email: lucia-timea.deaconu@ed.univ-lille1.fr

To: Journal of Atmospheric Measurement Techniques (AMT) Editorial Offices

Subject: Submission of a revised paper by L. Deaconu and co-workers

Dear Mam/Sir,

Please find a copy of the revised manuscript entitled “Consistency of aerosols above clouds characterisation from A-Train active and passive measurements” for publication in the Journal of Atmospheric Measurement Techniques Discussions (AMTD). Also, we uploaded the reviews and a point-by-point answer from the authors. We have done our best to respond the questions and to improve the paper.

Please note that we have included Mr. Jacques Pelon in the list of authors, as he has contributed in the answers provided for the questions related to the CALIOP Depolarisation Ratio Method.

This manuscript has not been published in any language in any other journal and is not submitted to another journal. All co-authors have read the revised version of the manuscript and concur with submission in its revised form.

Yours sincerely,

Lucia Deaconu

Consistency of aerosols above clouds characterisation from A-Train active and passive measurements

Abstract. This study presents a comparison between the retrieval of aerosol above clouds (AAC) optical properties from different techniques developed for the A-Train sensors CALIOP/[CALIPSO](#) and POLDER/PARASOL. The main objective is to analyse the consistency between the results ~~of~~ [derived from](#) the active and the passive measurements. We ~~assess-compare~~ the Aerosol Optical Thickness (AOT) ~~of~~ [above](#) optically thick clouds (Cloud Optical Thickness (COT) larger than 3) and their Ångström Exponent (AE). These parameters are retrieved with the CALIOP operational method, the POLDER operational polarization method and the CALIOP-based depolarization ratio method (DRM) – for which we also propose a calibrated version (denominated DRM_{SODA}, SODA as Synergized Optical Depth of Aerosols). We analyse six months of data over three distinctive regions characterized by different types of aerosols and clouds. Additionally, for these regions, we select three case studies: a biomass-burning event over the South Atlantic Ocean, a Saharan dust case over the North Atlantic Ocean and a Siberian biomass-burning event over the North Pacific Ocean. ~~4-5~~ [Four and a half](#) years of data are studied over the entire globe for distinct situations where aerosol and cloud layers are in contact or vertically separated. Overall, the regional analysis shows a good correlation between the POLDER and the DRM_{SODA} AOTs when the microphysics of aerosols is dominated by fine-mode particles of biomass-burning aerosols from southern Africa (correlation coefficient (R^2) of 0.83) or coarse-mode aerosols of Saharan dust (R^2 of 0.82). A good correlation between these methods (R^2 of 0.68) is also observed in the global treatment, when the aerosol and cloud layers are well separated. The analysis of detached layers also shows a mean difference in AOT of 0.07 at 532 nm between POLDER and DRM_{SODA}, at a global scale. The correlation between the retrievals decreases when a complex mixture of aerosols is expected (R^2 of 0.37) – as in the East Asia region, and when the aerosol-cloud layers are in contact (R^2 of 0.36). The correlation coefficient between the CALIOP operational method and POLDER is [found to be](#) low, as the CALIOP method largely underestimates the aerosol loading above clouds by a factor that ranges from two to four.

Potential biases on the retrieved AOT as a function of cloud properties are also investigated. For different types of scenes, the retrieval of above-cloud AOT from POLDER and from DRM are compared for different underlying cloud properties (droplet effective radius (r_{eff}) and COT retrieved with MODIS). The results reveal that DRM AOT vary with r_{eff} .

When accounting for r_{eff} in the DRM algorithm, the consistency between the methods increases. The sensitivity study shows that an additional polarized signal coming from aerosols located *within* the cloud could affect the polarization method, which leads to an overestimation of the AOT retrieved with POLDER algorithm. In addition, the aerosols *attached* or *within* the cloud can potentially impact the DRM retrievals through the modification of the cloud droplet chemical composition and its ability to backscatter light. The next step of this work is to combine POLDER and CALIOP to investigate the impacts of aerosols on clouds and climate when these particles are transported above or within clouds.

1 Introduction

By interacting with radiations and by modifying the cloud reflectivity and ~~the cloud formation~~ microphysics, aerosols have important impacts on the Earth's radiative budget and water cycle (IPCC, 2014). These atmospheric particles absorb and scatter the sunlight, resulting in the so-called "Direct Radiative Effect" (DRE). Although aerosols always produce a cooling effect at the Earth's surface, the sign and the amplitude of the DRE of aerosols at the top of the atmosphere depends on the aerosol properties but also on the reflective properties of underlying surface. For instance, in cases where absorbing aerosol layers are located above clouds, the DRE of aerosols is predominantly positive as a result of the reduction of the local planetary albedo (Keil and Haywood, 2003). By absorbing sunlight, aerosols also warm the layer of the atmosphere where they reside. This modifies the vertical profile of temperature in the atmosphere, which may affect the process of evaporation and cloud formation. This effect is called the "semi-direct effect" (Hansen et al., 1997; Ramanathan et al., 2001). Aerosols also impact the cloud properties by acting as cloud condensation nuclei and ice nuclei. They may modify the cloud microphysics and cloud brightness with potential impacts on precipitation and cloud lifetime (Rosenfeld, 2000; Twomey, 1974). These effects are referred as "aerosol indirect effects" and tend to cool the Earth.

The lack of knowledge of aerosol properties in cases of aerosols above clouds (AAC) scenes has been recently highlighted as a source of uncertainty for the estimation of ~~the all-sky~~ DRE of aerosols (Peers et al., 2016). Different approaches have been developed to quantify the DRE of AAC using satellite observations (Chand et al., 2009; Feng and Christopher, 2015; Meyer et al., 2013) (~~Chand et al., 2009; Meyer et al., 2013~~). But despite recent observational and modelling studies (De Graaf et al., 2014; Peers et al., 2015, 2016; Zhang et al., 2016), the aerosol DRE for AAC remains a subject ~~to of~~ large ~~diserepancies~~ uncertainty. In the process of quantification and interpretation of the aerosol impact on climate, the aerosol interactions with clouds constitute the largest uncertainty in global climate models (Myhre et al., 2013a, 2013b). The study of AAC may also contribute to reduce those uncertainties. For instance, in case of absorbing AAC, the warming of the atmosphere occurring above stratocumulus clouds might reduce the strength of the convection and consequently impact the vertical development and the cloud properties. This warming might inhibit the entrainment of dry air at the top of the cloud, preserving the humidity of the cloud and increasing the liquid water content and the persistence of clouds (Johnson et al., 2004; Wilcox, 2010). Evidence of the first indirect effect was also found over the South Atlantic region, where AAC events are frequently observed. Costantino and Bréon (2012) notably found a strong decrease in the

droplet effective radius when the aerosol layers are ~~touching the top of the cloud layer~~ in contact with the top altitude of the cloud deck.

The scientific community is working on better monitoring the load and microphysical properties of AAC in order to assess the influence of those particles on the Earth's radiative budget and clouds. The constellation of satellites called A-Train provides different passive and active sensors for monitoring clouds and aerosols (<http://atrain.nasa.gov/publications/A-TrainFactSheet.pdf>). Passive ~~techniques have~~ imagers offer larger spatial coverage, but have no direct information of the vertical distribution of particles in the atmosphere. Active methods offer unique capabilities, complementary with the passive methods and are dedicated to the study of the vertical profiles of clouds and aerosols. The main retrieved optical properties for aerosols, in "clear-sky" conditions, are the Aerosol Optical Thickness (AOT) and the Ångström Exponent (AE), which is a parameter indicative of the particles size (Kaufman et al., 2002). Recent methods also allow retrieving the aerosol Single Scattering Albedo (SSA) over clear-sky ocean scenes (Torres et al., 2013; Waquet et al., 2016).

The active sensor Cloud-Aerosol Lidar with Orthogonal Polarization (CALIOP) installed on CALIPSO (Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation) ~~satellite provides high-resolution vertical profiles of aerosols and clouds (Chand et al., 2008; Winker et al., 2010).~~ ~~satellite provides high-resolution vertical profiles of aerosols and clouds (Chand et al., 2008; Winker et al., 2003).~~ CALIOP provides the total attenuated backscatter signal ($\text{km}^{-1} \text{sr}^{-1}$) at 532 nm and 1064 nm. From the backscatter measurements, an operational aerosol algorithm allows for retrieval of the vertical extinction profiles as well as the AOT in clear and cloudy skies by assuming an aerosol lidar ratio (extinction to backscatter) (Omar et al., 2009; Young and Vaughan, 2009). ~~(Vaughan et al., 2009; Winker et al., 2009).~~ Moreover, two orthogonally polarized channels measure the parallel and perpendicular backscatter signal at 532 nm that allows calculating the depolarization ratio (i.e. the ratio of the two orthogonal polarization signals) (Hunt et al., 2009). ~~(Winker et al., 2007).~~ Depolarization measurements are used for discrimination between spherical and non-spherical particles (Sassen, 1991). CALIOP provides exhaustive details on the vertical distribution of optical and microphysical properties of aerosols and clouds, including their shape, and a qualitative classification of aerosol type (via the wavelength dependence of the backscatter) (Winker et al., 2009; Young and Vaughan, 2009).

Alternative CALIOP-based research methods have also been introduced to retrieve Above-Cloud AOT (ACAOT). The depolarization ratio method (DRM) (Hu et al., 2007a) and the color ratio method (CRM) (Chand et al., 2008) use fewer assumptions for the retrieval of aerosol properties. These methods are based on light transmission methods and treat the liquid water clouds situated underneath the aerosol layer as a target. Hu et al. (2007b) have shown that, in the case of opaque water clouds, the layer integrated attenuated backscatter at 532 nm and layer integrated attenuated depolarization ratio at 532 nm can be used to retrieve the aerosol optical depth of the overlaying aerosol or optically thin cloud layers. The CRM uses the layer integrated attenuated color ratio, which is the ratio of integrated attenuated backscatter at 1064 nm to 532 nm. Over the visible to near-infrared spectral region, fine-mode absorbing aerosols above clouds exhibit a strong wavelength dependence color ratio (Chand et al., 2008). This makes possible the detection of absorbing biomass-burning aerosols transported above clouds. The color ratio observed in the case of coarse mode particles or purely scattering fine mode

aerosols transported above clouds exhibits little or no wavelength dependence and thus, these particles can be less accurately detected with the CRM method.

Passive sensors have also been used to obtain information on aerosols above clouds. For example, Torres et al. (2012) have developed an algorithm to retrieve the ACAOT and the underlying aerosol-corrected cloud optical depth, using radiance measurements performed in the ultra violet (UV) by the Ozone Monitoring Instruments (OMI). The method takes advantage of the ability of biomass burning and mineral dust aerosols to strongly absorb UV radiations. Another method that can retrieve the ACAOT and, simultaneously, the aerosol-corrected COT is the “color ratio” method proposed by Jethva et al. (2013) that employs measurements in visible and shortwave infrared (SWIR) channels from the Moderate Resolution Imaging Spectroradiometer (MODIS). Also, Meyer et al. (2015) developed an algorithm that employs reflectance measurements from six MODIS channels (from the visible to the shortwave infrared) to retrieve the ACAOT, as well as the COT and droplet effective radius (r_{eff}) of the underlying cloud.

The multi-directional polarization measurements have shown sensitivity to AAC scenes (Waquet et al., 2009, Hasekamp, 2010; Knobelspiesse et al., 2011). Polarization and Directionality of Earth Reflectances (POLDER) instrument is measuring the directionality and polarization of light reflected by the Earth-atmosphere system. The aerosols generate an additional polarized light at forward and side scattering angles (70° to 130°) and reduce the polarized signal of the cloud bow (i.e. a strong polarized rainbow feature observed near 140° in scattering angle). Mineral dust particles do not much polarize light, but they strongly minimize the cloud bow magnitude. Based on these effects, Waquet et al. (2009) have developed a method for retrieving the properties of aerosols above clouds that relies on the polarized radiances measured by POLDER. Because polarized radiances are not affected by the optical thickness of the cloud (i.e. the polarized radiance reflected by the cloud is saturated when the cloud is optically thick enough), the method is able to retrieve the scattering ACAOT at two wavelengths (670 nm and 865 nm) without much assumption on cloud properties. An analysis of the global results obtained with the operational algorithm is given in Waquet et al. (2013a). Furthermore, Peers et al. (2015) have developed a complementary method that uses additional total multidirectional radiances measured by POLDER. The method provides the aerosol SSA and the aerosol-corrected cloud optical thickness. So far, the algorithm of Peers et al. (2015) is a research method, only applied for regional studies (Peers et al., 2016).

Jethva et al. (2014) performed an intercomparative analysis of the ACAOT retrieved with the aforementioned methods, in order to ~~check the consistency among independent techniques~~ assess the consistency (or lack of) between the two independently derived ACAOTs. The results were encouraging and, despite the use of different assumptions and measurements, a close agreement was reported over homogeneous clouds. Similar to this study, our paper will focus on the comparison between collocated active and passive AAC inversion products, improving our understanding of the ACAOT. But, compared to Jethva et al. (2014), who focused only on two study cases, we perform a global and multi-annual investigation to provide robust statistics results. The vertical distribution of the aerosol and cloud layer will be also considered. We will concentrate on the following methods: (a) the CALIOP operational method (CALIOP_{OM}) because of the numerous studies in which it was used, (b) the DRM developed by Hu et al. (2007a), (c) a calibrated version of the DRM

algorithm and (d) the POLDER polarization method. The DRM and POLDER methods were chosen because both are measuring AAC properties above the same type of cloudy scenes (i.e. optically thick and homogeneous liquid water clouds). Moreover, both techniques are sensitive to all types of particles (scattering or absorbing particles, fine or coarse ones), which is not the case for CRM that can operate only for absorbing aerosols. It is also interesting to compare these two approaches since the POLDER method requires a hypothesized aerosol microphysics, while DRM doesn't require any hypothesis for the aerosols but requires assumptions and an approximate model to estimate the signal backscattered by clouds.

To begin with, we briefly recall the principle of each algorithm and the data selection strategy. The results of AOT intercomparison are presented in sections 3 and 4. We first present a regional comparison and then describe a global comparison for a period of ~~four and a half~~^{4.5} years in function of the type of aerosols and AAC scenes (aerosol and cloud layers in contact or well separated). Discussions and conclusions will be drawn in sections 5 and 6.

2 Methodology and data selection

2.1 POLDER polarisation method

POLDER, an instrument on the PARASOL (Polarization and Anisotropy of Reflectances for Atmospheric Science coupled with Observations from a Lidar) satellite, is a wide-field imaging radiometer/polarimeter (Tanré et al., 2011). This instrument measures the angular and spectral behaviour of the normalized total and polarized radiances (Herman et al., 2005).

The method for retrieving the above-cloud scattering AOT developed by Waquet et al. (2013b) consists of a comparison between polarized radiances measured by POLDER at 670 nm and 865 nm and polarized radiances pre-computed with a Successive Order of Scattering (SOS) code (Deuzé et al., 1989) for seven aerosol models that follow a single lognormal size distribution. Six models correspond to spherical aerosols (fine-mode particles) with radius from 0.06 to 0.16 μm , for which a complex refractive index of $1.47-0.01i$ is assumed. The seventh model is bimodal and characteristic of non-spherical aerosols (dust) with a refractive index of $1.47-0.0007i$. In the search for the best fitting aerosol model, the operational algorithm follows the strategy described by Waquet et al. (2013b). After a first step, the algorithm produces an approximation of the AOT at 865 nm. As a function of this AOT value, a decision tree is applied: if the AOT is larger than 0.1 then the algorithm will search the best fitting model within all the seven models without any angular constraint for the selection of the POLDER data (scattering angle ranging from 0° to 180°). Next, if the mineral dust model fails to reproduce the data or if the AOT retrieved in the first step is smaller than 0.1, then only fine-mode models are considered in the retrieval scheme and the viewing geometries are restricted to side or forward viewing geometries (scattering angles smaller than 130°). The AOT threshold of 0.1 at 865 nm is empirical and was introduced since the retrieval of the aerosol type (dust or fine mode particles) becomes difficult for small AOT.

Collocated cloud properties retrieved from MODIS (Moderate Resolution Imaging Spectroradiometer) at high resolution ($1 \times 1 \text{ km}^2$ at nadir) are used to characterize and to select the cloudy scenes within a POLDER pixel ($6 \text{ km} \times 6 \text{ km}$

at nadir). We only consider fully covered cloudy pixels associated with optically thick liquid water clouds: the cloud optical thickness retrieved by MODIS has to be larger than three and a cloud phase algorithm is applied to select liquid water clouds (Riedi et al., 2010). Moreover, Waquet et al. (2013b) have introduced a mask to eliminate cirrus above liquid clouds that makes use of the MODIS Brightness Temperature Difference (BTD) between 8.5 and 11 μm wavelength bands as well as MODIS and POLDER cloud top pressure estimates. Lastly, the AOT retrievals at the ~~high~~ $6\text{ km} \times 6\text{ km}$ ~~spatial-POLDER~~ ~~pixel~~ resolution are aggregated to $18\text{ km} \times 18\text{ km}$ spatial grid. The retrieved solution is kept if the number of $6\text{ km} \times 6\text{ km}$ pixels is larger than 5 and if the standard deviation computed for the mean AOT is smaller than 0.1. This latter procedure allows to remove edges of clouds. In our study, we use the version 3.00 of the official output product PARASOL_PM02-L2 for AAC scenes available at ICARE website (<http://www.icare.univ-lille1.fr/parasol/products/>).

2.2 CALIOP methods

2.2.1 Operational method

The CALIPSO lidar (CALIOP) is a frequency-doubled Nd:YAG laser, dual-wavelength, dual-polarization, elastic backscatter lidar (Winker et al., 2009). ~~(Winker et al., 2003)~~. The lidar returned signal is normalized and range-corrected to provide the total attenuated backscatter coefficient ($\text{km}^{-1}\text{ sr}^{-1}$).

In order to retrieve the attenuated backscatter data and the columnar AOT at 532 nm and 1064 nm, the operational CALIOP algorithm combines the feature and layer detection scheme (Vaughan et al., 2009) ~~(Winker et al., 2009)~~ with the extinction retrieval algorithm (Young and Vaughan, 2009) that employs assumptions on the extinction-to-backscatter ratio of aerosols. There are several steps involved in the operational data processing: 1) cloud and aerosol layers are detected in the backscattered signal along with their altitudes, 2) the algorithm determines which layers have cloud or aerosol features, 3) the cloud ice-water phase is estimated and the aerosol lidar-ratio is determined, using assumptions on the aerosol models, and finally, 4) the extinction coefficients and AOT are retrieved at 532 and 1064 nm.

Lidar systems have a limited capability to determine the composition and size of aerosols. Hypotheses are then used on the aerosol phase function at 180° and on the aerosol single scattering albedo (SSA) in order to calculate the aerosol lidar ratio. In the operational algorithm, the aerosol models consist in a mixture of aerosol components characteristic of a region or an air mass. It should be noted that an incorrect assumption for the lidar ratio ~~is~~ could be a source of substantial errors in the AOT retrieved with this method.

For our study we use the level 2 version 3.01 of the inversion products, officially named CAL_LID_L2_05kmALay (ALay) and CAL_LID_L2_05kmCLay (CLay) (that can be found at <http://www.icare.univ-lille1.fr/calipso/products/>), which provide respectively the aerosol and cloud layer parameters at a nominal horizontal resolution of 5 km. From these products we used the AOTs retrieved at 532 nm and 1064 nm, the aerosol base and top altitudes, the cloud top altitude, the ice-water cloud phase and the feature type. We also use CALIOP level 1 dataset, labelled CAL_LID_L1-ValStage1 (link above) that

provides the attenuated backscatter coefficient calculated at a vertical resolution of 30 m and 333 m and at a horizontal resolution from -0.5 to 8.2 km altitude (Winker et al., 2007).

2.2.1 Depolarisation Ratio Method

For retrieving the optical thickness of a thin high layer (aerosols or clouds) above a lower and optically thick water cloud layer, Hu et al. (2007a) and Chand et al. (2008) describe the depolarization ratio method applied to CALIOP measurements. An opaque cloud with a minimum optical depth of three will attenuate the lidar beam completely. For optically thick clouds, we estimate the optical thickness of the above thin aerosol or cloud layer by treating the opaque cloud as a target and by using the Beer-Lambert law to estimate the direct transmission of light above this cloud layer. We will refer to this product hereafter as DRM_{Hu} .

The physical properties used in this method are the cloud attenuated backscatter coefficient (γ'_{water}) integrated from the base to the top of the cloud layer at 532 nm and the integrated attenuated depolarization ratio (δ') at 532 nm. When Rayleigh scattering contribution has been corrected for, the definition of γ'_{water} is given by the following equation:
The definition of γ'_{water} is given by the following equation:

$$\gamma'_{water} = \int_{z_{top}}^{z_{base}} \beta'(z) dz, \quad (1)$$

where β' is the total attenuated backscatter coefficient ($km^{-1} sr^{-1}$).

In situations where the cloud is optically thick and there are no aerosol above the cloud, the lidar equation simplifies to the following definition, expressed as a function of the lidar ratio (S_c) and layer effective multiple scattering factor (η_c) (Platt, 1979):

$$\gamma'_{water,calc} = \int_{z_{top}}^{z_{base}} \beta'(z) dz = (2\eta_c S_c)^{-1}, \quad (2)$$

S_c is narrowly constrained to about 19 sr at a wavelength of 532 nm. This value is typically used for liquid water clouds with droplets smaller than about 50 μm (O'Connor et al., 2004; Pinnick et al., 1983). η_c , which takes values between 0 and 1, is strongly related to the cloud depolarization ratio δ' (defined as the ratio of the parallel and perpendicular polarization signals), since multiple scattering processes tend to depolarize light. An approximate relation was derived from Monte Carlo simulations (Hu et al., 2006):

$$\eta_c = \left(\frac{1-\delta'}{1+\delta'} \right)^2, \quad (3)$$

After γ'_{water} is corrected for molecular and gaseous absorptionattenuation, the ratio between γ'_{water} and $\gamma'_{water,calc}$ should be equal to 1 in the absence of higher aerosol or cloud layer, and with an accurate lidar calibration. Instead, in case of an overlying aerosol or cloud layer, this ratio can be written as

$$\frac{\gamma'_{\text{water}}}{\gamma'_{\text{water,calc}}} = T^2 = \exp(-2\tau_{\text{top,DR}}), \quad (4)$$

where T^2 is the transmission of light after a two-way propagation between the sensor and the targeted cloud, and $\tau_{\text{top,DR}}$ is the higher layer's optical thickness. It follows from Eq. (4) that the optical depth ($\tau_{\text{top,DR}}$) is given by:

$$\tau_{\text{top,DR}} = \frac{-1}{2} \ln(2S_c \gamma'_{\text{water}} \eta_c), \quad (5)$$

DRM_{Hu} differs from the operational method by the fact that it does not rely on assumptions related to aerosol microphysical properties (aerosol phase function and SSA) and does not require accurate layer detection for the overlying aerosol layer in order to estimate the AOT integrated over the atmospheric column. The main uncertainties of the DRM_{Hu} are linked to the calibration of the lidar, which impact the estimate of the parameters in Eq. (5).

Providing a robust, self calibrated method at global scale and for the whole CALIPSO dataset is not trivial and in order to improve the estimate of the AOT with the DR method, the creators-developers of the Synergized Optical Depth of Aerosols and ICE clouds (SODA & ICE, available at the ICARE thematic center), Josset et al. (2010; 2012), modified the original formalism of DRM_{Hu}. The main reason for these modifications is that the relationship between the multiple scattering factor and the depolarization by the cloud shows a systematic deviation from the theory (see Fig. 2 in Hu, 2007). The multiple scattering–depolarization relationship has been confirmed by laboratory experiments (Cao et al., 2009). Even if it has to be modified in presence of submicrometer or non-spherical particles, the origin of the discrepancy between theory and observation points towards an instrumental issue. The long transient response of the receiver has been proposed as an explanation and a correction was also proposed (Hu et al., 2007b). There are, however other issues related to the calibration of the polarization channel that could explain the discrepancy. The low gain/ high gain merging scheme and the day/night calibration transfer are a significant source of uncertainty. Previous research (Sassen and Zhu, 2009) found a bias in the linear depolarization of cirrus clouds of around 30%.

