned lubricating oil, however,  
465 most likely dominates the SVOC emissions in the particulate phase, as shown in Figure 4.

466

## 467 **5. CONCLUSION**

468 The SVOC contents in diesel fuel, 5W30 synthetic lubricating oil, and diesel exhaust emissions  
469 (both in the gas and particulate phases) were characterized using TD-GC×GC-ToFMS. By  
470 exploiting the mass spectrometric fingerprint of eluting compounds in highly structured and ordered  
471 chromatograms, a method has been constructed that quantifies the contributions of ‘isomer sets’ (i.e.  
472 structural isomers in specific compound classes) to the overall composition of a sample. We found  
473 that the ion current for identified homologous series exhibited very similar responses, illustrating  
474 that quantitative calibrations derived from the *n*-alkane series could be used to estimate the  
475 concentrations of isomeric aliphatic compounds with similar molecular weight. Using this  
476 methodology together with a range of standards, and aggregating compound classes of similar  
477 functionality together (i.e. *n*-alkanes, branched alkanes etc.), we present comprehensive  
478 characterization of diesel fuel, lubricating oil and diesel exhaust emissions.

479

480

481 Furthermore, combining conventional 70eV EI ionization mass spectrometry with lower ionization  
482 energy (10-14eV), allowed the identification of constitutional isomers of the same molecular weight  
483 and compound class, enabling a clear distinction between carbon number and functionality. By  
484 utilising this innovative method, a number of findings were achieved. 1) A mass closure accounting  
485 for *ca.* 90 % and 75 % for the analysis of diesel fuel and lubricating oil, respectively. 2) Acyclic and

486 monocyclic alkanes were found to be predominant in both the diesel fuel and synthetic lubricating  
487 oil (76% and 68%, respectively). 3) Diesel exhaust emissions in the gas phase were extremely  
488 similar to the composition of diesel fuel. 4) Diesel exhaust emissions in the particulate phase were  
489 similar to the composition of lubricating oil. 5) The presence of combustion products of diesel fuel  
490 (e.g. aromatics and oxygenates) in the particulate phase indicates a contribution to POA.

491

492 Diesel exhaust hydrocarbons are a significant precursor of secondary organic aerosol (Dunmore et  
493 al., 2015; Gentner et al., 2012). Diesel fuel and lubricant, contributors to diesel exhaust, contain  
494 large numbers of isomers. Separation into isomer sets improves our understanding of the fates of  
495 these oil-derived materials in the environment (Lim & Ziemann, 2009; Kroll & Seinfeld, 2008).  
496 By utilizing GC×GC-ToFMS with soft ionisation, we enable the identification of the composition of  
497 the UCM, characterising the chemical composition by carbon number and compound class, and the  
498 possibility of branching structural information. Along with a grouping methodology using CLIC  
499 expressions and unique compound fragmentation patterns, we demonstrate the reliable quantitative  
500 integration of structural isomers. These methods exploit the improved resolution and isomer  
501 separation capabilities of the advanced instrumentation and have potential applications to the  
502 observations of petroleum degradation, and SOA formation and evolution. This method is ideal for  
503 investigating fossil fuel sources (*e.g.* lubricating oil, motor vehicles, fuel *etc.*) and can be extended  
504 to atmospheric measurements where there exist many oxygenates. The analysis of atmospheric  
505 particulate phase samples (not using thermal desorption), may benefit from exploring different  
506 extraction solvents (*e.g.* methanol or a hexane/methanol mix) to allow the larger expected  
507 proportion of oxygenated species to be efficiently extracted. Although the presence of oxygenated  
508 species adds chromatographic complexity, as co-elution can be a limitation, using carefully

509 constructed CLIC expressions and mass fragmentation patterns, various oxygenates can be  
510 identified (*e.g.* 2-ketones ( $m/z$  58), 3-ketones ( $m/z$  72), carboxylic acids ( $m/z$  60) *etc.*), making this  
511 technique applicable in any scientific field that routinely characterizes complex hydrocarbon  
512 mixtures. Although not explored here, this technique of low ionization mass spectrometry may  
513 benefit from reducing the temperature of the ionisation source, as demonstrated by Isaacman et al.  
514 (2012); who retained a larger fraction of the molecular parent ion on reducing the ion source  
515 temperature of their VUV photoionization technique. This would particularly aid identification for  
516 atmospheric samples which would contain more oxygenated compounds.

517

518

519

## 520 **ACKNOWLEDGEMENTS**

521 The authors would like to thank L. McGregor and N. Bukowski on valuable discussions on aspects  
522 of GC×GC-ToFMS and assistance in CLIC qualifiers. Financial support from the European  
523 Research Council (ERC-2012-AdG, Proposal No. 320821) for the FASTER project is gratefully  
524 acknowledged. The assistance of Y. Al-Qahtani in collecting samples from the engine facility is also  
525 acknowledged.

526

## 527 **Author Contribution**

528 MSA prepared the manuscript with contributions from ARMK and RMH; RMH, MSA and SZR  
529 designed the engine experiments; SZR, MSA and ZL carried out the engine experiments; MSA and  
530 CS developed the GC×GC methodology and completed subsequent analyses. HX overlooked the  
531 engine facility and RMH oversaw the entire project.

532

533 **Conflict of Interests**

534 The authors declare no competing financial interest.
