

23

24 **Abstract**

25 Glass transitions from liquid to semi-solid and solid phase states have important implications for
26 reactivity, growth, and cloud forming (cloud condensation nuclei and ice nucleation) capabilities
27 of secondary organic aerosols (SOA). The small size and relatively low mass concentration of
28 SOA in the atmosphere make it difficult to measure atmospheric SOA glass transitions using
29 conventional methods. To circumvent these difficulties, we have adapted a new technique for
30 measuring glass forming properties of atmospherically relevant organic aerosols. Aerosol
31 particles to be studied are deposited in the form of a thin film onto an interdigitated electrode
32 (IDE) using electrostatic precipitation. Dielectric spectroscopy provides dipole relaxation rates
33 for organic aerosols as a function of temperature (373 to 233K) that are used to calculate the
34 glass transition temperatures for several cooling rates. IDE-enabled broadband dielectric
35 spectroscopy (BDS) was successfully used to measure the kinetically controlled glass transition
36 temperatures of glycerol and citric acid aerosols with selected cooling rates. The glass transition
37 results agree well with available literature data for these two compounds. The results indicate
38 that the IDE-BDS method can provide accurate glass transition data for organic aerosols under
39 atmospheric conditions. The BDS data obtained with the IDE-BDS technique can be used to
40 characterize glass transitions for both simulated and ambient organic aerosols and to model their
41 climate effects.

45 Interdigitated Electrodes Thin Films Aerosol Climate Effects

46 **1 