In order to overcome these difficulties and improve the accuracy of the method, SODA takes advantage of the high number of CALIOP observations of liquid water clouds in the absence of AAC. Practically, the SODA algorithm introduces global scale correction factors in the multiple scattering coefficient to depolarization relationship and a recalibrated value of the liquid water cloud lidar ratio as a function of latitudes. These two corrections come from the fact that, when the liquid water clouds are optically dense and in absence of AAC, the lidar equation can be reduced to Eq. (2). Over the ocean, the lidar ratio of most liquid water clouds is relatively constant (Hu et al., 2006) and the multiple scattering coefficient can be measured directly if the lidar is well calibrated. This correction follows the original intent of DRM_{Hu} (Hu et al., 2007a), which has always been to be a self calibrated method, unaffected by instrumental or geophysical uncertainties (see Eq. (4) of Hu et al. (2007a) and related discussion). However, because the discrepancy between theory and observations is due to an instrumental artefact linked to the receiver electronics, SODA introduces a clearer separation between the parallel and perpendicular channel than in DRM_{Hu} (Hu et al., 2007b). DRM_{Hu} relates the total backscatter coefficient to the ratio of perpendicular and parallel backscatter coefficient while SODA links the parallel backscatter coefficient to this ratio. This

approach is supported by the theory of light propagation in dense medium where the contribution of multiple scattering to the perpendicular and parallel channel is identical (Xu and Alfano, 2005) and by the analysis of CALIOP data.

A preliminary and mandatory step of the calibration procedure is to select optically opaque liquid water clouds with no AAC. The calibration modules of SODA use the following criteria. Note that there is some level of redundancy in order to increase data quality selection.

a) Criteria of optical density:

- the top and bottom of the cloud is given by the 333 m CALIPSO cloud product. This ensures a minimum level of signal strength and the presence of a transparent atmosphere above it. Note that SODA corrects the molecular attenuation above the cloud, but does not contain an explicit correction of it within the cloud because of the high scattering ratio of liquid water clouds. Nonetheless, the molecular contribution is statistically taken into account by the calibration procedure.
- the maximum of the lidar signal is above the base of the cloud. This ensures an an ~~minimum~~-adequate level of attenuation of the signal from the surface return.
- the ocean surface integrated attenuated backscatter is below a detectability threshold of $7.5 \times 10^{-6} \text{ km}^{-1} \text{ sr}^{-1}$ for nighttime data and $1 \times 10^{-3} \text{ km}^{-1} \text{ sr}^{-1}$ for daytime data. This corresponds to a cloud optical thickness of around 2 during daytime and 4-5 during nighttime, which is when this filter is the most useful. The intent of this threshold is the same as the previous criteria. More specifically, the goal is to use a threshold such that half the shots are below the noise sensitivity of the instrument.

b) Criteria of cloud in liquid phase

- the temperature at the top of the cloud is higher than 0°C . The isotherm is defined by the GMAO (Global Modelling and Assimilation Office) temperature when interpolated on the CALIPSO vertical grid.
- the total cloud liquid water contained in a vertical column of atmosphere retrieved from collocated pixels of AMSR-E/AMSR2 is larger than 0 mm.

c) Criteria of clear air above the cloud

- the total 532 nm integrated attenuated backscatter coefficient from 20 km of altitude to the top of the cloud is below the following threshold:

$$\int_{z_{\text{top}}}^{20\text{km}} \beta'(z) dz < \frac{1 - \exp(-2\tau_{\text{air,mol}})}{2 \frac{8\pi}{3} 1.5}, \quad (6)$$

where $\tau_{\text{air,mol}}$ is the optical depth due to air Rayleigh scattering and ozone absorption. The factor 1.5 allows reducing the occurrences of false positives due to noise. It also allows to simplify the formalism as the King factor (Bates, 1984; King, 1923) can be neglected with no expected impact on the results. As this filter introduces more aerosol contamination during daytime (similar to Josset et al. 2010, Fig. 4), it could be desirable to consider the shot-to-shot CALIOP cloud mask for future version of the algorithm as SODA already uses this information for the scene classification flag.

As previously mentioned, even if the multiple scattering–depolarization relationship has been confirmed by laboratory experiments (Cao et al., 2009), the relationship between the multiple scattering factor and the depolarization by

the cloud shows a systematic deviation from the theory. It has to be corrected, as it would introduce a bias in aerosol optical depth with the particularly undesirable trait to correlate with cloud microphysical properties. As a first step, SODA calibrates the multiple scattering to depolarization relationship for nighttime data on a monthly basis. The data of interest are based on Eq. (2) and can be written as: ~~As a first step, SODA calibrates the multiple scattering to depolarization relationship for nighttime data on a monthly basis. For all opaque liquid water clouds defined with the above criteria, SODA looks for the least square fit between the data and η_{calibr} defined as:~~

$$\eta_{calibr} = A\eta_c + B\eta_c^2, \quad (7)$$

~~The data of interest are based on Eq. (2) and can be written as~~

$$\eta_{geocalibr} = \frac{1}{2 \times 19 \times \gamma'_{water,parallel}}, \quad (78)$$

where $\gamma'_{water,parallel}$ is the parallel-integrated backscatter coefficient. This equation provides a direct measurement of the multiple scattering coefficient of liquid water clouds (η_{geo}) when their lidar ratio is constant. The constant value of 19 sr used in the SODA algorithm is based on (Hu et al., (2006) who found a lidar ratio equal to 19.1 ± 0.21 sr when the 41 droplet size distributions of (Miles et al., (2000) are used as inputs of a Mie scattering code.

For all opaque liquid water clouds defined with the above criteria, SODA then compares the direct measurement of the multiple scattering coefficient (η_{geo}) and the theory (η_c) to find the second order polynomial that best fit the data in the least square fit sense. This defines the calibrated multiple scattering coefficient (η_{calibr}):

$$\eta_{calibr} = fit[\eta_{geo}(\eta_c)] = A\eta_c + B\eta_c^2 \quad (8)$$

This procedure allows us to use a relationship between depolarization and multiple scattering that fits the observation. Using Eq. (3) instead of Eq. (8) would create an aerosol optical depth bias that would typically range between 0.02 and 0.08. Although this is not always significant, this correction is necessary as the resulting ACAOD bias does correlate with the clouds microphysical properties. This is particularly undesirable as the link between aerosol and cloud microphysical properties is an active topic of research.

As a second step, SODA calculates the apparent lidar ratio $S_{c,lat}$ of all opaque liquid water clouds as a function of each degree of latitude and for both 532 and 1064 nm. This procedure is done separately for daytime and nighttime data. The latitudinal dependency is aimed at correcting the calibration inaccuracies of CALIOP, which are dependent on latitude (Powell et al., 2010) and possible geophysical variations of cloud microphysical properties between the northern and southern hemisphere.

$$S_{c,lat} = \frac{1}{2 \times \eta_{calibr} \times \gamma'_{water,parallel}}, \quad (9)$$

For the four and a half years of data we considered in this study, the median of $S_{c,lat}$ for the nighttime data is 19.36 sr, which is interestingly close from the theoretical value determined by (Hu et al. 2006). For daytime data, $S_{c,lat}$ is systematically higher and with a median of 20.64 sr. The systematic daytime/nighttime difference could be geophysical.

However, it is premature to reach such conclusion until all nighttime/daytime differences in the CALIPSO data have been addressed.

Lastly, All these coefficients are finally integrated in the AOT retrieval equation:

$$\tau_{\text{top,DRcalibr}} = -\frac{1}{2} \ln(2S_{\text{c,lat}} \eta_{\text{calibr}} \gamma'_{\text{water,parallel}}), \quad (10)$$

Through this study, we will refer to this product as DRM_{SODA} and can be found at ICARE data center (<http://www.icare.univ-lille1.fr/projects/soda/>).

2.3 Data selection

2.3.1 Collocation

The A-Train satellites pass through close orbits within several minutes, providing coincident observations of POLDER, MODIS and CALIOP instruments. Using the nearest pixel approximation, CALIOP files are used as a space reference for sampling POLDER and MODIS products. CALTRACK is the output dataset and can be found at ICARE data and service center. It contains coincident data from POLDER at $18 \text{ km} \times 18 \text{ km}$ and MODIS, extracted under the CALIOP track at 5 km horizontal resolution. The DRM_{Hu} and DRM_{SODA} optical depth retrievals are processed at the CALIOP native resolution of 333 m and aggregated afterwards at 5 km horizontal resolution. Moreover, for a better consistency of the AOT comparison, the POLDER AOT was extrapolated at 532 nm using the AE retrieved with the POLDER algorithm.

We also limited the cloud top altitude at 5 km because we are interested in low-level clouds. Likewise, we eliminated from our data analysis all situations in which the aerosol top altitude exceeds 10 km. The maximal aerosol top altitude is limited at 10 km. This maximal value should be sufficient, since most of the biomass burning and dust aerosol layers are typically observed between 0.5 and 4.0 km over ocean (Torres et al., 2013).

2.3.2 Distinction between vertical profiles

Additionally, we have employed an approach that is similar to the concept of Costantino and Bréon (2012) to classify the type of AAC scenes. The respective positions of the aerosol and cloud layers are defined using the CALIOP ALay and CLay products. We classify the AAC scenes into three categories: “attached”, “detached” and “undetermined”. The so-called “attached cases” correspond to situations where the aerosol layer touches the top of the beneath cloud layer. For these cases, we assume that the vertical distance of the aerosol bottom altitude from cloud top altitude must be lower than 100 meters, without penetrating the cloud layer for more than 50 meters. Inversely, the “detached cases” correspond to aerosol and cloud layers that are considered well separated, considering a distance higher than 500 m between the aerosol base altitude and the cloud top. Aerosol and cloud layers with the base altitude within a distance between 100 and 500 meters above the cloud layer are considered too uncertain and are excluded from our study. We also removed the situations for which the detected CALIOP aerosol top and/or bottom altitudes are located below the cloud top, the aerosols are located

~~within or below the cloud layers~~, assuming that these data are ~~too~~ highly uncertain. Practically, we rejected the CALIOP data for which the aerosol layer penetrates the cloud layer by more than 50 meters. The third category, ~~called~~ “undetermined” corresponds to situations for which the respective position of the aerosol or cloud layer is not identified by the CALIOP layer detection algorithm (i.e. missing data), even though POLDER and DRM AAC AOT retrievals are valid. We chose to
5 keep these data in our analysis as they cover the majority of POLDER AAC detected cases with a non-negligible AOT (even if CALIOP classifies them as invalid or noise), as the purpose of the paper is to better understand the differences between the methods cannot be determined by CALIOP (i.e. missing data).

We also distinguish the “two layer situation” (i.e. one aerosol layer and one cloud layer) from the “multiple layer situations” (more than one aerosol layer and/or more than one cloud layer). These latter situations are filtered in our analysis
10 for the sake of simplicity (see Sect. 3.4 and Sect. 4).

3 Regional analysis and case studies

The results presented in this section were acquired from May to October 2008. We selected three distinctive regions (see Fig. 2) that are under the influence of various aerosol species and different types of clouds: a) an area that extends from 30° S to 5° N and 12° W to 14° E over the South Atlantic Ocean (SAO), b) an area between 10 to 35° N and 10 to 40° W
15 over the North Atlantic Ocean (NAO) and c) an area located between 35 to 60° N and 140 to 170° E over the North Pacific Ocean (NPO). The south of the African continent is the main contributor to biomass-burning aerosols above clouds, originating from man-made crops fires (Waquet et al., 2013b). These aerosols are highly absorbing (SSA of approximately 0.84 at 865 nm) and associated with high AE values; they mainly contribute to the fine mode. The NAO area is mainly under the influence of dust aerosols originating from the Saharan Desert for the time period of interest. These particles are mainly
20 non-spherical and contribute primary to the coarse mode. They are moderately absorbing at the wavelength of CALIOP (532 nm) and almost non-absorbing at 865 nm (SSA of approximately 0.98) (Balkanski et al., 2007; Dubovik et al., 2002; Peers et al., 2015). The North Pacific Ocean (NPO) is associated with various types of particles: fine mode aerosols with rather scattering properties originating from man-made pollution (Waquet et al., 2013a; Yu et al., 2008), biomass-burning from forest fires (Peers et al., 2015; Zhang et al., 2003) and dust originated from the Asian deserts. Potential mixture of these
25 different species is also possible for this area (Yu et al., 2006).

Cloud types and their associated optical and microphysical properties are expected to be different in these three regions (Warren et al. 1988). Low-level stratocumulus clouds typically cover the SAO, with some occurrences of cumulus and altostratus clouds. Cumulus, altostratus clouds and some stratocumulus clouds generally cover the NAO. The cloud cover is generally fractional over this part of the Atlantic Ocean. Stratocumulus clouds also frequently cover the NPO.
30 Higher altostratus and cumulus clouds are also often observed over this area. Cirrus clouds can be frequently found at mid-latitudes and also in the intertropical convergence zone, which includes the NPO and the NAO regions.

We studied six months of data over each region to observe the consistency between different techniques for various types of aerosols. For this part of the study, we mixed the “two-layer” and “multiple layer” situations and we analysed all the data, disregarding the position of the aerosol and cloud layers. A case study was selected for each region in order to show the spatial variability of the AOT at 532 nm retrieved along the CALIOP transect. The first case is related to a biomass-burning event detected off the coast of Namibia on 13 August 2006. The second event concerns Saharan dust lifted above clouds westwards over the North Atlantic Ocean on 4 August 2008, and the third case concerns Siberian biomass-burning aerosols transported over the Okhotsk Sea, on 3 July 2008.

Figure 1 presents the backscatter profile at 532 nm and at 1064 nm ($\text{km}^{-1} \text{sr}^{-1}$) of the lidar CALIOP for the three case studies, which directly provides information on the aerosol and cloud vertical distribution. In addition, the AOT and AE values measured by different techniques are presented along the CALIOP track. Additional results for the study cases comparison are shown in Table 1.

Figure 23 shows the regional comparison between the AOT and AE retrieved with POLDER and DRM_{SODA} for a period of six months in 2008. The retrieval of aerosol type becomes difficult at small AOT. Therefore the AE comparison was performed only when the values of POLDER AOT at 865nm and DRM_{SODA} AOT at 532 nm were larger than 0.1. The AE mean value is shown with a dashed blue line. The lateral histograms show the data distribution. For the AOT comparison the color scale represents the POLDER $\text{AE}_{670/865}$. In the case of AE comparison, the POLDER $\text{AOT}_{532\text{nm}}$ was also reported with a color scale. The above-mentioned description is also considered in Fig. 3, which presents the regional comparison between the AOT and AE retrieved with POLDER and $\text{CALIOP}_{\text{OM}}$ for the same period. Additional results for the regional inter-comparison are reported in Table 2.

3.1 African biomass-burning aerosols

According to the CALIOP vertical profile at 532 nm of the biomass-burning case (Fig. 1a), the cloud top is at around 1.5 km and the aerosol layer is located between 3 and 5 km. The 1064 nm backscatter profile (Fig. 1b) exhibits an aerosol layer with a larger vertical extent, showing up more potential contact area with the underlying cloud. We observe a thin cirrus cloud between 10° and 12° S that was not filtered, probably since the cirrus is optically too thin (Fig. 1cb and 1de). In general, there is an excellent agreement between POLDER, DRM_{Hu} and DRM_{SODA} AOT retrievals with a square correlation $R^2 = 0.93$ (see Table 1). High values of AOT are retrieved by the different methods, with AOT values as large as 1.5. The retrieved POLDER $\text{AE}_{670/865}$ is larger than 1.8 (Fig. 1de), which is characteristic for fine mode particles (Dubovik et al., 2002). The DRM_{SODA} $\text{AE}_{532/1064}$ is consistent with the POLDER AE, with values higher than 1.5. AOT values retrieved by $\text{CALIOP}_{\text{OM}}$ are much lower than the ones retrieved by the three other techniques. The maximal AOT retrieved by $\text{CALIOP}_{\text{OM}}$ at 532 nm is 0.5. A possible explanation for this potential low bias was proposed by Jethva et al. (2014): in case of optically thick aerosol layer, the sensitivity of the backscattered signal to the altitude of the base of the aerosol layer would be reduced or lost, being strongly attenuated by the two-way transmission term. As a result, the operational algorithm may overestimate the aerosol base altitude and so underestimate the geometrical thickness of the aerosol layer and

consequently the AOT. The selection of an inappropriate aerosol model (i.e. aerosol lidar ratio S_g for biomass burning, varies between 70 ± 28 at 532 nm and 40 ± 24 sr at 1064 nm (Catrall et al., 2005; Omar et al., 2005)) or the significant biases found in the V3.01 CALIOP 1064 nm calibration, might also contribute to the underestimation of the AOT for this case study. The CALIOP_{OM} mean $AE_{532/1064}$ seems quite low for fine mode particles (AE values are lower than 1). The selection of an inappropriate aerosol model might also contribute to the underestimation of the AOT for this case study.

Regional analysis shows that South Atlantic region is mostly characterized by biomass-burning aerosols with large AOT and AE (Fig. 23a and 23b). On average, the cloud top height is located below 1.5 km, while the aerosol layers are frequently located between 2.5 and 4 km (see Table 3). The AOT_{532nm} measured by DRM_{SODA} and POLDER may reach values as large as 1.30 (Fig. 23a), with 80 % of the retrieved AOTs ranging between 0.05 and 0.8. This AOT inter-comparison shows close correlation between DRM_{SODA} and POLDER ($R^2 = 0.83$). The mean value of POLDER $AE_{670/865}$ is 2.05, whereas the mean DRM_{SODA} $AE_{532/1064}$ is 1.79 (Table 5) (both typical for BBA). DRM_{Hu} and DRM_{SODA} give rather same results. From the linear regressions performed (see Table 2) we can observe that the offset is always positive for DRM_{Hu} and systematically larger than the absolute value for DRM_{SODA}, when compared to POLDER method. The AOT estimated by POLDER is constantly between DRM_{Hu} and DRM_{SODA}.

We do not find a good correlation between the CALIOP_{OM} and POLDER AOT and AE retrievals. The CALIOP_{OM} mean AOT_{532nm} is 0.12 and the mean $AE_{532/1064}$ is 0.97. Comparing with POLDER and DRM_{SODA}, CALIOP_{OM} is underestimating the ACAOT by a factor of 2.92.

3.2 Saharan desert dust aerosols

For the mineral dust case (Fig. 1ed), the cloud top altitude is located at approximately 1 km altitude whereas the aerosol layer is located between 2 and 5 km for latitudes between 18° and 23° N. Figure 1ge shows that the POLDER, DRM_{SODA} and DRM_{Hu} AOT_{532nm} increase up to 0.92, following the same gradient. The correlation coefficients between POLDER parameters and DRM_{Hu} and DRM_{SODA} parameters are close (Table 1). The majority of POLDER $AE_{670/865}$ and DRM_{SODA} $AE_{532/1064}$ are associated with values lower than 0.4 (Fig. 1hf), which indicates that coarse mode particles are predominant (Dubovik et al., 2002). Except for few retrievals associated with an abrupt change in the AE and AOT measured by CALIOP_{OM} (around 21° N in latitude), 90 % of the CALIOP_{OM} AOT_{532nm} is lower than 0.45, being once again underestimated with respect to the other estimates. Most of CALIOP_{OM} $AE_{532/1064}$ values are underestimated (i.e. overestimation of the particles size) in comparison with the AE retrieved by the two other algorithms. These low values of AOT and AE may be explained once more by a biased CALIOP calibration at 1064 nm combined with an unfitted model selection (i.e. for desert dust, S_g is equal to 40 ± 20 sr at 532 nm and 55 ± 17 sr at 1064 nm (Catrall et al., 2005; Omar et al., 2005)).

A regional study shows similar AOT and AE results over the North Atlantic region (Fig. 23c). On average, the aerosol layers are located between 3 and 4.5 km and the cloud top heights are typically around 1.4 km (see Table 3). The values of AOT_{532} retrieved from POLDER and DRM_{SODA} are well correlated ($R^2 = 0.82$), with maximum values of

respectively 1.19 and 0.95. Nonetheless, we observe a larger offset between DRM_{SODA} and $\text{POLDER AOT}_{532\text{nm}}$ for this region (-0.09) compared to the South Atlantic Ocean region (-0.03). The use of only one dust model in the LUT algorithm used for POLDER remains a limitation that might explain this larger offset. The introduction of additional dust models with larger or smaller effective radius values may contribute to improve the AOT retrievals for dust ACC events. Regarding the POLDER $\text{AE}_{670/865}$ retrievals, most of the values are lower than 0.4, which is expected for desert dust aerosols (Fig. 23c and 23d). However, for AOT values lower than 0.2, the $\text{AE}_{670/865}$ retrieved by POLDER is between 1.4 and 2.2. This is explained by the fact that the selection of the dust model is not permitted in the POLDER algorithm in case of low AOTs. Nonetheless, all three methods are consistent in revealing the predominance of the coarse mode. The mean values for the AE are 0.49 for POLDER, 0.10 for DRM_{SODA} and -0.19 for $\text{CALIOP}_{\text{OM}}$. The $\text{AOT}_{532\text{nm}}$ correlation between $\text{CALIOP}_{\text{OM}}$ and POLDER is low, with $R^2 = 0.42$.

3.3 East Asian mixture of aerosols

The CALIOP transect shows that Siberian biomass-burning case is located between 40° and 52° N, the cloud top altitude is constantly around 1 km, and the base of the aerosol layer decreases from 10 km in the south (at 45° N) to around 2 km in the north (at 54° N) (Fig. 1ig). We notice also cirrus clouds at high altitude (around 10 km) between 47° and 51° N, which were efficiently eliminated from the retrievals (Fig. 1kh). The maximum POLDER AOT value is as large as 1.9, while DRM reaches 1.3 in AOT. Nonetheless, Table 1 shows that POLDER and DRM methods $\text{AOT}_{532\text{nm}}$ retrievals are consistent ($R^2 = 0.90$). POLDER $\text{AE}_{670/865}$ values are between 1.7 and 2.3, indicating small particles of smoke, while DRM_{SODA} $\text{AE}_{532/1064}$ has a large range of values (Fig. 1j). The number of sampled ACAOT events by $\text{CALIOP}_{\text{OM}}$ is 4.5 times less than of POLDER and DRM_{SODA} . For these, the $\text{CALIOP}_{\text{OM}}$ AOTs are underestimated by a factor of 1.5 compared to ones retrieved by the other methods. Also the correlation coefficient with POLDER is 0.45.

On a regional scale, this area is under the influence of various aerosols (BBA, DDA, pollution) and elevated cirrus clouds are frequent. The mean cloud top altitude is around 1 km and the aerosols are between 2.5 km and 4.0 km. As indicated in Table 3, the maximum aerosol altitude is 9.85 km, which might suggests cirrus misclassification. In some cases, DRM_{SODA} gives large values of $\text{AOT}_{532\text{nm}}$ (larger than 1) whereas the POLDER estimates $\text{AOT}_{532\text{nm}}$ smaller than 0.2. These situations could be explained by a misinterpretation of thin cirrus clouds as aerosols. Otherwise, the POLDER mean $\text{AOT}_{532\text{nm}}$ and DRM_{SODA} $\text{AOT}_{532\text{nm}}$ are in rather close agreement (0.18 and 0.15, respectively, see Table 4), but the correlation between them is low ($R^2 = 0.37$, Table 2). All methods show a large variability for the retrieved AE, with values that correspond to particle size distributions dominated by coarse or fine modes and mixtures (Table 5). As previously mentioned, the algorithm developed for POLDER uses a bimodal aerosol model for dust. However, the possibility of mixing different fine and coarse aerosol models in various proportions is not yet included. This might explain why we found a lower correlation between the POLDER and DRM retrievals for this region. As for above, the $\text{CALIOP}_{\text{OM}}$ and POLDER $\text{AOT}_{532\text{nm}}$ are not correlated ($R^2 = 0.24$).

In general, there is a good agreement between POLDER and DRM_{SODA} AOTs, especially when the fine mode or coarse mode dominates the particle size distribution (i.e. BBA and DDA). Overall, DRM_{SODA} and DRM_{Hu} give similar results. However, the AOTs retrieved with DRM_{Hu} are generally larger than those of DRM_{SODA} for all the three regions (i.e. 0.37 compared to 0.28 for SAO, see Table 4). While DRM_{SODA} has a constant negative offset when compared to POLDER, DRM_{Hu} rarely retrieves null AOT values (offsets always larger than 0, see Table 2). This is likely to be a consequence of the calibration performed for the DRM_{SODA} method. Also, there is no obvious correlation between the $\text{CALIOP}_{\text{OM}}$ and POLDER $\text{AOT}_{532\text{nm}}$ retrievals for all regions.

Finally, in addition to the six months regional study, we also examined the impact of the vertical aerosol-cloud profiles over the three regions using data acquired from May to October between 2006 and 2010. We systematically found higher correlation coefficients between the DRM_{SODA} and POLDER AOTs when the layers were well separated than when they were in contact (see Table 6). These results have led us to consider the vertical distribution of aerosols and clouds in the global comparison.

4 Global analysis on different types of scenes

4.1 Detached, attached, undetermined

Figure 45a shows the global comparison between the $\text{AOT}_{532\text{nm}}$ and AE retrieved with POLDER and DRM_{SODA} for the *detached* cases. The AE comparison was only performed when the POLDER AOT at 865 nm and DRM_{SODA} AOT at 532 nm are larger than 0.1. The color scales used in Fig. 45 represent either the POLDER $\text{AE}_{670/865}$ for the AOT comparison (Fig. 45a) or the POLDER $\text{AOT}_{532\text{nm}}$ for the AE comparison (Fig. 45d). Considering the large amount of selected data (85.6 % of the two-layer cases) in terms of both spatial and temporal coverage, the comparison shows a good correlation between the two methods ($R^2 = 0.68$). A better agreement between the methods is found when the values of DRM_{SODA} and POLDER AE are larger than 1.8. This is likely due to the fact that the POLDER method is more sensitive to fine mode aerosols, due to polarization measurements, and also because an improved description of the fine mode properties was included in the LUT (i.e. six fine mode aerosol models are used).

Events for which the aerosol layer is *attached* to the cloud top represent 14.4 % of the total number of two-layer cases. They are associated with lower AOT and the correlation between the two retrievals largely decreases (compare to the detached events). The correlation between the two AOT retrievals also decreases ($R^2 = 0.36$, Fig. 4c). The POLDER AOT is larger by a coefficient of 1.7 than the DRM_{SODA} AOT on average. The AE given by both methods is approximately 1.0 (when considering only AE values associated with $\text{AOT} > 0.1$). The lateral histogram shows that the POLDER method identifies AAC events associated with both low and high AE values resulting in a mean AE of about 1.0.

The *undetermined* situations correspond to retrievals when CALIOP does not give all the information regarding the layer altitudes. The number of cases is significant (approximately 92 % of the total number of global retrievals) but most of data (95 %) corresponds to $\text{AOT}_{532\text{nm}}$ lower than 0.2. This probably explains why the layer detection algorithm has

difficulties in estimating the base and top of the aerosol layer. For the *undetermined* cases, we observe that there is not much correlation between POLDER and DRM_{SODA} measurements. On average, the DRM_{SODA} AOTs are centred around zero for this category whereas POLDER has a non-negligible low AOT for most cases. In this category, the AE comparison shows a better consistency between the methods for $\text{AOT}_{532\text{nm}} > 0.5$ and for AE of approximately 2.0.

Table 7 shows the results of the linear regressions performed between the AOTs retrieved with POLDER and the other active method considered in our study for each category (i.e. detached, attached and undetermined). We recapture the systematically larger offsets of DRM_{Hu} $\text{AOT}_{532\text{nm}}$ compared to DRM_{SODA} , and the underestimation of $\text{CALIOP}_{\text{OM}}$ AOT with respect to the other methods.

4.2 Evolution of the above cloud AOT retrievals with cloud properties

In principle, the retrieval of AAC properties from the methods considered in this study should not depend on the properties of the underlying clouds. However, hypotheses and empirical relations used in the retrieval methods to exploit the signal backscattered by the underlying cloud cover ~~have~~ obviously have their limitations. In order to understand potential issues linked with diversity of cloud properties, we analyse in this section the difference between the AOT retrievals of POLDER, DRM_{SODA} and DRM_{Hu} by classes of cloud properties (COT and r_{eff} retrieved with MODIS). We considered global measurements acquired for ~~four and a half~~ 4.5 years of data and used the classification defined in Sect. 2.3.2.

Figure ~~56~~ presents POLDER and DRM_{SODA} AOT_{532} retrievals as a function of the MODIS droplets effective radius (r_{eff}), while Fig. ~~78~~ displays POLDER and DRM_{SODA} $\text{AOT}_{532\text{nm}}$ as a function of the MODIS cloud optical thickness (COT). Histograms of the cloud properties are also reported in Fig. ~~56~~, ~~67~~ and ~~78~~. The results of the POLDER and DRM_{Hu} AOT_{532} comparison as a function of the effective radius are shown in Fig. ~~67~~. DRM_{SODA} and DRM_{Hu} $\text{AOT}_{532\text{nm}}$ generally exhibit rather similar behaviour, at least qualitatively. Therefore, we did not report the results found for the DRM_{Hu} AOT_{532} as a function of MODIS COT.

4.2.1 AOT versus r_{eff}

The lateral histograms plotted in Fig. ~~56~~ and Fig. ~~78~~ show that most of the AAC scenes correspond to cloud droplets effective radius values between 8 and 15 μm (mean r_{eff} equal to 12 μm) and COT ranging from 5 to 15 (mean COT of 10). These mean values are expected since most of the AAC events are generally associated with low-level non-precipitating clouds, such as stratocumulus ones, which typically show rather small droplets (approximately 10 μm) and optical thickness values of approximately 10.

Figure ~~56a~~ shows the POLDER and DRM_{SODA} AOTs for the *detached* situations. For the two methods, the retrieved AOTs are maximal for the smallest values of r_{eff} and progressively decrease with r_{eff} . Same tendencies are observed for the DRM_{Hu} (see Fig. ~~76a~~). The two curves have however an offset. The histogram of the differences between POLDER and DRM_{SODA} AOT ($\Delta\tau$) is presented in Fig. ~~65d~~. The mean $\Delta\tau$ value computed over the entire range of r_{eff} is equal to 0.073. This offset is not constant and slightly increases with r_{eff} , suggesting a sensitivity of one of the two methods to the cloud

droplets effective radius. ~~The DRM algorithm does not use an explicit parameterization of the lidar ratio as a function of the cloud droplets effective radius. An implicit dependence will arise from the latitudinal correction (Eq. 9) when clouds at different latitudes will exhibit different microphysical properties. In order to understand the usefulness of adding an explicit parameterization, we recalculated the $\text{DRM}_{\text{SODA}} \text{AOT}_{532\text{nm}}$ taking into account the dependence of S_c on r_{eff} . This calculation assumes a simplified and unique droplet size distribution and is based on MODIS r_{eff} retrieval. We expect that even if the cloud droplet size distribution is variable (Miles et al., 2000) and that the ACAOD creates a bias in r_{eff} , the results will still provide guidance for future algorithm development. The DRM algorithm assumes a constant lidar ratio of 19 sr, independent of the cloud droplet effective radius. In order to evaluate the accuracy of this approximation, we recalculated the $\text{DRM}_{\text{SODA}} \text{AOT}_{532\text{nm}}$ taking into account the dependence of S_c on r_{eff} .~~ As defined in Josset et al. (2011), S_c was computed using a Mie code with the following equation:

$$S_c = \frac{4\pi}{\omega_0 \times p(180^\circ)}, \quad (11)$$

where $p(180^\circ)$ is the average value of the phase function in the backscatter direction computed over the size distribution. ω_0 is the Single Scattering Albedo of the particles, defined as the ratio between the mean scattering coefficient and the mean extinction coefficient computed over the particle size distribution. We used a two-parameter gamma size distribution with an effective variance of 0.088. The real refractive index was set to 1.337. Liquid water droplets do not significantly absorb at 532 nm and the imaginary part of the complex refractive index was set to 0. As shown in Figure 98, S_c slightly decreases with r_{eff} from 19.5 to 15.5 as the effective radius values increases from 5 to 40 μm . With this correction, the mean difference between POLDER and the $\text{DRM}_{\text{SODA}} \text{AOT}_{532\text{nm}}$ ($\Delta\tau$ corr S_c in Fig. 56d) decreases from 0.073 to 0.065. We found equivalent results for the *attached* and *undetermined* cases (Fig. 56b and 56c). After correction of S_c , the difference between POLDER and DRM_{SODA} decreases on average by 0.01, for the *attached* cases, and by 0.019 for the *undetermined* cases. We also observe that most of the negative AOT values retrieved by the DRM_{SODA} shift either to null values or weakly positive values when this correction is included (Fig 56a, 56b and 56c). We are aware that MODIS effective radius may be affected by the presence of aerosols above clouds. For example, Haywood et al. (2004) found biases of $\pm 2 \mu\text{m}$ for r_{eff} ~~were found by Haywood et al. (2004) for in case of~~ strong dust events above clouds and (Meyer et al., (2015) found an increase in the r_{eff} monthly mean of 2% in case of above-cloud absorbing aerosols. We expect that large biases on r_{eff} could be possible in case of high aerosol loading for *detached* cases. However, we consider that the impact of the biases on the retrieved r_{eff} on our findings and conclusions can be neglected, since the analysis hold for (i) a wide range of droplets effective radius (from 5 to 40 μm) and (ii) AAC events associated with low aerosol loadings (see the results for the *undetermined* cases), where the impacts of the aerosols on the cloud retrievals are expected to be minimized or negligible.

4.2.2 AOT versus COT

The two methods were developed to detect AAC events in the case of optically thick and homogeneous liquid water clouds. In the following, we only discuss results obtained for large values of COT (larger than 5). If the clouds are optically

thinner, the two methods are potentially less accurate since they become sensitive to the surface contribution. [Hu et al., \(2007a\)](#) noticed the surface impact on DRM_{Hu} when the underlying cloud is not entirely opaque, therefore the assumptions used in the DRM_{Hu} AOT retrievals are not met. For COTs ranging between 5 and 30 and for *detached* cases, the POLDER AOTs are almost constant and reach 0.3 on average at 532 nm (see Fig. 78a). Most of the associated COT values are then ranging between 5 and 10. For these cases, DRM_{SODA} and POLDER AOTs are offset by around 0.07 on average, as noted above. However, the DRM_{SODA} AOT progressively increases with the COT, which is not observed for the POLDER AOT. Consequently, the differences in AOT between the two methods become almost negligible for the largest (and less frequent) values of COT (larger than 20). For COTs larger than 3, the polarized signal reflected by the cloud is saturated and the POLDER method should be insensitive to COT. DRM_{SODA} is sensitive to the multiple scattering processes occurring within the cloud layers and might be impacted by the COT since multiple scattering increases with the optical thickness. The measured depolarization (δ') and the multiple scattering factor (η_{calibr}) plotted as a function of the COT are shown in Fig. 78d. As expected, the depolarization and the multiple scattering factor respectively increase and decrease as COT increases. The increase in the DRM_{SODA} AOT observed at large COTs might be due to an increase in the multiple scattering. We recall that DRM_{SODA} uses a relationship to connect the depolarization and the multiple scattering factor and that this relation is calibrated based on CALIOP data. The calibration might be less accurate in case of AAC events associated with clouds for which the properties are statistically less representative. Again, we presume that our conclusions are not impacted by the fact that the MODIS COTs can be potentially biased in case of AAC events since the tendencies we observed hold for a large range of variability in COT (5 to 30) and also for AAC events associated with low AOT above clouds (see the results for the *undetermined* cases).

5 Discussion

In the first part of this section, we quantify and discuss the overall differences found between the active and passive methods in terms of the retrieved AOT. In the second part, we address more specifically the *attached* cases and make hypotheses regarding the meaning of these results.

On average, the difference between POLDER and DRM_{SODA} AOTs at 532 nm is equal to 0.073 for the *detached* cases and 0.087 for the *undetermined* cases. These differences slightly decrease to 0.065 and 0.068, respectively, when we account for the dependency of the cloud droplets lidar ratio (S_c) to r_{eff} in Eq. 10. The POLDER AOTs are systematically smaller than the ones retrieved with DRM_{Hu} . On average, these differences between these two methods are equal to -0.039 and -0.057, for the *detached* cases, and reach -0.036 and -0.048 for the *undetermined* cases, respectively without and with corrections for S_c . Thereby, the POLDER AOT estimates range, on average, between the DRM_{Hu} and DRM_{SODA} ones. The differences in AOTs found between the POLDER method and the two DRM ones could be set to zero by modifying the lidar calibration by roughly $\pm 10\%$. One another main difference between the three methods is their different responses in terms of AOT when the atmosphere above the clouds becomes pristine. The majority of AOT (94 %) is lower than 0.1 at 865 nm

for the *undetermined* cases. For these cases, the POLDER algorithm retrieves a mean AOT of about 0.04 at 865 nm. The accuracy of the POLDER AOT product is in the same order of magnitude. For an AOT_{865nm} of 0.2, the error for a real refractive index uncertainty of ± 0.06 would be about 0.05; for an imaginary refractive index uncertainty of ± 0.01 , the error would be of 0.02 (Peers et al., 2015). The impact of the assumed refractive index is lower at smaller AOT (especially for an AOT of 0.04). ~~The background of the extrapolated POLDER AOT at 532 nm for the undetermined cases reaches 0.09~~
~~The background reaches 0.09 in AOT at 532 nm.~~ This latter value is only reported for the sake of comparison with the two other methods since the Ångström exponent retrieved by POLDER, (and consequently the AOT extrapolated at 532 nm) cannot be accurately retrieved for low AOTs. DRM_{SODA} found a mean AOT of about 0.005 at 532 nm for the undetermined cases (see Fig. 56c). The result is likely due to the re-calibration process since DRM_{Hu} found a background even larger than the POLDER one, of about 0.12 at 532 nm. It is difficult to assess the truthfulness of this background, considering the given level of accuracy of the POLDER method and the uncertainties associated with the lidar calibration. We assume that these background values are not physical and could be due to some inherent limitations of the retrieval methods. From our data, however, we cannot exclude the possibility that there is always a background loading of particles above clouds (e.g. aerosols or fine droplets in formation). Nevertheless, the main result of our investigation is that POLDER and DRM methods compare well for most situations with a mean difference of about ± 0.07 in AOT at 532 nm.

Although the number of cases is small, the results of the *attached* cases are interesting. They suggest that the lidar CALIOP and POLDER could be affected by layers of aerosols that physically and locally interact with the upper part of the cloud. In order to understand how the vertical profiles differ from one situation to another, we compared the CALIOP attenuated backscatter coefficient for *attached* and *detached* cases. We considered the period 2006–2010 and used data acquired over the entire globe. We only select the *attached* and *detached* cases where the cloud top altitude is below 1.5 km, ~~the COT is larger than 5~~ and the DRM_{SODA} AOT_{532nm} is larger than 0.1. These criteria allow for selection of data that corresponds to AAC events associated with similar cloud vertical extents and with significant AOTs. For these cases, we computed the average and median of the CALIOP level 1 attenuated backscatter coefficients at 532 nm. Figure 910 presents these results and some information concerning the mean and median values of CALIOP level 2 products: cloud top altitude, aerosol layer's base and top altitudes. The mean and median values computed for the AOTs retrieved by POLDER and DRM_{SODA} and the numbers of sampled events are also reported. Two different types of profiles can be observed for the *detached* and *attached* situations. For the *detached* cases, the aerosol and cloud backscattering profiles can be easily distinguished in both the median and mean profiles. The strong peaks in the backscatter profiles at around 1 km correspond to the top of the clouds, whereas the increase in the lidar backscatter signal observed between 2 and 4 km in altitude comes from the aerosols. For the *attached* situations, the backscatter profiles are noisier, which is likely due to the fact that the number of detected events is smaller compared to *detached* cases. The top of the cloud layer is still clearly visible in the mean and median backscattered lidar signals, but two maxima can be observed. We assume that we sampled two different regimes of clouds. In addition, there is a continuous transition in the backscatter signal between the top of the cloud and the above molecular atmosphere that is most clearly visible in the median profiles. This signal doesn't appear for the *detached*

cases. This signal could explain the non-negligible above-cloud AOTs retrieved by POLDER and DRM_{SODA} for the *attached* cases (see Fig. 45). It is difficult to assess the origin of this signal. This might be due to aerosols layers that penetrate the cloud layers at the top of the clouds. Natural aerosol or fine droplets in formation, commonly present in the vicinity of the clouds, might also create this additional signal.

Another hypothesis that could explain the low AOT correlation for the *attached* cases is that the aerosols located within the cloud layer could affect the polarized radiances measured by POLDER. Note that the polarised radiance at 865 nm is not affected by the vertical position of the aerosol layer as long as there is no contact between the aerosol and the cloud. Since the operational algorithm developed for POLDER assumes that the entire aerosol layer is located above the clouds, an additional polarized signal coming from aerosol located within the cloud would lead to an overestimation of the above cloud AOT retrieved from POLDER. To test this assumption, we modelled the polarized radiance measured by POLDER for AAC scenes, considering different vertical locations of the aerosol layer (Fig. 110). We used the Successive orders of scattering (SOS) radiative transfer code (Lenoble et al., 2007) for this simulation. We considered a liquid water cloud located between 0 and 1 km. The particles (aerosol and cloud) are vertically homogeneously mixed. The COT is equal to 10 and the effective radius and variance are equal to 10 μm and 0.08, respectively. The aerosol layer is characterized by an AOT of 0.25 at 865 nm, a refractive index of $m = 1.47 - 0.01i$ and an effective radius of 0.15 μm . Fig. 119 shows the typical polarized feature for AAC events in case of *detached* situations (i.e. aerosols located between 1.25 and 1.75 km): a creation of polarization is observed at side and forward scattering angles, whereas the cloud bow magnitude decreases. For the *attached* case (aerosols between 0.75 and 1.25 km), the amount of polarization created at forward scattering angles decreases and the cloud bow attenuation is less significant in comparison with the *detached* scenario. When the aerosol layer is located within the upper part of the cloud layer (between 0.5 and 1 km) we still observe a weak polarized signal created at forward scattering angles. When the aerosol layer is located in the lower part of the cloud layer, the effects of the aerosols disappear since the polarized radiance scattered by the aerosols is lost due to multiple scattering occurring within the clouds. These simulations were processed with the POLDER algorithm (Waquet et al., 2013b). We recall that the LUTs used in this algorithm were built for *detached* situations. The algorithm retrieved an AOT of 0.09 at 865 nm when the aerosols are located within the upper part of the cloud layer. This demonstrates that polarized radiances are sensitive to aerosols situated *within* the clouds for the *attached* cases.

The DRM methods might also be impacted by the presence of aerosols within the clouds. Aerosols ~~is-as a~~ solution within the cloud droplets (i.e. internal mixture) might impact the chemical composition of the droplets and modify their ability to backscatter light. Fig. 98 shows lidar ratio computed for absorbing cloud droplets. We used an imaginary part of 0.0001 for the complex refractive index of the droplets. This might simulate, for instance, the properties of brown clouds contaminated by absorbing aerosols. The chosen value is in agreement with the refractive indices given for water containing soot inclusions with volume fractions ranging between 10^{-4} and 10^{-2} (Erlick, 2006). We observe a drastic increase of S_c with r_{eff} (from 21.7 sr at 5 μm to 50 sr at 40 μm) when the water droplet is weakly absorbing. In the case of an external mixture, we assume that the presence of aerosols at the top of cloud might also modify the value of S_c . Any deviation from the 19 sr

value assumed for the droplets lidar ratio in Eq. (10), will necessarily impact the retrieved AOT and the differences observed between the AOT estimates provided by the POLDER and DRM methods.

6 Conclusions

5 In this study, we compared and analysed the consistency of the AOT and AE retrievals above clouds from different passive and active techniques. We used the CALIOP operational algorithm (Winker et al., 2009) the POLDER polarisation method (Waquet et al., 2013b), and the CALIOP-based depolarisation ratio method (DRM_{Hu}) (Hu et al., 2007a) – for which we proposed a re-calibrated version of the DRM algorithm (DRM_{SODA}). The observations were made for: a) three case studies corresponding to an African biomass-burning event, a Saharan dust event and a Siberian biomass-burning event; b) a regional scale analysis, over South Atlantic Ocean, North Atlantic Ocean and North Pacific Ocean for a period of six months
10 in 2008 and c) a global scale analysis for different vertical layer distributions for the period 2006–2010.

In the regional analyse, we observed that POLDER method and DRM are in good agreement when the microphysics of aerosols is dominated by fine-mode particles of biomass-burning aerosols (in the South Atlantic region, $R^2 = 0.83$) or coarse-mode aerosols of dust (in the North Atlantic region, $R^2 = 0.82$). A good correlation between these methods ($R^2 = 0.68$) is also noticed in the global treatment, when the aerosol and cloud layers are well separated. Nevertheless, some of the detached cases considered in our study, mainly the ones associated with optically thick smoke layers, are likely to be incorrectly classified as detached. As a future perspective, these misclassified detached cases (due to strong attenuation of the CALIOP 532 nm signal) could be detected by controlling the CALIOP 1064 nm signal, which was shown to provide more sensitivity to the entire vertical extent of these absorbing aerosol layers. The CALIOP operational method largely underestimates the AOT above clouds in all situations, with respect ~~with the~~ other methods.

20 The differences between the DRM and POLDER retrievals increase when a complex mixture of aerosols is expected (such as in the East Asia region). This is probably due to the fact that the current algorithm developed for POLDER uses a limited number of microphysical models of aerosols. Also, the relative position of the aerosol layer above the cloud impacts the AOT retrievals from both active and passive measurements: the correlation decreases when the layers are in contact ($R^2 = 0.36$), suggesting that aerosols at the top or within the cloud can affect the AOT retrievals. One hypothesis is
25 that an additional polarized signal coming from aerosol located *within* the cloud could affect the polarization signal and method, which leads to an overestimation of the AOT retrieved with POLDER algorithm. The aerosols *attached with* or *within* the cloud also have the potential to impact the DRM retrievals, by modifying the lidar ratio (and consequently the AOT) as a result of internal or external mixture.

Furthermore, we investigated potential biases in the retrieved AOT measured by POLDER and DRM_{SODA} as a
30 function of MODIS cloud properties (i.e. droplet effective radius (r_{eff}) and cloud optical thickness (COT)). The tendencies show an increase in the difference between the two methods for larger r_{eff} , suggesting sensitivity to the cloud droplet effective radius. For this reason, we recalculated the DRM_{SODA} AOT_{532nm} taking into account the dependence of lidar ratio on

r_{eff} , as this method assumes a constant lidar ratio regarding the droplet effective radius. By doing so, we observed a decrease in the difference between POLDER and DRM methods and a shift of the DRM AOT values from negative to positive. For a better accuracy of DRM retrievals in future studies, this correction should be taken into account. The results show also that the multiple scattering processes, which are more pronounced in optically thick clouds, could also affect the DRM technique.

All of the aforementioned situations have revealed that DRM_{Hu} has larger mean AOT than that of DRM_{SODA} . This is likely to be a consequence of the re-calibration performed for the DRM_{SODA} method. Actually, $POLDER\ AOT_{532nm}$ values are consistently smaller than the ones of DRM_{Hu} and larger than those of DRM_{SODA} . The primary conclusion of our investigation is that POLDER and DRM techniques are comparable for the majority of cases, with a mean difference of about ± 0.07 in AOT at 532 nm, depending on lidar calibration.

Given the fact that each method relies upon different physical concepts, applied to different sensors and measurements, the high value of the correlation obtained for the AOT retrievals is a remarkable result that highlights the coherence between active and passive methods for aerosols above clouds. Nonetheless, more efforts have to be done to increase the accuracy of the methods, in order to better understand aerosols above clouds and their related effects. Airborne measurements are extremely useful in providing information on aerosols above cloud properties. Several ongoing and planned airborne field campaigns will attempt to characterize the properties of biomass burning aerosols over the Southern Atlantic Ocean (Zuidema et al., 2016). Planned measurements from the French Falcon 20 aircraft, equipped with a high-resolution lidar, an airborne sun-photometer and a POLDER-like sensor, will notably be considered for a future validation of CALIOP DRM and POLDER above-cloud aerosol products. A ~~first~~^{another} perspective is to improve the POLDER algorithm by introducing additional dust or mixture models with larger or smaller effective radii values in the LUT. This would definitely improve the AOT and AE retrievals in more complex situations (such as East Asia region). Also, our results suggest that a combination of POLDER and DRM methods has the potential to detect aerosols *within* clouds. It is very relevant to study these situations, since they can affect the retrievals and provide important information regarding the cloud processes. A ~~second~~^{further} perspective would be to exploit the synergy between CALIOP and POLDER to infer the direct aerosol radiative forcing, aerosol heating rates and the semi-direct effect of absorbing aerosols located above clouds.

Table 1: Linear regressions of AOT calculated between different methods for three case studies: African biomass-burning aerosols (BBA), Saharan desert dust aerosols (DDA) and Siberian biomass-burning aerosols. R^2 represents the coefficient of determination (COD) between the two sets of data.

Linear regressions		African BBA (13.08.2006)	Saharan DDA (04.08.2008)	Siberian BBA (03.07.2008)
DRM _{SODA} vs. POLDER	Slope	0.89±0.01	0.74±0.04	0.56±0.01
	Intercept	0.04±0.01	0.01±0.02	0.07±0.009
	R^2 (COD)	0.93	0.79	0.90
DRM _{Hu} vs. POLDER	Slope	0.91±0.01	0.74±0.03	0.60±0.01
	Intercept	0.11±0.01	0.15±0.02	0.23±0.009
	R^2 (COD)	0.93	0.82	0.89
CALIOP _{OM} vs. POLDER	Slope	0.19±0.01	0.86±0.11	0.47±0.08
	Intercept	0.05±0.01	-0.16±0.07	-0.04±0.08
	R^2 (COD)	0.35	0.41	0.45

Table 2: Linear regressions of AOT calculated between different methods for data acquired over six months (May to October 2008), over three different regions: South Atlantic Ocean (SAO), North Atlantic Ocean (NAO) and North Pacific Ocean (NPO).

Linear regressions		SAO	NAO	NPO
DRM _{SODA} vs. POLDER	Slope	0.89±0.004	0.81±0.009	0.76±0.01
	Intercept	-0.03±0.001	-0.09±0.004	-0.03±0.003
	R ² (COD)	0.83	0.82	0.37
DRM _{Hu} vs. POLDER	Slope	0.90±0.004	0.86±0.01	0.76±0.01
	Intercept	0.05±0.001	0.04±0.004	0.13±0.003
	R ² (COD)	0.82	0.82	0.44
CALIOP _{OM} vs. POLDER	Slope	0.34±0.004	0.52±0.02	0.28±0.02
	Intercept	-0.04±0.002	-0.01±0.01	0.01±0.01
	R ² (COD)	0.43	0.42	0.24
CALIOP _{OM} vs. DRM _{SODA}	Slope	0.34±0.002	0.62±0.01	0.35±0.01
	Intercept	-0.01±0.002	0.04±0.006	0.01±0.007
	R ² (COD)	0.42	0.48	0.28

Table 3: Regional analysis using CALIOP measurements over six months (May to October 2008), over South Atlantic Ocean (SAO), North Atlantic Ocean (NAO) and North Pacific Ocean (NPO): mean cloud altitude for altitudes smaller than 5 km; mean aerosol base and top altitudes for altitudes smaller than 10 km.

	SAO	NAO	NPO
Mean cloud top altitude [km]	1.24±0.43 Min: 0.30 Max: 4.95	1.35±0.5 Min: 0.20 Max: 3.25	1.09±0.84 Min: 0.05 Max: 5.0
Mean aerosol top altitude [km]	3.83±0.093 Min: 0.50 Max: 6.73	4.50±1.03 Min: 0.44 Max: 6.67	2.74±1.68 Min: 0.47 Max: 9.85
Mean aerosol base altitude [km]	2.90±0.97 Min: 0.02 Max: 5.80	2.97±1.12 Min: 0.02 Max: 5.74	3.48±1.78 Min: 0.05 Max: 9.31

Table 4: Calculated mean, minimum value and maximum value of AOT_{532nm} over six months in 2008, for three regions (SAO, NAO, NPO) and for different methods.

AOT_{532nm}		SAO	NAO	NPO
POLDER	Mean	0.35 ± 0.23	0.39 ± 0.21	0.18 ± 0.21
	Min	0.005	0.005	0.005
	Max	1.27	1.19	2.17
DRM _{SODA}	Mean	0.28 ± 0.22	0.23 ± 0.19	0.15 ± 0.38
	Min	-0.13	-0.16	-0.16
	Max	1.30	0.95	3.26
DRM _{Hu}	Mean	0.37 ± 0.23	0.38 ± 0.20	0.32 ± 0.40
	Min	-0.07	-0.06	-0.06
	Max	1.50	1.17	3.68
CALIOP _{OM}	Mean	0.12 ± 0.11	0.23 ± 0.18	0.14 ± 0.23
	Min	0.001	0.005	0.001
	Max	1.88	2.38	2.01

Table 5: Mean value of AE over six months in 2008, for three regions (SAO, NAO, NPO) for different methods after filtering the POLDER $\text{AOT}_{865\text{nm}} > 0.1$ and $\text{DRM}_{\text{SODA}} \text{AOT}_{532\text{nm}} > 0.1$, respectively $\text{CALIOP}_{\text{OM}} \text{AOT}_{532\text{nm}} > 0.1$.

		SAO	NAO	NPO
POLDER	Mean $\text{AE}_{670/865}$	2.05 ± 0.27	0.49 ± 0.27	1.67 ± 0.50
	Min	0.36	0.36	0.36
	Max	2.56	2.03	2.39
DRM_{SODA}	Mean $\text{AE}_{532/1064}$	1.79 ± 0.58	0.10 ± 0.27	1.47 ± 0.84
	Min	-1.15	-1.14	-1.21
	Max	4.19	1.43	3.93
$\text{CALIOP}_{\text{OM}}$	Mean $\text{AE}_{532/1064}$	0.97 ± 0.51	-0.19 ± 0.32	0.41 ± 0.72
	Min	-2.27	-1.62	-2.63
	Max	3.16	1.27	4.41

Table 6: Linear regression calculated between $\text{DRM}_{\text{SODA}} \text{AOT}_{532\text{nm}}$ and $\text{POLDER} \text{AOT}_{532\text{nm}}$ for situation when the aerosol layer is attached to the cloud top and when the aerosol layer is well separated from the cloud over three regions (South Atlantic Ocean, North Atlantic Ocean and North Pacific Ocean) and for a period of ~~4.5~~four and a half years.

	SAO		NAO		NPO	
	Attached	Detached	Attached	Detached	Attached	Detached
Slope	0.60 ± 0.02	0.77 ± 0.003	0.63 ± 0.07	0.59 ± 0.01	0.78 ± 0.12	0.80 ± 0.02
Intercept	0.04 ± 0.006	0.02 ± 0.001	-0.005 ± 0.02	-0.011 ± 0.006	-0.04 ± 0.02	-0.015 ± 0.007
R^2 (COD)	0.54	0.715	0.39	0.57	0.19	0.435

Table 7: Linear regressions calculated between different methods for data acquired over June 2006 to December 2010, on a global scale above the ocean in the case of aerosol *attached* to the cloud top, *detached* from the cloud and *undetermined* situations for AOT smaller than 1.5.

Linear regressions		Detached	Attached	Undetermined
DRM_{SODA} vs. POLDER	Slope	0.84±0.003	0.59±0.01	0.24±0.001

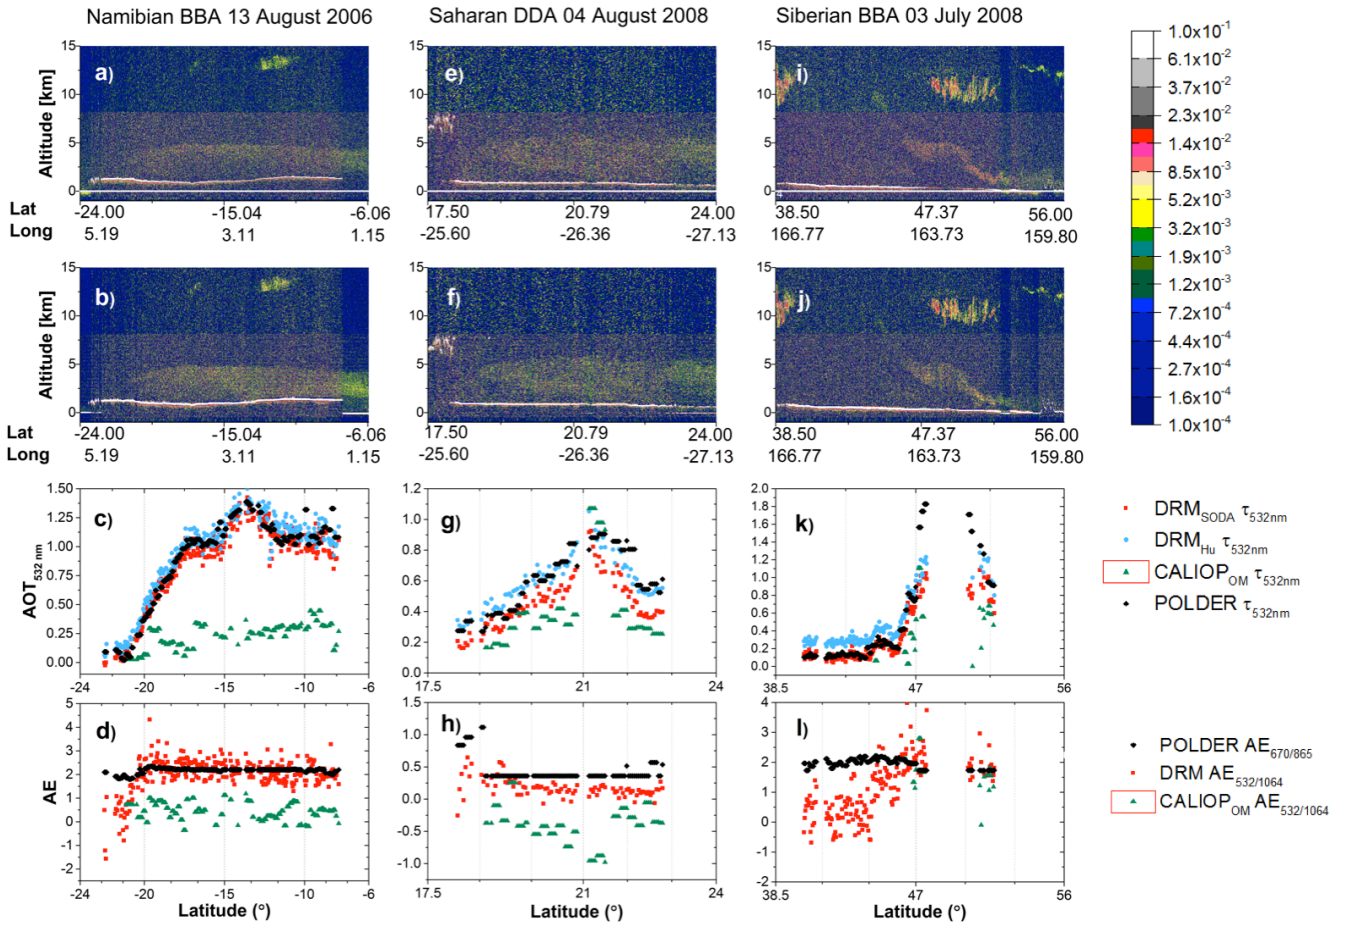

Figure 1: The first row of the panel shows the lidar CALIOP attenuated backscatter coefficients at 532 nm ($\text{km}^{-1} \text{sr}^{-1}$) and the second row presents the CALIOP attenuated backscatter coefficients at 1064 nm for three case studies: African biomass-burning (BBA) aerosols above clouds on 13 August 2006 ((a), (b), (c), (d)), Saharan dust (DDA) on 4 August 2008 ((e), (f), (g), (h)) and Siberian biomass-burning aerosols over the Okhotsk Sea on 3 July 2008 ((i), (j), (k), (l)). For these cases, the above-cloud AOT at 532 nm and the Ångström exponent (AE) as a function of latitude, measured with several techniques are displayed. The first row of the panel shows the lidar CALIOP backscatter profile at 532 nm ($\text{km}^{-1} \text{sr}^{-1}$) for three case studies: African biomass burning (BBA) aerosols above clouds on 13 August 2006 ((a), (b), (c)), Saharan dust (DDA) on 4 August 2008 ((d), (e), (f)) and Siberian biomass-burning aerosols over the Okhotsk Sea on 3 July 2008 ((g), (h), (i)). For these cases, the above-cloud AOT at 532 nm and the Ångström exponent (AE) as a function of latitude, measured with several techniques are displayed.

Figure 2: The map presents the latitudinal and longitudinal boundaries of the three regions used in the regional study (Sect. 3): South Atlantic Ocean (SAO) extends from 30° S to 5° N and 12° W to 14° E, North Atlantic Ocean (NAO) is situated between 10 to 35° N and 10 to 40° W and North Pacific Ocean (NPO) is located between 35 to 60° N and 140 to 170° E.

Figure 3: The first row of the panel shows the comparison of AOT at 532 nm retrieved from DRM_{SODA} and POLDER methods, with the corresponding POLDER AE color scale, computed between 670 and 865 nm. The second row presents the Ångström exponent comparison for AOTs larger than 0.1, retrieved from DRM_{SODA} and POLDER methods, with the corresponding POLDER AOT at 532 nm color scale. The measurements were made over a period of six months (May to October 2008) and over three distinctive regions: South Atlantic Ocean - between 30° S to 5° N and 12° W to 14° E ((a) and (b)), North Atlantic Ocean - between 10 to 35° N and 10 to 40° W ((c) and (d)) and North Pacific Ocean - between 35 to 60° N and 140 to 170° E ((e) and (f)). The histograms present the data distribution. The error bars in figures (a), (c) and (e) represent the standard error of the mean (SEM).

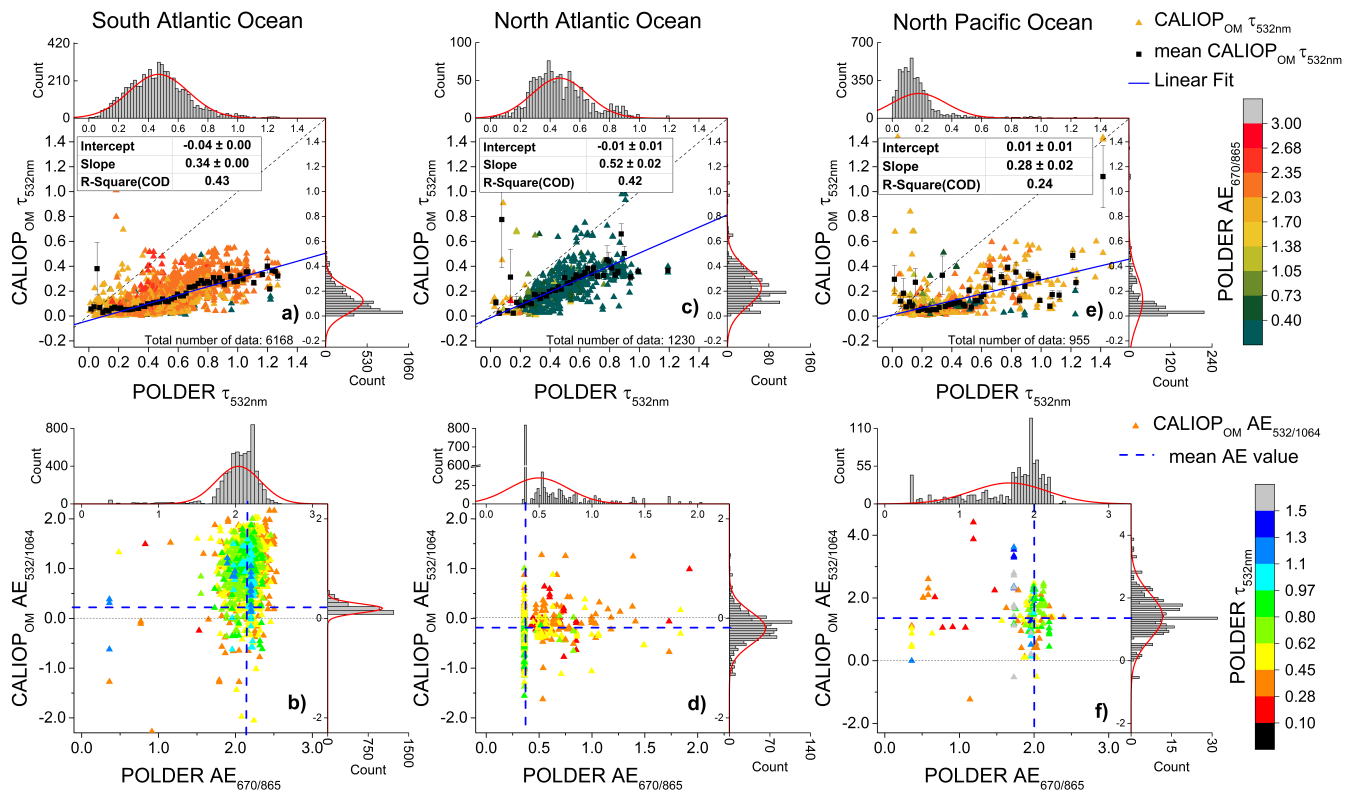

Figure 4: Same as Fig. 2, retrieved from CALIOP operational method and POLDER method.

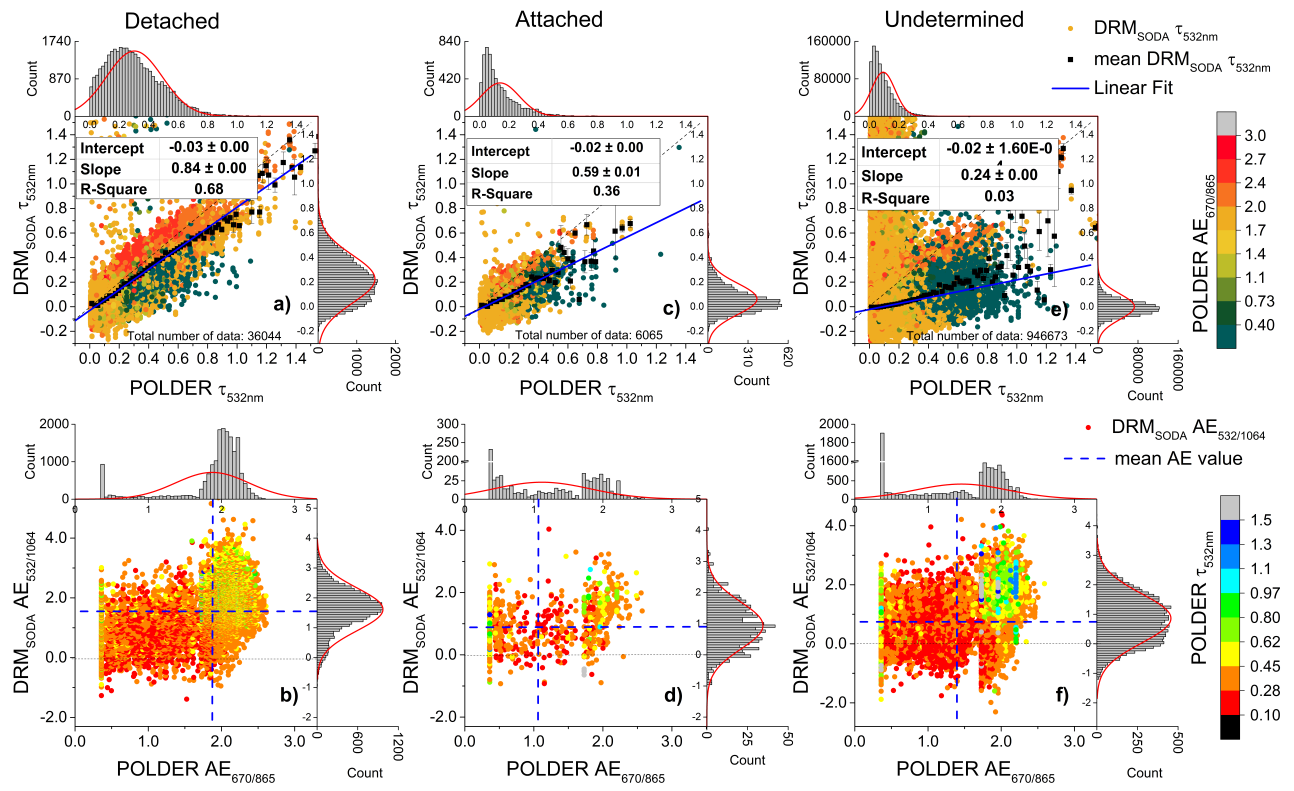

Figure 5: Global comparison over a period of **4.5four and a half** years (June 2006 to December 2010) for situations with aerosol layer well separated from the cloud top - *detached* ((a) and (b)), for cases where the aerosol layer is in contact with the cloud – *attached* ((c) and (d)) and for *undetermined* situations ((e) and (f)). The comparison of AOT at 532 nm retrieved from DRM_{SODA} and POLDER methods is shown in the first row. The color scale represents the corresponding POLDER AE computed between 670 and 865 nm. The second row presents the Ångström exponent for AOTs larger than 0.1, with a POLDER AOT at 532 nm color scale. The histograms present the data distribution. The error bars in figures (a), (c) and (e) represent the standard error of the mean (SEM).

Figure 6: **Four and a half** years of global study on the evolution of POLDER and DRM_{SODA} above cloud AOT retrievals as a function of MODIS effective radius (r_{eff} , μm) for situations where: the aerosol layer is *detached* from the cloud top ((a) and (d)), for cases where the aerosol layer is *attached* to the cloud top ((b) and (e)) and for *undetermined* situations (c) and (f)). The histograms from figures (a), (b) and (c) represent the distribution of r_{eff} . The histograms in figures (d), (e) and (f) present the difference between POLDER and DRM_{SODA} mean AOTs, before the correction of DRM_{SODA} AOT with r_{eff} ($\Delta\tau$) and after this correction ($\Delta\tau$ corr. S_c). The associated tables indicate the number of cases, mean, standard deviation (σ) and median values of these differences. The error bars in figures (a), (b) and (c) represent the standard error of the mean (SEM).

Figure 7: Same as Fig. 5, POLDER and DRM_{Hu} above cloud AOT retrievals as a function of MODIS effective radius (r_{eff} , μm).

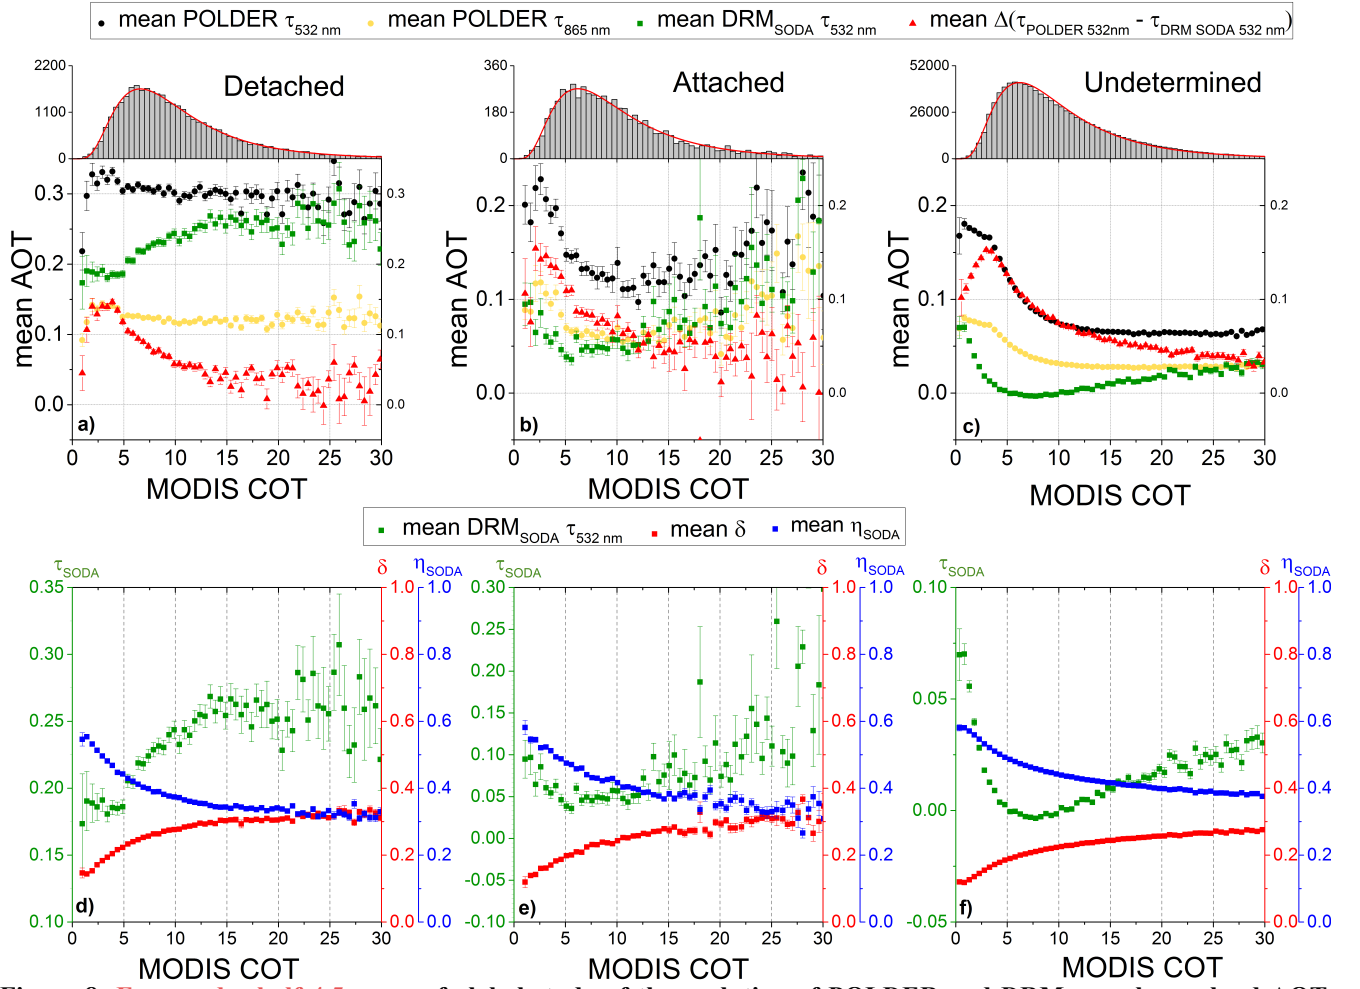

Figure 8: Four and a half 4.5 years of global study of the evolution of POLDER and DRM_{SODA} above cloud AOT retrievals, as well as the difference of these two methods as a function of MODIS cloud optical thickness (COT), for situations where: the aerosol layer is *detached* from the cloud top (a), for cases where the aerosol layer is *attached* to the cloud top (b) and for *undetermined* situations (c). The histograms represent the distribution of COT. The error bars show the standard error of the mean (SEM). Figures (d), (e) and (f) display the evolution of DRM_{SODA} AOT (τ_{SODA}), depolarization ratio (δ) and multiple scattering factor (η_{SODA}) as a function of MODIS COT, for the abovementioned situations.

Figure 9: Sensitivity study of lidar ratio (S_c , sr) as a function of the cloud droplets effective radius, using a two-parameter Gamma size distribution in Mie code. The effective variance, v_{eff} is set to 0.088. The real part of the refractive index is fixed to 1.337, while the imaginary part, k , was set to 0 (blue) and to 0.0001i (red).

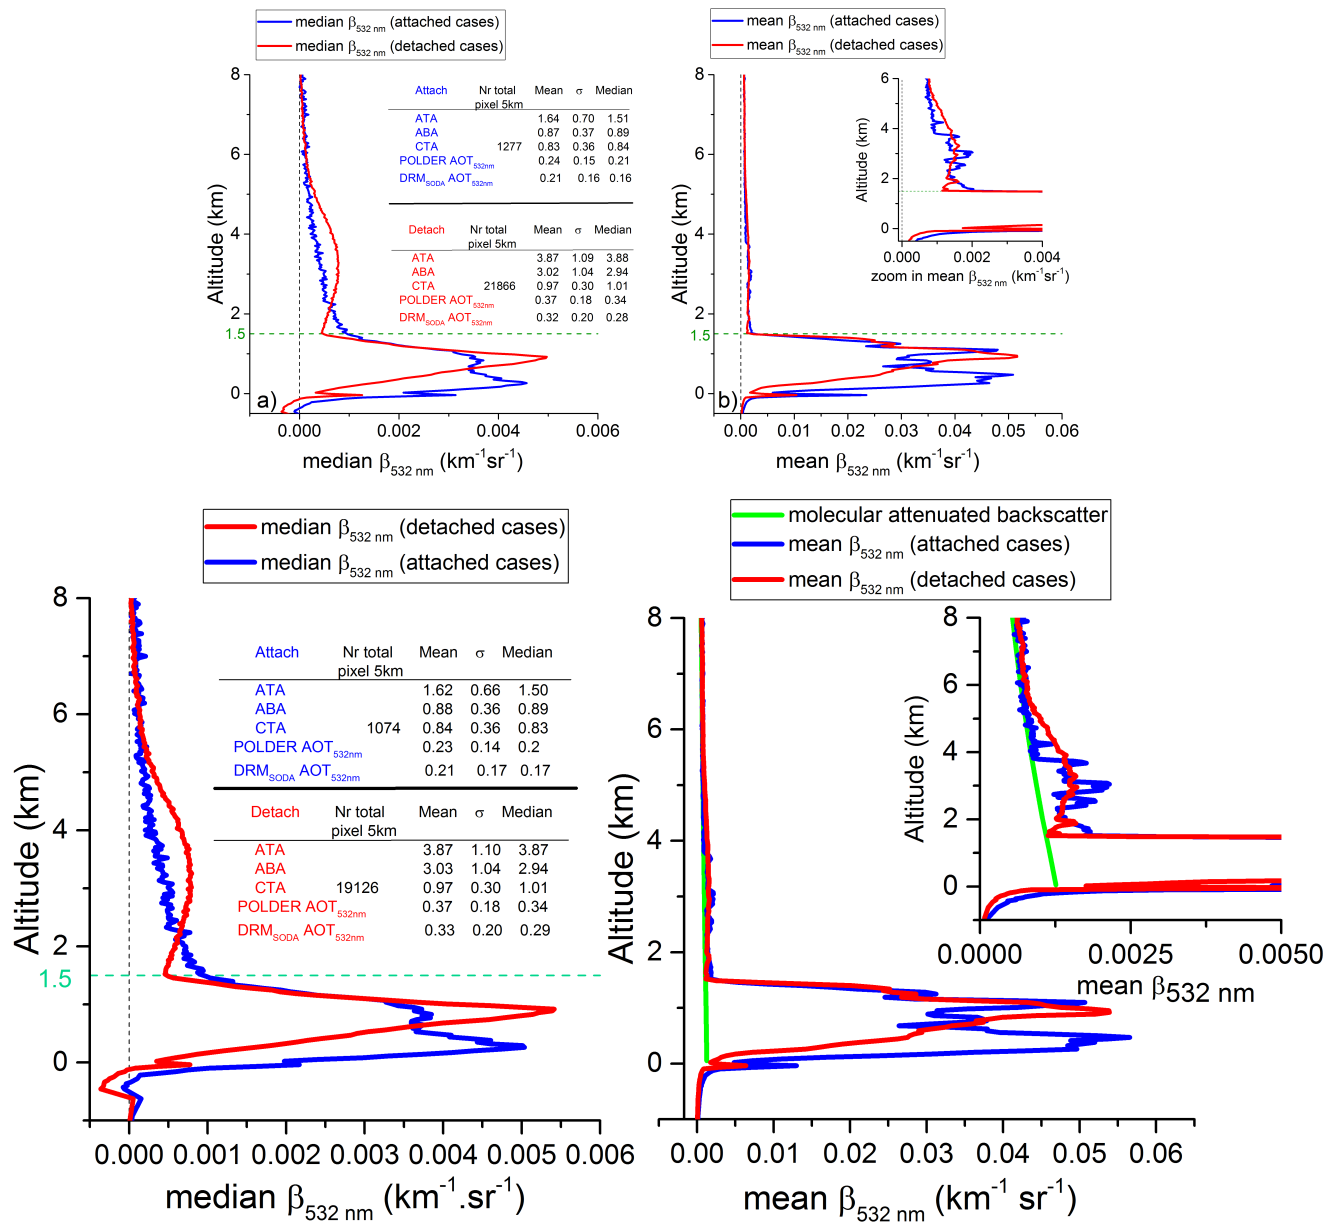

Figure 10: Median (a) and averaged (b) backscatter profiles ($\text{km}^{-1}\text{sr}^{-1}$) for aerosol layer detached from the cloud layer (red) and aerosols attached to the top of the cloud (blue), for a period of four and a half years on the global scale. For comparison, the molecular attenuated backscatter profile is shown in green line. The data was filtered for a cloud top altitude lower than 1.5 km, a cloud optical thickness COT larger than 5 and for a DRM_{SODA} AOT at 532 nm larger than 0.1. The number of 5 km horizontal resolution pixels is also shown. The mean, standard deviation (σ) and median of aerosol top altitude (ATA), aerosol base altitude (ABA) and cloud top altitude (CTA) are given for each situation. Same values are shown for POLDER AOT at and DRM_{SODA} AOT at 532 nm.

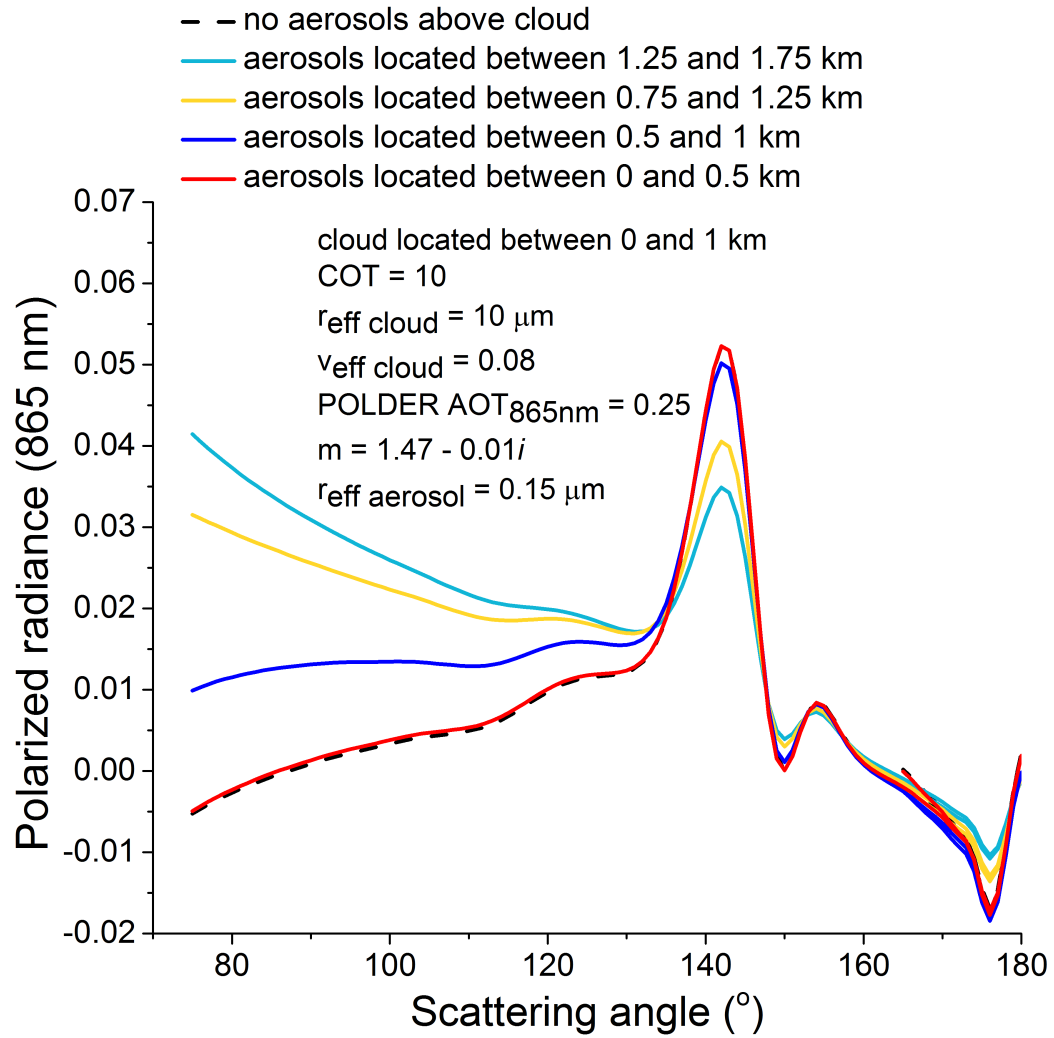

Figure 119: Sensitivity study of polarized radiance at 865 nm to the relative position of the aerosol layer above the cloud. Simulation performed for a cloud layer located between 0 and 1 km and aerosol layers varying at different altitudes. The cloud droplet effective radius is fixed to 10 μm and the effective variance is 0.08. The aerosol layer is characterized by an AOT of 0.25 at 865 nm, a refractive index of 1.47-0.01*i* and an aerosol effective radius of 0.15 μm .

Authors want to thank Referee #1, Hiren Jethva, for his contribution and interactive comments. The answers to specific questions (in red) are addressed below in blue, while the modifications made in the manuscript are in green.

Q1. The first thing that struck me while reviewing the paper was that authors didn't include the CALIOP-based "color ratio" retrievals, which have been shown to perform best in the smoke-above-cloud environment (Chand et al., 2007, 2008, Jethva et al., 2014), in the present analysis. This product is currently not available in the public domain. However, I strongly recommend authors to take Duli Chand (PNNL), the developer of color ratio based ACAOT retrieval, on board and include the results at least for the Southeastern Atlantic region where smoke particles above the cloud decks are observed during biomass burning period (July-Aug-Sep). We, the OMI aerosol group at NASA Goddard, have also developed a near-UV based method to detect and retrieve ACAOT on a global scale [Torres et al., 2012; Jethva et al, 2016]. The method has been applied to the entire record of OMI on board Aura platform (Oct 2004 to present). The resultant OMACA (OMI above cloud aerosols) product was made available freely to public in July 2016 and can be accessed at the Aura validation web portal: <https://avdc.gsfc.nasa.gov/pub/data/satellite/Aura/OMI/V03/L2/OMACA/>

The paper is already length and full of POLDER-CALIOP results. However, if space and time permit, I would suggest the author carry out a comparison between POLDER and OMI on a monthly scale for the Southeastern (smoke) and North Atlantic Ocean (dust) regions in order to check the consistency between the two passive retrieval techniques. Regional maps of ACAOT from POLDER/OMI for a season (say July-Aug-Sep) would be sufficient.

Author's response: The main objective of this paper was to assess the consistency of the POLDER polarisation method developed at LOA laboratory (the data are available now on ICARE Data Center site: <http://www.icare.univ-lille1.fr/archive?dir=PARASOL/PM-L2.v3.01/>). We chose to check the consistency between the retrievals of POLDER polarisation method and DRM because both methods are retrieving AAC properties above the same type of cloudy scenes (optically thick and homogeneous liquid water clouds) and, most of all, they are sensitive to all types of particles (scattering or absorbing aerosols, fine or coarse ones). This is not the case for CRM, which can operate mostly for absorbing aerosols.

The aim of this paper was to analyse the two methods in more detail (from regional to global comparisons, relationships between AAC AOT retrievals and cloud properties), in order to better understand their limitations and sensitivities to different situations. We do not attempt to make an assessment of other available AAC products and methods because the time and space do not permit to make a more detailed evaluation.

Nonetheless, as both CRM and OMACA products are now available, we would be very interested in a future collaboration with Mr. Duli Chand and the OMI aerosol group, that will allow a detailed assessment and inter-comparison of the methods developed for retrieving absorbing aerosol properties above clouds. It would be

likely that such work would have a very different focus than this one and it would be more fruitful to conduct such a work in a follow on paper.

Modifications: No modifications have been added to the manuscript.

Q2. While the paper presents the results of the comparison in detail and also investigates the causes of differences between different techniques, a discussion on how to actually ‘validate’ the satellite-based ACAOT against the airborne ‘truth’ is completely missing. I am sure the authors are aware of the ongoing ORACLES (<https://espo.nasa.gov/oracles>) and CLARIFY-2016 field campaigns that are specifically aimed to provide us in situ and remote sensing measurements of the optical and microphysical properties of aerosols above cloud over the Southeastern Atlantic Ocean. These datasets will be extremely valuable in validating not just the satellite based ACAOT retrievals but also for verifying and improving the aerosol and cloud models assumed in the inversion. A paragraph or two is needed that describes the validation plan for the CALIOP and POLDER above-cloud aerosol products.

Author’s response: These data will be indeed extremely valuable. The authors are well informed on the completed and ongoing field campaigns focused on understanding the aerosol-cloud-radiation interaction off the coast of African continent, especially the field measurements located in the South Atlantic Ocean. In fact, AEROCLO-SA (AErosol RadiatiOn and CLOUDs in Southern Africa) is the French contribution to an international project that reunites researchers from other campaigns, called COLA: CLARIFY-ORACLES-LASIC-AEROCLO, which will attempt to characterize smoke properties from in situ and remote sensing. The AEROCLO-SA campaign is scheduled for August-September 2017 and will be based in Walvis Bay, Namibia. The LOA laboratory will deploy the OSIRIS instrument, which is the airborne prototype of the 3MI instrument (Multi-viewing, Multi-channel, Multi-polarisation) that is currently developed by ESA and EUMETSAT and will be launched on a Post-EPS platform in 2022. OSIRIS and 3MI instruments are based on the concept of the POLDER instrument; therefore a validation of POLDER polarisation method used for aerosol above cloud retrievals is envisioned. The aircraft is also expected to follow the satellite CALIOP/CALIPSO and simultaneously measure AAC properties. This will allow the validation of the DRM retrievals. Moreover, an airborne sun-photometer PLASMA and a lidar will also be onboard the aircraft that will provide useful information on aerosols above clouds properties. Therefore, the authors have already envisaged the validation plan for the CALIOP DRM and POLDER above-cloud aerosol products, by using the combined retrievals from the AEROCLO-SA.

Modifications: Page 21, Line 23 – 26: Airborne measurements are extremely useful in providing information on aerosols above cloud properties. Several ongoing and planned airborne field campaigns will attempt to characterize the properties of biomass burning aerosols over the Southern Atlantic Ocean (Zuidema et al., 2016). Planned measurements from the French Falcon 20 aircraft, equipped with a high-resolution lidar, an airborne sun-photometer and a POLDER-like sensor, will notably be considered for a future validation of CALIOP DRM and POLDER above-cloud aerosol products.

Specific comments:

1. Page 1 Line 11: CALIOP/CALIPSO (in order to be consistent with POLDER/PARASOL)

Author’s response: Thank you. We added your observation in the text.

Modifications: Page 1, Line 11: A-Train sensors CALIOP/CALIPSO and POLDER/PARASOL

2. Page 1, Line 12: "We compare" would be the better word. "...between the results derived from the active and passive measurements"

Author's response: Thank you for the contribution.

Modifications: Page 1, Line 12: The main objective is to analyse the consistency between the results derived from the active and the passive measurements. We compare the Aerosol Optical Thickness (AOT) of above optically thick clouds (Cloud Optical Thickness (COT) larger than 3) and their Ångström Exponent (AE).

Author's response: We modified the text

Modifications: Page 2, Line 30: [...] when the aerosol layers are in contact with the top altitude of the cloud deck.

11. Page 3, Line 4: "Passive imagers offer larger spatial coverage"

Author's response: Thank you. We modified the text.

Modifications: Page 3, Line 4: We changed "Passive techniques have large spatial coverage" into "Passive imagers offer larger spatial coverage [...]"

12. Page 3, Line 7-8: These claims are referred to the cloud-free aerosol retrievals. Torres et al. (2012) paper introduced the near-UV technique to quantify the AOD above cloud, not SSA.

Author's response: We corrected in the text

Modifications: Page 3, Line 7-9: The main retrieved optical properties for aerosols, in "clear-sky" conditions, are the Aerosol Optical Thickness (AOT) and the Ångström Exponent (AE), which is a parameter indicative of the particles size (Kaufman et al., 2002). Recent methods also allow retrieving the aerosol Single Scattering Albedo (SSA) over clear-sky ocean scenes (Torres et al., 2013; Waquet et al., 2016).

We added Kaufman et al., 2002 in the list of reference.

13. Page 3, Line 23: "...situated underneath the aerosol layer as the background"?

Author's response: Both POLDER polarisation method and DRM consider the cloud as background for retrieving the AAC properties. The word "target" for the water clouds situated underneath an aerosol layer was previously used by Hu et al., (2006); Jethva et al., (2014); Waquet et al., (2013b).

Modifications: Page 3, Line 23: No modifications have been made

14. Page 4, Line 24: "...with an aim of assessing the consistency (and lack thereof) between the two independently derived ACAOTs.

Author's response: Thank you.

Modifications: Page 4, Line 24: Jethva et al. (2014) performed an intercomparative analysis of the ACAOT retrieved with the aforementioned methods in order to assess the consistency (or lack of) between the two independently derived ACAOTs.

15. Page 4, Line 32: Chand et al. (2008, 2009) and Jethva et al. (2014) have shown that the CALIOP-based CRM works best for fine mode absorbing particles. Two of the regions selected in this study, i.e., Southeastern Atlantic Ocean and Siberian wildfire areas are known for the presence of strongly absorbing biomass burning aerosols. The CRM retrieval owing to its suitability in these environments would give a better estimate of aerosol loading above clouds. Note that CRM, similar to the DRM, does not require to assume specific aerosol and cloud microphysical model. I strongly recommend the author to take Duli Chand, the developer of CRM, on board and include the ACAOT retrievals for the inter-comparison.

Author's response: Please refer to the answer addressed at question Q1.

Modifications: Page 4, Line 32: No modifications have been made in the manuscript.

16. Page 6, Line 1-2: "Lastly, AOT retrieved at 6 km spatial resolution are aggregated to 18 km x 18 km spatial grid."

Author's response: We modified the text

Modifications: Page 6, Line 1-2: Lastly, the AOT retrievals at the 6 km × 6 km spatial resolution are aggregated to 18 km × 18 km spatial grid.

17. Page 6, Line 2-3: Restricting the standard deviation in AOT to 0.1 would likely mask the actual spatial inhomogeneity in the above-cloud aerosol field.

Author's response: Indeed, we assume that the aerosol layer is homogeneous under the 18x18 km² pixel. Please see Waquet et al., (2013b) for more details regarding the POLDER algorithm and the filters used to improve the quality of the products.

Modifications: Page 6, Line 2-3: No modifications have been made

Author's response: We added A-Train in the phrase

Modifications: Page 10, Line 8: The A-train satellite pass [...]

20. Page 10, Last paragraph: CALIOP Aerosol Layer Product ALay uses the signal at 532 nm to locate the layers of aerosols. In the presence of heavy loading of absorbing aerosols, such as observed over the Southeastern Atlantic Ocean, the signal at 532 attenuates rapidly due to aerosol absorption effects within the top layers of aerosols. This results in diminished magnitudes of backscatter as the lidar light penetrates further into the aerosol layer. After some depth of penetration, the signal falls within the noise levels and therefore rejected for any meaningful interpretation. This is precisely the reason why standard CALIOP above-cloud AOD product at least over the Southeastern Atlantic Ocean is underestimated compared to other A-train based above-cloud AOD retrievals [Jethva et al., 2014]. I believe in such cases, the CALIOP ALay product would show a greater number of separated ("detached") layers than mixed layers.

Author's response: The authors considered the limitations of CALIOP layer detection products and agree with the reviewer's observations, as we have already highlighted in the manuscript at Page 12, Line 25. The choice of 500 m between the cloud top altitude and aerosol base altitude was made as a compromise between keeping enough data to be statistically meaningful and choosing a large enough distance to minimize the possible contact between the layers.

As a future perspective, the lidar signal measured at 1064 nm could be use to refine our classification of « attached » and « detached » cases. « Apparent » false detached cases (due to strong attenuation at 532 nm)

could be identified by controlling the attenuated backscattering coefficient measured at 1064 nm between the aerosol layer base and the cloud top.

Modifications: We added in the text at Page 20, Line 23: Nevertheless, some of the *detached* cases considered in our study, mainly the ones associated with optically thick smoke layers, are likely to be incorrectly classified as *detached*. As a future perspective, these misclassified detached cases (due to strong attenuation of the CALIOP 532 nm signal) could be detected by controlling the CALIOP 1064 nm signal, which was shown to provide more sensitivity to the entire vertical extent of these absorbing aerosol layers.

21. Page 12, Line 3-4: It would be extremely useful to also show the CALIOP 1064-nm backscatter curtain plot for these events. I expect the 1064-nm results would show deeper extent aerosols in the vertical column.

Author's response: Figure 1.R1 presents the attenuated backscatter profiles for 1064 nm and 532 nm for the three case studies presented in the article. We observe a larger geometrical thickness of the aerosol layer situated above the clouds for Namibian biomass burning, when we consider the CALIOP 1064 nm retrievals. Also, the aerosol layer appears mostly detached from the underlying cloud at 532 nm, while at 1064 nm we notice more contact area. Nonetheless, for this peculiar case (13 August 2006), we still have a very good agreement between DRM and POLDER (see Table 1 in the manuscript). The Saharan desert dust and the Siberian biomass-burning cases present small differences of backscatter profile between the 532 nm and 1064 nm.

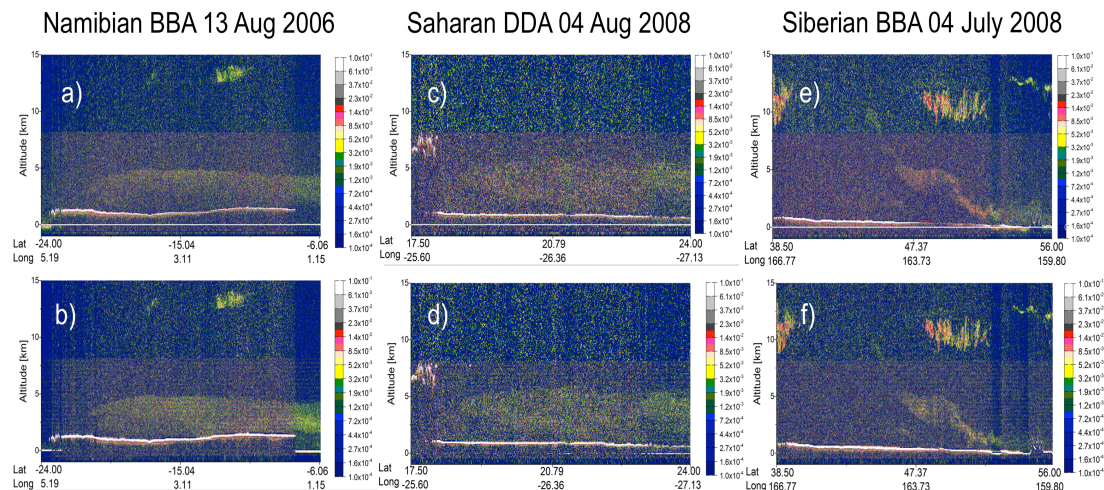

Figure 1.R1: The first row of the panel shows the CALIOP attenuated backscatter coefficients at 532 nm, while the second row presents the CALIOP attenuated backscatter coefficients at 1064 nm for three case studies: a), b) African Biomass-Burning (BBA) aerosols above clouds on 13 August 2006; c), d) Saharan dust (DDA) on 4 August 2008 and e), f) Siberian biomass-burning aerosols over the Okhotsk Sea on 3 July 2008.

Modifications: Figure 1 from the manuscript was modified in order to include the CALIOP attenuated backscatter coefficients at 1064 nm.

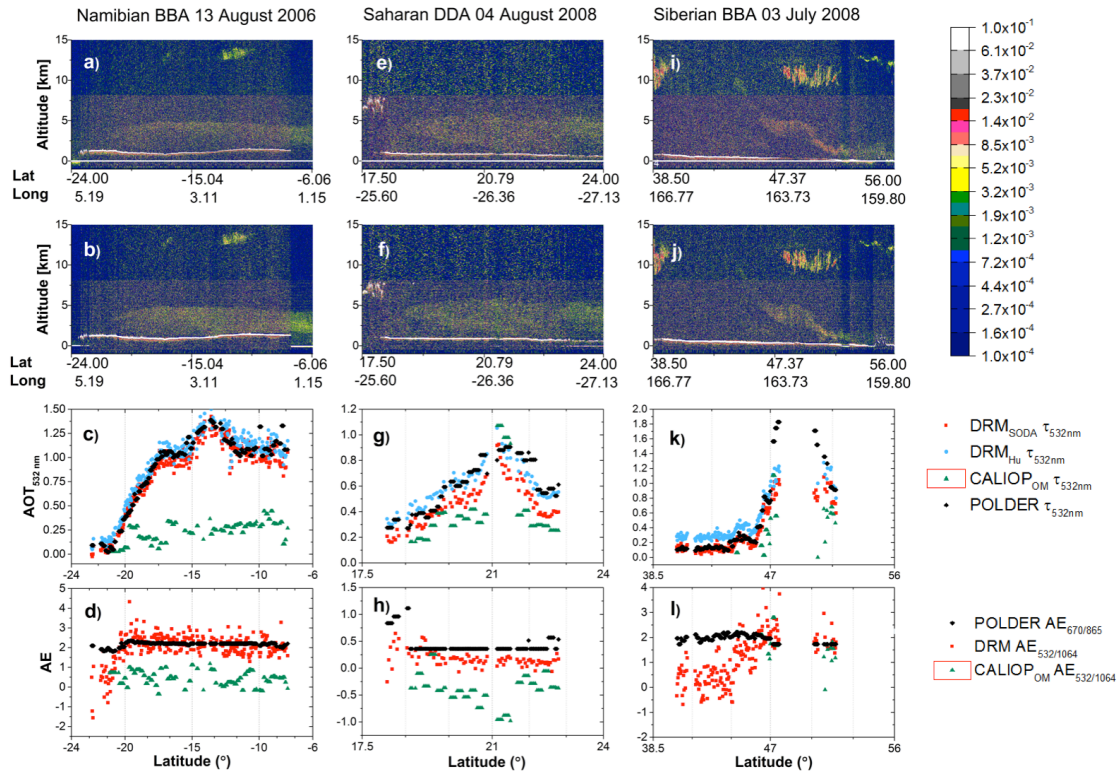

Figure 1. The first row of the panel shows the lidar CALIOP attenuated backscatter coefficients at 532 nm (km⁻¹ sr⁻¹) and the second row presents the CALIOP attenuated backscatter coefficients at 1064 nm for three case studies: African biomass-burning (BBA) aerosols above clouds on 13 August 2006 ((a), (b), (c), (d)), Saharan dust (DDA) on 4 August 2008 ((e), (f), (g), (h)) and Siberian biomass-burning aerosols over the Okhotsk Sea on 3 July 2008 ((i), (j), (k), (l)). For these cases, the above-cloud AOT at 532 nm and the Ångström exponent (AE) as a function of latitude, measured with several techniques are displayed.

Page 12, Line 16-18: According to the CALIOP vertical profile at 532 nm of the biomass-burning case (Fig. 1a), the cloud top is at around 1.5 km and the aerosol layer is located between 3 and 5 km. The 1064 nm backscatter profile (Fig. 1b) exhibits an aerosol layer with a larger vertical extent, showing up more potential contact area with the underlying cloud.

22. Page 17, Line 9: Please refer to Meyer et al. [2015] paper which documents the uncertainty in the cloud effective radius retrievals due to the presence of absorbing aerosols over cloud. I guess it is <5%.

Here is the citation: Meyer, K., S. Platnick, and Z. Zhang (2015), Simultaneously inferring above-cloud absorbing aerosol optical thickness and underlying liquid phase cloud optical and microphysical properties using MODIS. *J. Geophys. Res. Atmos.*, 120, 5524–5547. doi: 10.1002/2015JD023128.

Author's response: Thank you for the new reference.

Modifications: Page 17, Line 10-13: For example, Haywood et al. (2004) found biases of $\pm 2 \mu\text{m}$ for r_{eff} in case of strong dust events above clouds and Meyer et al., (2015) found an increase in the r_{eff} monthly mean of 2% in case of above-cloud absorbing aerosols.

23. Page 17, Line 10-14: The effect of cloud effective radius on DRM(SODA) could be larger for moderate to high aerosol loading ("detached" cases).

Author's response: Thank you. We modified the following in the text.

Modifications: Page 17, Line 10-11: [...] 2% in case of above-cloud absorbing aerosols. We expect that large biases on r_{eff} could be possible in case of high aerosol loading for *detached* cases.

24. Page 20, Line 7: "Aerosols as a solution within the cloud droplets..."

Author's response: We have corrected the text

Modifications: Page 20, Line 7: Aerosols as a solution within the cloud droplets [...]

25. Page 20, Line 13-14: What is the overall uncertainty in DRM-retrieved AOT when lidar ratio changed from say 19 sr to 25 sr or 29 sr.

Author's response: By modifying the lidar ratio from 19 sr (corresponding to DRM_{Hu}) to 25 sr, the retrieved AOT values decreases by around 0.1 In order to illustrate this, we computed the AOT at 25 sr for the Namibia biomass-burning study case from 4 August 2008 in Figure. 2.R1.

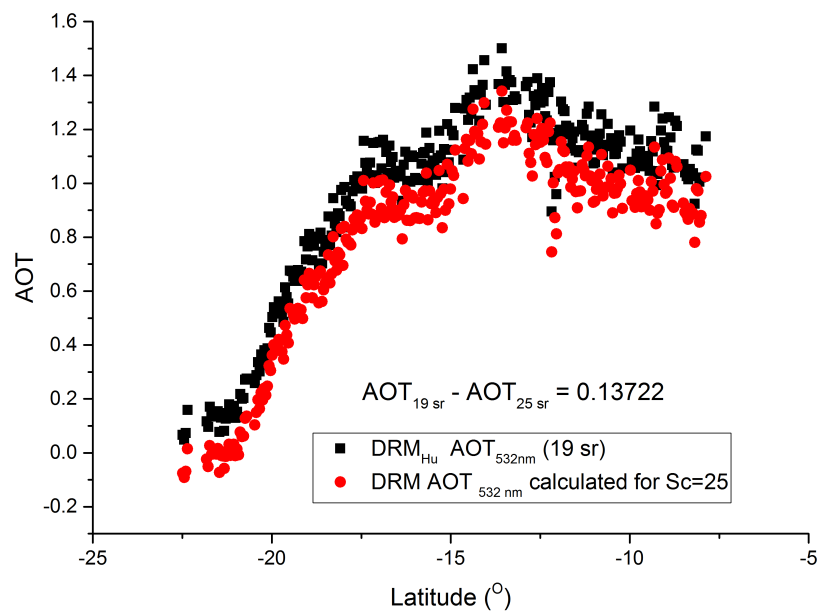

Figure 2.R1 presents the above-cloud AOT at 532 nm for DRM_{Hu} (19 sr) and DRM at 25 sr in function of latitude for 4 August 2008, for a case of biomass-burning off-coast of Namibia.

Modifications: No changes were made in the manuscript.

26. Page 20, Line 28: "...with respect to other methods."; Line 32: "impacts"

Author's response: Thank you. We corrected the text

Modifications: Page 20, Line 28: [...] with respect to other methods.[...] impacts the AOT [...]

27. Page 21, Line 23: Do author think that the imaginary part of the refractive index is also important and can affect the retrieval accuracy?

Author's response: Yes, as demonstrated in Figure 2.R1, the inclusion of soot within the droplets may significantly modify their imaginary refractive index and impact the DRM method. The polarisation method is primary sensitive to the scattering property of the aerosols and the operational method (Waquet et al., 2013)

retrieves the scattering AOT. The assumption made for the imaginary part of the refractive index does not much perturb the retrieval of the AOT. Please see the sensitivity study in Peers et al. (2015) for more details.

Modifications: No modifications have been added.

28. Figure 9. Aerosols above cloud is a regional phenomenon. The global plot of attenuated backscatter shown in Figure 9 is not a representative of what is happening over the prominent region of AAC i.e., over the Southeastern Atlantic Ocean, the tropical Atlantic Ocean off the coast of Sahara, South-East Asia (springtime agricultural fires), and northern Arabian Sea (dust above cloud). The author should focus on these regions and create similar plots, particularly for the Southeastern Atlantic Ocean, tropical Atlantic Ocean.

Author's response: The authors agree with the reviewer's observations. Nonetheless, as the global number of *attached* situations in our database is quite low compared to the *detached* cases (1277, respectively 21866 at 5 km resolution at a global scale – see Figure 9), in the manuscript we have decided to present the global result for statistical reasons. In order to address the review's question, we generated the median and average backscatter coefficients for the South Atlantic Ocean region, for a period of six months (May to October) during 4.5 years (2006-2010). Figure 3.R1 presents the results. As in the global situation, we notice that for *detached* cases the aerosol and cloud backscattering profiles can be easily distinguished in both the median and mean profiles. For the attached cases the continuous transition in the backscatter signal between the cloud top and the above atmosphere is still present (like in the global case). The results confirm our previous analysis made for global observations.

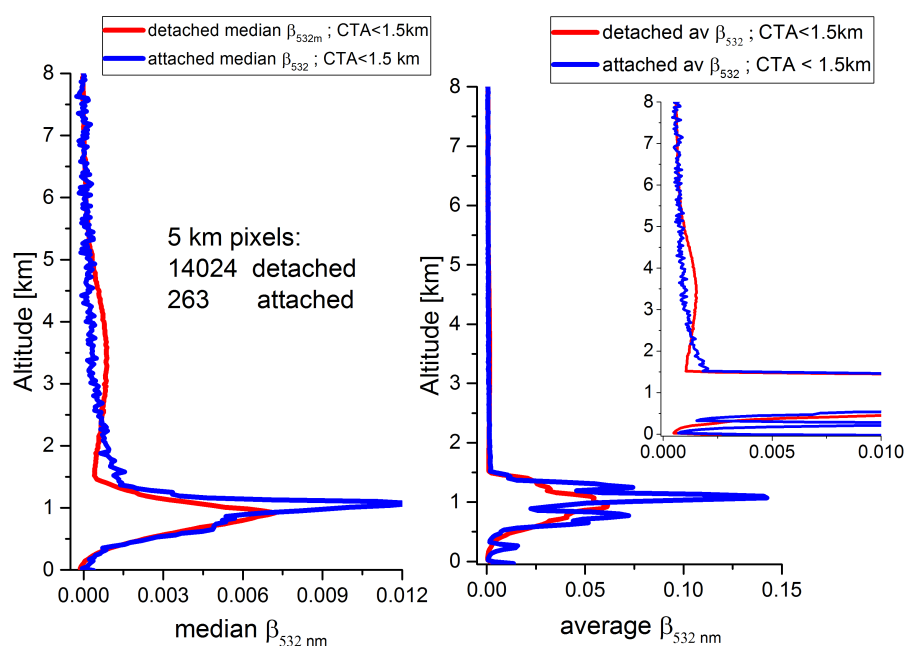

Figure 3.R1. Median (a) and averaged (b) backscatter profiles ($\text{km}^{-1}\text{sr}^{-1}$) for aerosol layer detached from the cloud layer (red) and aerosols attached to the top of the cloud (blue), for the period May-October from 2006 to 2010, over the South Atlantic Ocean region. The data was filtered for a cloud top altitude lower than 1.5 km.

Modifications: No changes were added in the manuscript.

29. Figure 10 should be recomputed in accordance with the CALIOP backscatter results for above regions. Figure 10. This simulation is a bit confusing. The cloud layer is located between 0 and 1 km and two of four aerosol simulation cases (blue and red) locate aerosols within the clouds. The third case (orange) has an aerosol layer with half the depth merged into the clouds and the half on top of the cloud. The fourth one is truly a detached case.

Author's response: There is no need to recompute the simulation for different aerosol and cloud altitudes, because the polarised radiance computed at 865 nm is not affected neither by the vertical position of the aerosol, nor by the vertical position of the cloud layer (i.e. no difference in the AOT retrievals), as long as there is no contact between the aerosol and cloud.

For a cloud top altitude of 1 km and an aerosol layer of $AOT = 0.25$, we considered three different situations:

1. Aerosol layer detached from the cloud top (between 1.25 and 1.75 km): The retrieved AOT corresponds to the simulated AOT; the polarised signal is well simulated.
2. Aerosol layer attached to the cloud top (between 0.75 and 1.25): The polarised signal coming the aerosols located within the cloud layers is partially attenuated due to cloud multiple scattering.
3. Aerosol layer located in the upper part of the cloud (between 0.5 and 1km): We would expect complete attenuation of the polarised signal coming from the aerosols. However, Figure 10 shows that there is still a remaining polarized signal observed at forward scattering angles coming from the aerosols located in the upper part of the cloud. An additional signal coming from the aerosol located within the cloud would lead to an overestimation of the POLDER above cloud AOT. This signal could explain the situations where POLDER polarisation method retrieves nonzero AOT values whereas DRM method retrieves an AOT close to 0.

Modifications: We added at Page 19, Line 22: Note that the polarised radiance at 865 nm is not affected by the vertical position of the aerosol layer as long as there is no contact between the aerosol and the cloud.

Authors want to thank Referee #2 for his contribution and interactive comments. The answers to specific questions (in red) are addressed below in blue, while the modifications made in the manuscript are in green.

In this study, the authors compare and analyse the consistency of the AOT and AE retrievals above clouds from different passive and active remote sensing instruments (namely CALIOP and POLDER). Comparisons are conducted in the framework of a) three case studies corresponding to an African biomass-burning event, a Saharan dust event and a Siberian biomass-burning event; b) a regional scale analysis, over South Atlantic Ocean, North Atlantic Ocean and North Pacific Ocean for a period of six months in 2008 and c) a global scale analysis for different vertical layer distributions for the period 2006–2010. The paper is well written and well structured which makes it enjoyable to read in spite of the very complex methodological concepts and tedious analyses it conveys. The paper is well suited for AMT and certainly deserves publication, after addressing a minor point. I am aware that the authors only claim to check the consistency between the products, but a comparison of the products to actual airborne measurements made during field experiments off the coast of the Africa continent would be very good. Since the mid 2000s, a large number of airborne campaigns have attempted to characterize aerosols properties off-shore of West Africa (SAMUM 1 & 2, DODO, DABEX, AMMA, NAMMA, ICE-D, SALTRACE, DACCIWA) and southern Africa (SAFARI, and recently ORACLES). At least the authors should explain why they have not attempted to do so.

Author's response: Thank you. As you mentioned in the comment, this paper is focused on assessing the consistency between the two methods: POLDER and DRM methods developed for aerosols above clouds. As explained in the first part of this review (see responses to reviewer #1, Q2), the comparison of these methods with non-collocated measurements from different previous field campaigns would have a small contribution for the purpose of this paper. Nonetheless, we added few sentences in the manuscript mentioning the existence of ongoing field campaigns (please see the responses to reviewer 1) that includes dedicated validation flights.

Modifications: Page 21, Line 23 – 26: Airborne measurements are extremely useful in providing information on aerosols above cloud properties. Several ongoing and planned airborne field campaigns will attempt to characterize the properties of biomass burning aerosols over the Southern Atlantic Ocean (Zuidema et al., 2016). Planned measurements from the French Falcon 20 aircraft, equipped with a high-resolution lidar, an airborne sun-photometer and a POLDER-like sensor, will notably be considered for a future validation of CALIOP DRM and POLDER above-cloud aerosol products.

We added Zuidema et al., 2016 in the list of references.

Authors want to thank Referee #3 for his contribution and interactive comments. The answers to specific questions (in red) are addressed below in blue, while the modifications made in the manuscript are in green.

1. Page 9, lines 3 and 4: “This ensures a minimum level of attenuation of the signal from the surface.” I believe the authors want an adequate level of attenuation of the surface return, rather than a minimum (i.e. low) level of attenuation, otherwise the following statement that “The intent of this threshold is the same as the previous criteria” is not coherent.

Author’s response: Indeed, we made a mistake. Thank you.

Modifications: We wrote: adequate level of attenuation of the surface return.

2. Page 9, Line 20: The calibration of SODA is not very well explained. Presumably η_c comes from Eq. (3) and provides a way to estimate η_{calibr} when there are aerosols above clouds using the layer integrated depol. The implication of Eq. (8), that the global mean value of Sc is assumed to be 19 sr should be stated. How the binning by latitude is done should also be stated since otherwise substituting equation (8) into (9), at face value, suggests that $Sc_{lat}=19$.

Author’s response: We added several clarifications.

Modifications: Page 9, Line 20-28: As a first step, SODA calibrates the multiple scattering to depolarization relationship for nighttime data on a monthly basis. The data of interest are based on Eq. (2) and can be written as

$$\eta_{geo} = \frac{1}{2 \times 19 \times \gamma'_{water, parallel}} \quad (7)$$

where $\gamma'_{water, parallel}$ is the parallel-integrated backscatter coefficient. This equation provides a direct measurement of the multiple scattering coefficient of liquid water clouds (η_{geo}) when their lidar ratio is constant. The constant value of 19 sr used in the SODA algorithm is based on Hu et al. (2006) who found a lidar ratio equal to 19.1 ± 0.21 sr when the 41 droplet size distributions of Miles et al. (2000) are used as inputs of a Mie scattering code.

For all opaque liquid water clouds defined with the above criteria, SODA then compares the direct measurement of the multiple scattering coefficient (η_{geo}) and the theory (η_c) to find the second order polynomial that best fit the data in the least square fit sense. This defines the calibrated multiple scattering coefficient (η_{calibr}):

$$\eta_{calibr} = fit[\eta_{geo}(\eta_c)] = A\eta_c + B\eta_c^2 \quad (8)$$

As a second step, SODA calculates the apparent lidar ratio $S_{c,lat}$ of all opaque liquid water clouds as a function of each degree of latitude and for both 532 and 1064 nm. This procedure is done separately for daytime and nighttime data.

3. Page 9, Line 24: Providing ranges for A, B and $S_{c,lat}$ if not figures, would be helpful to the reader to understand how much the data is being corrected for potential calibration and other issues.

Author’s response: We provided the median value of $S_{c,lat}$ to give the reader a sense of the correction. As the SODA algorithm saves this value, it should be at the same time statistically correct and easy for the reader to grasp, even if more than 4 years of data are considered.

Concerning A and B, as they compensate each other, providing their value and their variations would probably confuse the reader. For the 4.5 years considered here, the median is 1.39 for A and -0.66 for B so the reader

could easily be lead to believe that the correction is in the order of 30 to 40%. For a typical range of multiple scattering coefficient between 0.3 to 0.5 (see Hu et al. 2007), the values become 0.35 to 0.52, respectively. Following your comment and a similar comment by M. Vaughan, we agree that it is important to improve the reader understanding and we added modified the text accordingly.

Modifications:

Page 9, Line 26: This procedure allows us to use a relationship between depolarization and multiple scattering that fits the observation. Using Eq. 3 instead of Eq. 8 would create an aerosol optical depth bias that would typically range between 0.02 and 0.08. Although this is not always significant, this correction is necessary as the resulting ACAOD bias does correlate with the clouds microphysical properties. This is particularly undesirable as the link between aerosol and cloud microphysical properties is an active topic of research

Page 10, line 2: For the 4.5 years of data we considered in this study, the median of $S_{c,lat}$ for the nighttime data is 19.36 sr, which is interestingly close from the theoretical value determined by (Hu et al. 2006). For daytime data, $S_{c,lat}$ is systematically higher and with a median of 20.64 sr. The systematic daytime/nighttime difference could be geophysical. However, it is premature to reach such conclusion until all nighttime/daytime differences in the CALIPSO data have been addressed.

4. This is also relevant to p.16 lines 25,26 where it is stated that “The DRM algorithm assumes a constant lidar ratio of 19 sr, independent of the cloud droplet effective radius.” It was previously stated that the latitudinal dependence in $S_{c,lat}$ allowed for calibration and actual variations in S_c . What is true?

Author’s response: You are correct, this statement is partially true only for the original DRM_{Hu} and when no further calibration is performed which is not how this methodology should be used. In order to improve clarity, we modified this sentence:

The DRM algorithm assumes a constant lidar ratio of 19 sr, whatever the cloud droplets effective radius is. In order to evaluate the accuracy of this approximation, we recalculated the DRM_{SODA} AOT_{532nm} taking into account the dependence of S_c on r_{eff} .

Modifications: Page 16, Line 25-30: The DRM algorithm does not use an explicit parameterization of the lidar ratio as a function of the cloud droplets effective radius. An implicit dependence will arise from the latitudinal correction (Eq. 9) when clouds at different latitudes will exhibit different microphysical properties. In order to understand the usefulness of adding an explicit parameterization, we recalculated the DRM_{SODA} AOT_{532nm} taking into account the dependence of S_c on r_{eff} . This calculation assumes a simplified and unique droplet size distribution and is based on MODIS r_{eff} retrieval. We expect that even if the cloud droplet size distribution is variable (Miles et al. 2000) and that the ACAOD creates a bias in r_{eff} , the results will still provide guidance for future algorithm development.

5. Page.18, Line 20: “The background reaches 0.09 in AOT at 532 nm.” Is this the extrapolated POLDER optical depth for the undetermined cases? If so, say so.

Author’s response: Yes, it is the extrapolated AOT at 532 nm.

Modifications: Page 18, Line 20: The background of the extrapolated POLDER AOT at 532 nm for the undetermined cases reaches 0.09.

6. Page 20, Line 9, 10: “imaginary part of 0.0001”, the authors should really provide an estimate of the volume mixing ratio of black carbon needed to provide such an imaginary index. It seems unlikely that such an imaginary index is plausible for droplets of 10 μm or more given the required mass of carbon.

Author’s response: Erlick (2006) calculated the range of visible refractive indices and single-scattering albedos at 550 nm in case of water with soot inclusion for different droplets size. In this study, the complex refractive indices are considered equal to $1.333+i1.96\times10^{-9}$ for water and $1.750 + i0.440$ for soot, respectively. The volume fractions of soot, f , varies for different dilute solutions $f=10^{-4}$, $f=0.01$ and $f=0.1$. In case of water with soot inclusion, the refractive index for $f=10^{-4}$ is around $1.33 + i4.5\times10^{-5}$, while for $f=0.01$ the water/soot refractive index is around $1.34 + i3.8\times10^{-3}$. In our study, we made the choice to use an intermediate value of complex refractive index, equal to $1.337+i10^{-4}$, which roughly corresponds to an intermediate volume fraction of $f=10^{-3}$. Therefore, we consider our choice to be realistic and in agreement with bibliography.

Modifications: Page 20, Line 9: We used an imaginary part of 0.0001 for the complex refractive index of the droplets. This might simulate, for instance, the properties of brown clouds contaminated by absorbing aerosols. The chosen value is in agreement with the refractive indices given for water containing soot inclusions with volume fractions ranging between 10^{-4} and 10^{-2} (Elrick, 2006).

We added the reference in the list of references:

Authors want to thank Mark Vaughan for his contribution and interactive comments. The answers to specific questions (in red) are addressed below in blue, while the modifications made in the manuscript are in green.

1. Page 3, Line 11 referring to (Winker et al., 2003): this is gray literature; suggest citing Winter et al., 2010, BAMS instead (doi:10.1175/2010BAMS3009.1)

Author's response: Thank you. We added the new reference

Modifications: Page 3, Line 11: [...] satellite provides high-resolution vertical profiles of aerosols and clouds (Chand et al., 2008; Winker et al., 2010).

2. Page 3, Line 14 referring to (Vaughan et al., 2009; Winker et al., 2009): more appropriate references would be Omar et al., 2009 (doi:10.1175/2009-JTECHA1231.1) and Young and Vaughan et al., 2009 (doi:10.1175/2009JTECHA1228.1)

Author's response: We added the new reference

5. Page 6, Line 12 referring to (Winker et al., 2009): CALIOP layer detection reference is Vaughan et al., 2009 (doi:10.1175/2009JTECHA1228.1)

Author's response: Thank you. We added the new reference

Modifications: Page 6, Line 12: [...] the feature and layer detection scheme (Vaughan et al., 2009).

6. Page 6, Line 21: cite references or reword (e.g., 'can be' a substantial source, rather than 'is')

Author's response: We modified the text.

Modifications: Page 6, Line 21: It should be noted that an incorrect assumption for the lidar ratio could be a source of substantial errors in the AOT retrieved with this method.

7. Page 7, Line 11, Eq. (1): incomplete; see feature finder ATBD (https://www-calipso.larc.nasa.gov/resources/project_documentation.php) or Vaughan et al., 2010 (doi:10.1029/2009JD013086) the equation given here will overestimate the integrated backscatter at 532 nm

Author's response: This is a reference to (Eq. 1) of (Hu et al., 2007). We agree with your comment and we understand you call it incomplete, as it does not contain as much detailed information as an ATBD would, however this pioneering paper defined the science basis of the depolarization method. Note that SODA does not contain an explicit correction of the Rayleigh scattering contribution because of the high scattering ratio of liquid water clouds. The underlying philosophy of this first version of the AOD over liquid water cloud dataset is to keep the algorithm simple. This helps for error tractability and it reduces potential algorithm artefacts that could end up creating a higher uncertainty that the second order error they are aimed at correcting (i.e. the amount of bugs scales non-linearly with algorithm complexity).

Modifications: Page 7, Line 10: When Rayleigh scattering contribution has been corrected for, the definition of γ'_{water} is given by the following equation:

Page 9, Line 2: Note that SODA corrects the molecular attenuation above the cloud, but does not contain an explicit correction of it within the cloud because of the high scattering ratio of liquid water clouds. Nonetheless, the molecular contribution is statistically taken into account by the calibration procedure.

8. Page 7, Line 16, Eq. (2): reference Platt, 1973 (doi:10.1175/1520-0469(1973)030<1191:LAROC>2.0.CO;2) or Platt, 1979 (doi:10.1175/1520-0450(1979)018<1130:RSOHC>2.0.CO;2)

Author's response: Thank you. We added the reference in the text.

Modifications: Page 7, Line 14: [...] the lidar equation simplifies to the following definition, expressed as a function of the lidar ratio (S_e) and layer effective multiple scattering factor (η_e) (Platt, 1979):

9. Page 7, Line 21, Eq. (3): add definition for integrated depolarization ratio

Author's response: We added the definition in the text.

Modifications: Page 7, Line 19: η_e , [...] is strongly related to the cloud depolarization ratio δ' (defined as the ratio of the parallel and perpendicular polarization signals), since multiple scattering processes tend to depolarize light.

10. Page 7, Line 22: should be either "molecular and gaseous attenuation" or "molecular attenuation and gaseous absorption"

Author's response: We modified the text.

Modifications: Page 7, Line 22: After γ'_{water} is corrected for molecular and gaseous attenuation [...]

11. Page 8, Line 1: also does not require accurate (any!) layer detection for the overlying aerosol layer

Author's response: Thank you for the contribution. We modified the text accordingly.

Modifications: Page 8, Line 2: [...] and does not require accurate layer detection for the overlying aerosol layer in order to estimate the AOT integrated over the atmospheric column.

12. Page 8, Line 14: what does 'significant' mean in this context? 1%? 10%? 100%?

Author's response: Sassen and Zhu (2009) found a bias in the linear depolarization of cirrus clouds of around 30% (0.1/0.34).

Modifications: we modified this sentence accordingly: [...] a significant source of uncertainty. Previous research (Sassen and Zhu, 2009) found a bias in the linear depolarization of cirrus clouds of around 30%.

13. Page 9, Line 5: can you translate this into an effective overlying optical depth (e.g., if the surface integrated attenuated backscatter in clear air is X, what optical depth does it take to reduce it to $7.5e-6$?)

Author's response: The reflectance of the ocean surface return is depending on wind strength so the corresponding COD that can be detected above threshold is variable. It's typically between an optical depth 4 to 5 during nighttime and 1.5 and 2.2 during daytime. Because of the increased noise, this filter has a limited usefulness during daytime but it is not deemed critical because of the redundancy between the different filters used here.

Modifications: Page 9, Line 6: We added the following sentence in the text: This corresponds to a cloud optical thickness of around 2 during daytime and 4-5 during nighttime, which is when this filter is the most useful.

14. Page 9, Line 16, Eq. (6): should use different threshold for day and night in order to account for very different contributions from solar background noise also, to mitigate noise effects and guard against the inclusion of poorly calibrated or otherwise unsuitable data, some minimum value of the integrated backscatter should also be imposed.

Author's response: In general, we avoided to introduce a day/night dissymmetry in the algorithm. The filter discussed in Page 9, Line 5 is an exception because the filter redundancy (one among three) is built to avoid algorithm artifacts.

Future prototypes of SODA would probably rely more on the CALIPSO products instead of developing independent custom thresholds. However, as in general it is interesting to introduce some redundancy, it could be a consideration to keep this filter with the modifications you suggested: a different day/night threshold along with a minimal value. To not overwhelmed the reader with detail of future releases but still clarify the matter, we completed the text.

Modifications: Page 9, Line 16: As this filter introduces more aerosol contamination during daytime (similar to Josset et al. 2010, Fig. 4), it could be desirable to consider the shot-to-shot CALIOP cloud mask for future version of the algorithm as SODA already uses this information for the scene classification flag.

15. Page 9, Line 18: why not use the molecular lidar ratio given in the CALIPSO L1 ATBD?

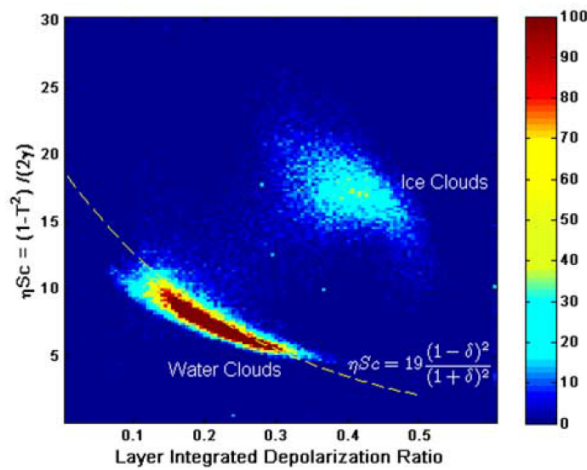

Author's response: It is mostly to simplify the algorithm. It avoids the use of a number with more significant figures (and adjust the threshold factor, i.e modify the 1.5 factor). This reduces the likelihood of a bug due to a typo when several people are involved in the development of the algorithm. SODA uses the same numbers than CALIPSO for the algorithm over the ocean so it could be a consideration to use the same number here.

Modifications: No modifications have been added in the text.

16. Page 9, Lines 20-26: this approach seems to homogenize the eta-delta relation, and I'm not sure that's valid. for example, I've seen (unpublished!) simulations suggesting that eta can change as a function of droplet size distribution (though perhaps the CALIOP FOV is too large to effectively resolve these differences?)

Some more discussion on the rationale for taking this approach and the possible pitfalls involved would be helpful here.

Author's response: The multiple scattering relationship used in SODA is indeed calibrated on the observed properties of dense liquid water clouds. This procedure avoids the issue visible in Hu, 2007 (GRL), Fig. 2 (see below) where the theoretical relationship given in Hu, 2007 (white line) does not exactly fit the data centroid. Using the proposed modified relationship avoids to create an aerosol optical depth bias which would correlate with the clouds microphysical properties. It would be particularly undesirable because we would knowingly keep an error in the dataset, which would look like a geophysical feature that interest researchers (i.e. the effect of aerosols on cloud microphysical properties).

There are alternative ways to implement this correction that we mentioned in the manuscript (Hu et al. 2007a) but it assumes a specific underlying cause (transient response) whereas the approach used in SODA is more general.

The published papers do not point towards a clear reason for the discrepancy between theory and data so we cite the different possibilities and the associated (limited) references. If the issue is linked to a variability of the eta/delta relationship as a function of the microphysical properties of the cloud, our approach would statistically address it but as it is inconsistent with the published results of Cao et al. (2009), it would be premature to include such a discussion. However we can clarify the consequences of not using this approach and we added and replaced lines 20 in the manuscript:

Modifications: As previously mentioned, even if the multiple scattering–depolarization relationship has been confirmed by laboratory experiments (Cao et al., 2009), the relationship between the multiple scattering factor and the depolarization by the cloud shows a systematic deviation from the theory. It has to be corrected, as it would introduce a bias in aerosol optical depth with the particularly undesirable trait to correlate with cloud microphysical properties. As a first step, SODA calibrates the multiple scattering to depolarization relationship for nighttime data on a monthly basis. The data of interest are based on Eq. (2) and can be written as:

$$\eta_{geo} = \frac{1}{2 \times 19 \times \gamma'_{water,parallel}} \quad (7)$$

where $\gamma'_{water,parallel}$ is the parallel-integrated backscatter coefficient. This equation provides a direct measurement of the multiple scattering coefficient of liquid water clouds (η_{geo}) when their lidar ratio is constant. The constant value of 19 sr used in the SODA algorithm is based on (Hu et al., (2006) who found a lidar ratio equal

to 19.1 ± 0.21 sr when the 41 droplet size distributions of (Miles et al., (2000)) are used as inputs of a Mie scattering code.

For all opaque liquid water clouds defined with the above criteria, SODA then compares the direct measurement of the multiple scattering coefficient (η_{geo}) and the theory (η_c) to find the second order polynomial that best fit the data in the least square fit sense. This defines the calibrated multiple scattering coefficient (η_{calibr}):

$$\eta_{calibr} = fit[\eta_{geo}(\eta_c)] = A\eta_c + B\eta_c^2 \quad (8)$$

This procedure allows us to use a relationship between depolarization and multiple scattering that fits the observation. Using Eq. (3) instead of Eq. (8) would create an aerosol optical depth bias that would typically range between 0.02 and 0.08. Although this is not always significant, this correction is necessary as the resulting ACAOD bias does correlate with the clouds microphysical properties. This is particularly undesirable as the link between aerosol and cloud microphysical properties is an active topic of research.

As a second step, SODA calculates the apparent lidar ratio $S_{c,lat}$ of all opaque liquid water clouds as a function of each degree of latitude.

17. Page 9, Line 28: a very good idea for the V3 data, especially during daytime (but unnecessary for V4). Was a SODA recalibration also done at 1064 nm?

Author's response: Yes, SODA was recalibrated for both 532 and 1064 nm.

Modifications: To clarify we added the following sentence Page 9, Line 28: [...] as a function of each degree of latitude and for both 532 and 1064 nm.

18. Page 10, Line 9: what is this 'nearest pixel approximation' based on? footprint location? is cloud altitude considered in the collocation scheme?

Author's response: For the *nearest pixel approximation* in CALTRACK product, the center of MODIS and POLDER pixels at different resolutions (1×1 km² for MODIS, 6×6 km² and 18×18 km² for POLDER) is collocated; with the closest CALIOP 5 km midpoint footprint. Within the algorithm, the cloud altitude is corrected for high-resolution pixels (such as MODIS 1×1 km²), but in the case of POLDER 18×18 km² pixels, the effect of parallax can be neglected as the distance of a parallax correction falls within the POLDER pixel.

Modifications: No modifications have been added.

19. Page 10, Line 13: this is retrieve then average vs. average then retrieve. why? in general, more stable and more accurate results are achieved with the latter approach. Please justify your choice of the former.

Author's response: The authors agree with your comment. As mentioned in answer to reviewer #1, comment 7, we assume that the aerosol layer is homogeneous under the 18×18 km² pixel. Please see Waquet et al., (2013b) for more details regarding the POLDER algorithm and the filters used to improve the quality of the products. For the moment, the SODA product is only available at 333 m. An algorithm is under development at ICARE data center, which will allow retrieving an average SODA product at 5 km with a homogeneity flag.

Modifications: No modifications have been added.

20. Page 10, Line 15: how is this accomplished? how do you estimate attenuation between 30 km and 10 km? or do you assume it's effectively zero? please clarify.

Author's response: Thank you for this question. The explanation was not clear enough in the text. In fact we eliminate data related to aerosol altitudes higher than 10 km (single-layer and multi-layer situations), in order to confine as much as possible the possible cirrus contamination. Also, high aerosol altitudes can suggest extreme events, which do not make in the aim of this paper. Therefore, we don't need to make any assumption of the attenuation above 10 km. Likewise for the cloud altitude limit of 5 km.

Modifications: Likewise, we eliminated from our data analysis all situations in which the aerosol top altitude exceeds 10 km. This maximal value should be sufficient, since most of the biomass burning and dust aerosol layers are typically observed between 0.5 and 4.0 km over ocean (Torres et al., 2013).

21. Page 10, Line 24: line 26 on page 6 says that you're using aerosol base and top heights from the CALIOP level 2 layer products. however, for highly absorbing aerosols the base detections are clearly in error. This can be seen by comparing the attenuated backscatter images to the vertical feature mask images for cases of dense smoke over opaque stratus. In these cases, the CALIOP layer detection algorithm frequently fails to detect the full vertical extent of the layer. (this has been noted in several prior publications.). How does this failure influence the partitioning of the aerosol layers into attached, detached, and undetermined? My guess is that optically thick smoke layers will largely (but incorrectly) be classified as detached (or maybe get excluded all together).

Here's a nighttime example (and note that the problem is much worse for daytime data, when the background noise further degrades the CALIOP detection efficiency). Between ~6°S and ~16°S, the depolarization and 1064 nm attenuated backscatter plots clearly indicate that the aerosol layer is in contact everywhere with the cloud. However, according to the layer detection results, the aerosol layer is only intermittently in contact with the cloud.

https://www-calipso.larc.nasa.gov/products/lidar/browse_images/show_detail.php?s=production&v=V4-10&browse_date=2013-08-28&orbit_time=01-29-00&page=2&granule_name=CAL_LID_L1-Standard-V4-10.2013-08-28T01-29-00ZN.hdf

the above URL shows version 4 results. version 3 results are here:

https://www-calipso.larc.nasa.gov/products/lidar/browse_images/show_detail.php?s=production&v=V3-30&browse_date=2013-08-28&orbit_time=01-29-00&page=2&granule_name=CAL_LID_L1-Standard-V4-10.2013-08-28T01-29-00ZN.hdf

Author's response: We are aware of the limitations of CALIOP layer detection products. In the detached cases, the choice of 500 m between the cloud top altitude and aerosol base altitude was made as a compromise between keeping enough data to be statistically meaningful and choosing a large enough distance to minimize the possible contact between the layers. Nonetheless, we agree that our «detached» cases indeed include some remaining contact situations.

“How does this failure influence the partitioning of the aerosol layers into attached, detached, and undetermined?”

That will impact the results of our linear regression in terms of slope, correlation coefficient (R^2) and offset. But, that will not change our main conclusion: a good agreement is found between the DRM_{SODA} and POLDER above cloud AOTs when we remove the attached cases from our analysis, whereas the correlation between the two products largely decreases when we keep the attached cases.

In order to strengthen this conclusion, we compared the DRM_{SODA} and POLDER AOTs at 532 nm over a period of 4.5 years (June 2006 to December 2010) for two other situations:

- a) all « valid » AAC measurements, which includes attached, detached and intermediate cases (aerosol base altitude between 100 and 500 m above the cloud top)
- b) detached cases, same as in the manuscript (see figure 4 in the manuscript), but the minimal distance between the aerosol base altitude and the cloud top height must be larger than 1.5 km instead of 500 meters.

When taking into account all the “valid” situations (attached, detached and intermediate cases), the correlation between the two methods is low ($R^2 = 0.48$, see Fig. 1.SC-a). When we consider the detached scenario with a minimal “cloud-top-aerosol-base” distance of 500 meters, a broader agreement is found ($R^2 = 0.68$, slope = 0.84, intercept = -0.03 - see figure 4 in the manuscript). When we consider the detached scenario with a minimal “cloud-top-aerosol-base” distance of 1.5 km instead of 500 meters (as shown in Fig. 1.SC-b), the agreement between the two methods further improves: the slope is closer to 1. (0.86 instead of 0.84, intercept = -0.03) and the correlation coefficient increases ($R^2 = 0.70$ instead of 0.68). These results show that the agreement between the DRM and POLDER AOTs progressively improves as the apparent distance found by CALIOP between the cloud top height and the aerosol base height increases.

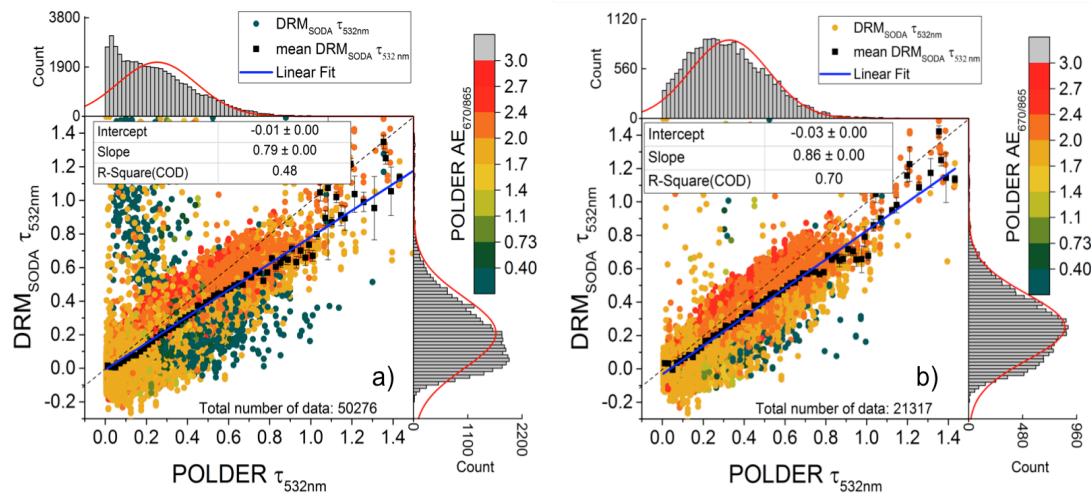

Figure 1.SC. Global comparison over a period of 4.5 years (June 2006 to December 2010) for (a) all valid AAC situations (in which the base of the aerosol layer penetrates the cloud maximum 50 m) and (b) situations where the aerosol layer is well separated from the cloud top with a minimum distance of 1.5 km between the two layers. The color scale represents the corresponding POLDER AE computed between 670 and 865 nm. The histograms present the data distribution. The error bars in figures (a), (c) and (e) represent the standard error of the mean (SEM).

As a future perspective, the lidar signal measured at 1064 nm could be used to refine our classification of « attached » and « detached » cases. « Apparent » false detached cases (due to strong attenuation at 532 nm) could be identified by controlling the attenuated backscattering coefficient measured at 1064 nm between the aerosol layer base and the cloud top.

Modifications: We added in the text at Page 20, Line 23: Nevertheless, some of the *detached* cases considered in our study, mainly the ones associated with optically thick smoke layers, are likely to be incorrectly classified as

detached. As a future perspective, these misclassified detached cases (due to strong attenuation of the CALIOP 532 nm signal) could be detected by controlling the CALIOP 1064 nm signal, which was shown to provide more sensitivity to the entire vertical extent of these absorbing aerosol layers.

22. Page 10, Line 27: not sure what this means? if the cloud is truly opaque, what possible evidence could you have for the presence of aerosols underneath? Likewise, what criteria are used to distinguish 'aerosol touching ' from 'aerosol within'?

Author's response: The authors do not claim to have any evidence of aerosols within or under the cloud. Nonetheless, after the collocation process (nearest pixel approximation), we can encounter situations where we have AAC AOT retrieved with POLDER that corresponds to CALIOP aerosol altitudes (top and/or base) lower than the cloud top altitude. This can be explained by the presence of fractional cloud cover within the super-pixel POLDER and different resolutions used in the CALTRACK product. Therefore, we classify these cases as "within" or "under" and they are eliminated from the study.

When the base altitude of the aerosol layer is situated between 100 m above the cloud top and 50 m below the cloud top, the data falls under the "attached" category.

When the base of the aerosol layer is below 50 m from the cloud top, the data falls into the "within" category.

There are no selection criteria for the aerosol top altitude, except that it has to be higher than the cloud top altitude in all cases.

Modifications: The so-called “attached cases” correspond to situations where the aerosol layer touches the top of the beneath cloud layer. For these cases, we assume that the vertical distance of the aerosol bottom altitude from cloud top altitude must be lower than 100 meters, without penetrating the cloud layer for more than 50 meters. [...] Aerosol layers with the base altitude within a distance between 100 and 500 meters above the cloud layer are considered too uncertain and are excluded from our study. We also removed the situations for which the detected CALIOP aerosol top and/or bottom altitudes are located below the cloud top, assuming that these data are highly uncertain.

23. Page 11, Line 1: this needs more explanation. For example, suppose the CALIOP layer detection algorithm fails to detect an aerosol layer that is readily visible in the CALIPSO images. Would this be an example of an 'undetermined' layer? Also, what is meant by 'missing data'?

Author's response: As for the previous question, the answer rests upon the different resolutions of CALTRACK products. If we retrieve valid POLDER AAC AOTs, but CALIOP layer detection algorithm fails to identify the aerosol or cloud altitude for the midpoint footprint used to collocate the data (even if the aerosol layer is readily visible in the CALIPSO images), then we treat the data as undetermined. We chose to keep these data in our analysis as they cover the majority of POLDER AAC detected cases, even if CALIOP classifies them as invalid. In these situations, the fill values of -9999 used for the aerosol or cloud altitudes in the ALay and CLay products are the “missing data” referred to in the manuscript.

Modifications: The third category, “undetermined”, corresponds to situations for which the vertical position of the aerosol or cloud layer is not identified by the CALIOP layer detection algorithm (i.e. missing data), even though POLDER AAC AOT retrievals are valid. We chose to keep these data in our analysis as they cover the majority of POLDER AAC detected cases with a non-negligible AOT (even if CALIOP classifies them as invalid or noise), as the purpose of the paper is to better understand the differences between the methods.

24. Page 11, Line 7: a map showing the boundaries of these three regions would be very helpful

Author's response: Figure 2.SC presents the global map on which the regions used in the manuscript are emphasized with a rectangle of different color.

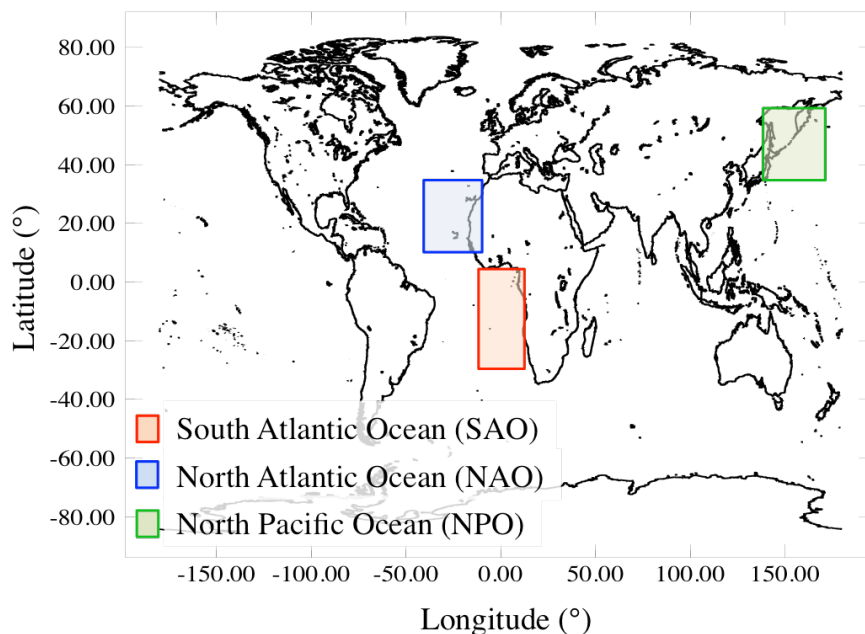

Figure 2.SC: The map presents the latitudinal and longitudinal boundaries of the three regions used in the regional study (Sect. 3): South Atlantic Ocean (SAO) extends from 30° S to 5° N and 12° W to 14° E, North Atlantic Ocean (NAO) is situated between 10 to 35° N and 10 to 40° W and North Pacific Ocean (NPO) is located between 35 to 60° N and 140 to 170° E.

Modifications: We added this new figure in the manuscript.

25. Page 11, Line 21: based on the text in this paragraph, you're partitioning the retrievals by cloud type and not necessarily by cloud properties (e.g., optical depth)

Author's response: Thank you for the observation.

Modifications: Cloud types and their associated optical and microphysical properties are expected to be different in these three regions (Warren et al. 1988).

26. Page 12, Line 21: add references

Author's response: We added the new reference

Modifications: [...] which is characteristic for fine mode particles (Dubovik et al., 2002).

27. Page 12, Line 23: techniques

Author's response: Thank you for the correction.

Modifications: [...] three other techniques.

28. Page 12, Line 27: when using V3 data, this is more likely to be 1064 calibration error; 1064 calibration is much improved in V4

Author's response: Thank you for this contribution.

Modifications: The selection of an inappropriate aerosol model (i.e. aerosol lidar ratio S_a for biomass burning, varies between 70 ± 28 at 532 nm and 40 ± 24 sr at 1064 nm (Cattrall et al., 2005; Omar et al., 2005)) or the significant biases found in the V3.01 CALIOP 1064 nm calibration, might also contribute to the underestimation of the AOT for this case study.

29. Page 13, Lines 15-18. I suspect this is due to a combination of a bad model (for dust in CALIOP V3.x analyses, $S = 40$ @ 532, $S = 55$ @ 1064) and maybe bad calibration.

Author's response: Thank you for this contribution. We added the following in the text.

Modifications: [...] two other algorithms. These low values of AOT and AE may be explained once more by a biased CALIOP calibration at 1064 nm combined with an unfitted model selection (i.e. for desert dust, S_a is equal to 40 ± 20 sr at 532 nm and 55 ± 17 sr at 1064 nm (Cattrall et al., 2005; Omar et al., 2005)).

30. Page 13. Line 26: add references

Author's response: We added the new reference

Modifications: which indicates that coarse mode particles are predominant (Dubovik et al., 2002).

31. Page 15, Line 4: I'd really like to see a more detailed description of the criteria used to distinguish between the "attached", "detached" and "undetermined" categories. Around line 25 on page 6 the authors state that they use the aerosol base and top altitudes reported in the CALIOP data products. However, the CALIOP layer detection scheme is known to have difficulties determining the full vertical extent of absorbing layers with high lidar ratios (e.g., smoke). Some recognition of this fact should be included, along with some discussion of its possible impacts on the authors' conclusions.

Author's response: Please refer to the answer provided for question 21.

32. Page 15, Line 23: not

Author's response: Thank you for the correction.

Modifications: [...] there is not much correlation [...]

33. Page 16, Line 4: 'obviously have' instead of 'have obviously'

Author's response: Thank you for the correction.

Modifications: [...] hypotheses [...] obviously have their limitations.

34. Page 17, Line 18: Hu et al., 2007 (doi:10.1109/LGRS.2007.901085) suggests that DRM_{Hu} would likely fail in these cases; e.g., see figure 3 in the region below 39°

Author's response: We took your contribution into account.

Modifications: [...] to the surface contribution. Hu et al., (2007a) noticed the surface impact on DRM_{Hu} when the underlying cloud is not entirely opaque, therefore the assumptions used in the DRM_{Hu} AOT retrievals are not met.

35. Page 17, Line 29: this “calibration” implicitly assumes that the multiple scattering characteristics of all water clouds are essentially identical. I'd be happier if more evidence was offered to support this assumption.

Author's response: We hope that the explanations we offered for comment question 16, Page 9, Line 23 clarify this calibration procedure.

Modifications: No modifications have been made to the text.

36. Page 19, Line 21: See my earlier comment on page 10, line 24. Assuming I properly understand how you distinguish between attached and detached cases, I suspect that the primary difference between attached and detached layers lies in (a) the above-cloud aerosol loading combined with (b) the above-cloud lidar ratio. For high aerosol loading, the CALIOP layer detection scheme is much more successful at identifying the full vertical extent of an aerosol layer when the aerosol lidar ratio is low. The high loading plus high lidar ratio cases (e.g., dense smoke or pollution) are the most difficult cases, because the attenuation within the layer drives the magnitude of the (uncorrected!) attenuated scattering ratios below 1.00, and hence below the layer detection threshold. This in turn leads to the premature identification of layer base. (To do: insert comparison of 532 nm and 1064 nm attenuated backscatter or attenuated scattering ratio profiles to illustrate the point...)

Author's response: The primary difference between the attached and detached cases lies in the detected CALIOP aerosol base altitude. Therefore, in case of high aerosol loading above-cloud and a high aerosol lidar ratio, the base of the aerosol layer can be misidentified. This can lead to cases of contact within our “detached” class.

Figure 3.SC presents the attenuated backscatter profiles for 1064 nm and 532 nm for the three case studies presented in the article. We can observe larger geometrical thickness of the aerosol layers situated above the clouds for Namibian biomass burning, when retrieved at 1064 nm. Also, the aerosol layer appears mostly detached from the underlying cloud at 532 nm, while at 1064 nm we notice more contact area. Nonetheless, for this particular Namibian biomass-burning case of 13 August 2006, we have a very good agreement between DRM and POLDER (see Table 1 in the manuscript). The Saharan desert dust and the Siberian biomass-burning cases present small differences of backscatter profile between the 532 nm and 1064 nm.

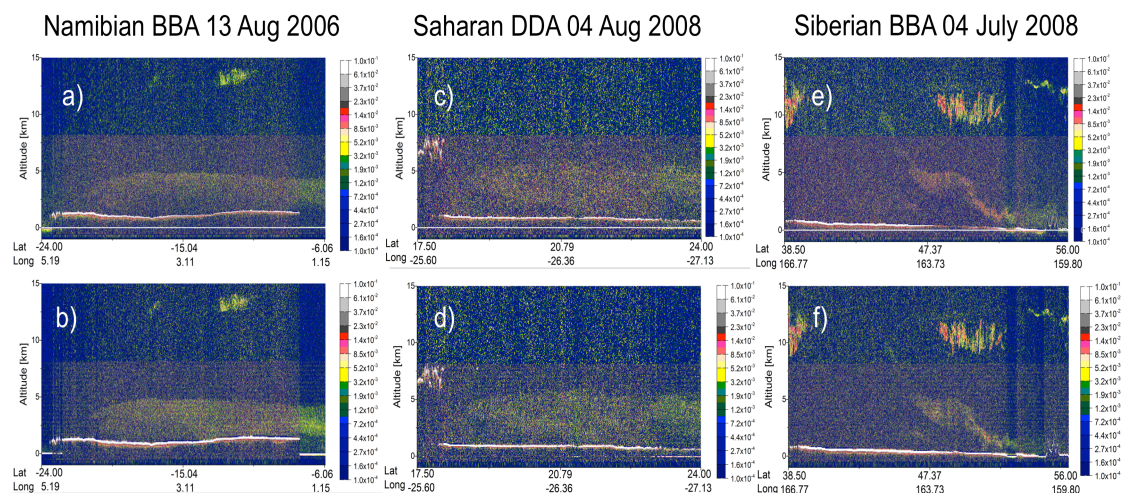

Figure 3.SC: The first row of the panel shows the CALIOP attenuated backscatter coefficients at 532 nm, while the second row presents the CALIOP attenuated backscatter coefficients at 1064 nm for three case studies: a), b)

African Biomass-burning (BBA) aerosols above clouds on 13 August 2006; c), d) Saharan dust (DDA) on 4 August 2008 and e), f) Siberian biomass-burning aerosols over the Okhotsk Sea on 3 July 2008.

Modifications: Figure 1 from the manuscript was modified in order to include the CALIOP attenuated backscatter coefficients at 1064 nm.

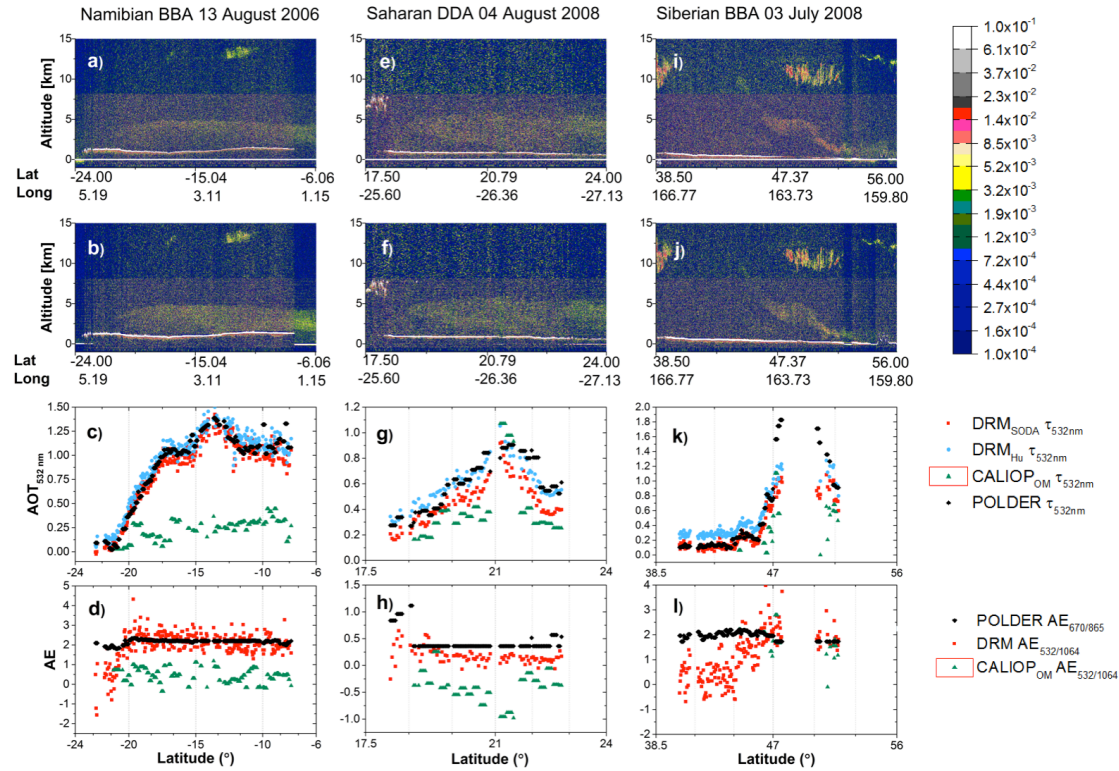

Figure 1: The first row of the panel shows the lidar CALIOP attenuated backscatter coefficients at 532 nm (km⁻¹ sr⁻¹) and the second row presents the CALIOP attenuated backscatter coefficients at 1064 nm for three case studies: African biomass-burning (BBA) aerosols above clouds on 13 August 2006 ((a), (b), (c), (d)), Saharan dust (DDA) on 4 August 2008 ((e), (f), (g), (h)) and Siberian biomass-burning aerosols over the Okhotsk Sea on 3 July 2008 ((i), (j), (k), (l)). For these cases, the above-cloud AOT at 532 nm and the Ångström exponent (AE) as a function of latitude, measured with several techniques are displayed.

Page 12, Line 16-18: According to the CALIOP vertical profile at 532 nm of the biomass-burning case (Fig. 1a), the cloud top is at around 1.5 km and the aerosol layer is located between 3 and 5 km. The 1064 nm backscatter profile (Fig. 1b) exhibits an aerosol layer with a larger vertical extent, showing up more potential contact area with the underlying cloud.

37. Page 34, Line 1, Fig. 1: attenuated backscatter coefficients

Author's response: Thank you for the correction.

Modifications: lidar CALIOP attenuated backscatter coefficients at 532 nm

38. Page 42, Fig. 9: it would be helpful to add another line showing molecular attenuated backscatter coefficients

Author's response: Figure 4.SC. presents the molecular attenuated backscatter, along with mean values of total attenuated backscatter for the attached and detached cases.

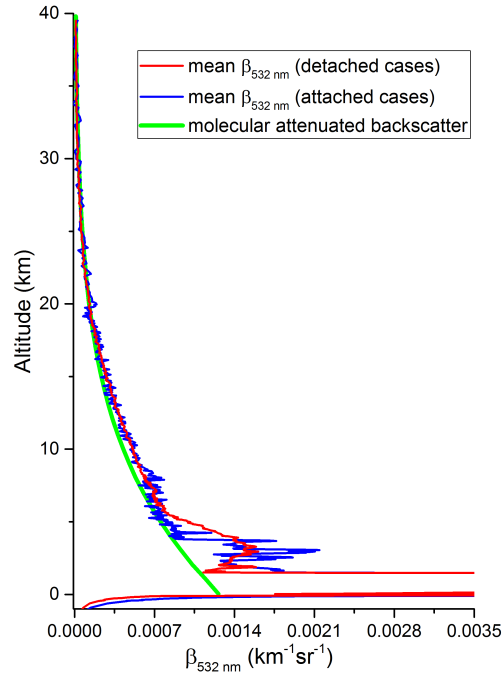

Figure 4.SC. Molecular attenuated backscatter and mean total attenuated backscatter for attached and detached cases, for global measurements from 2006 to 2010.

Modifications: We modified Figure 9 in the manuscript. See question below.

39. Page 42, Fig. 9: for both attached and detached cases, the surface is clearly visible in both the median and mean plots, suggesting strongly that the clouds selected were not 100% opaque

Author's response: Thank you for this observation. The explanation for the surface signal is related to the CALTRACK product. Starting from CALTRACK 5 km with POLDER and DRM valid AOT retrievals, we searched for the corresponding CALIOP 333 m backscatter profiles. The different resolutions of the methods could justify the detected surface signal at 333 m resolution, as fractioned/ heterogeneous cloud covers could not be detected under the aggregated MODIS resolution aggregated at 6x6 km² as used in the CALTRACK files. We also pointed out in the manuscript (Page 17, Line 18) that POLDER method and DRM are potentially less accurate for COT < 5 as the algorithm requirements are not met.

As an attempt to rectify the drawback of this procedure we filtered the MODIS COT lower than 5 and then recomputed the median and mean of the backscatter coefficients on a global scale, between 2006 and 2010. As we can observe in Figure 5.SC, the surface signal has been eliminated in the majority of the situations. Nonetheless, there are still cases that can't be filtered just by eliminating all the data with a COT smaller than 5.

Modifications: We modified Figure 9 in the manuscript:

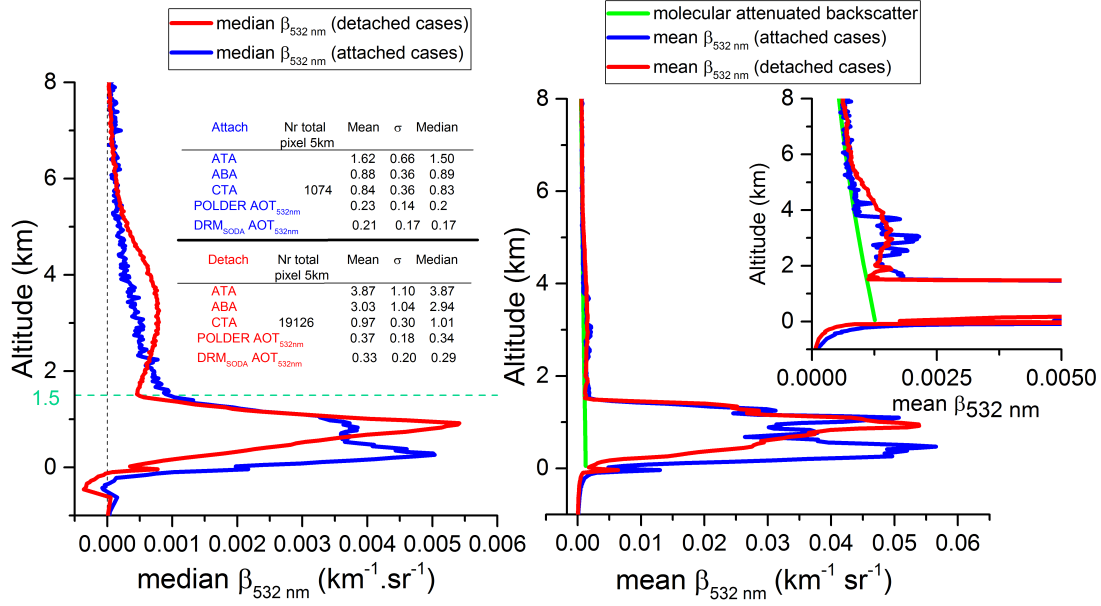

Figure 9. Median (a) and averaged (b) backscatter profiles (km⁻¹ sr⁻¹) for aerosol layer detached from the cloud layer (red) and aerosols attached to the top of the cloud (blue), for a period of 4.5 years on the global scale. For comparison, the molecular attenuated backscatter profile is shown in green line. The data was filtered for a cloud top altitude lower than 1.5 km, a cloud optical thickness COT larger than 5 and for a DRM_{SODA} AOT at 532 nm is larger than 0.1. The number of 5 km horizontal resolution pixels is also shown. The mean, standard deviation (σ) and median of aerosol top altitude (ATA), aerosol base altitude (ABA) and cloud top altitude (CTA) are given for each situation. Same values are shown for POLDER AOT at and DRM_{SODA} AOT at 532 nm.

Page 19, Line 2: We only select the attached and detached cases where the cloud top altitude is below 1.5 km, the COT is larger than 5 and the DRM_{SODA} AOT_{532nm} is larger than 0.1.
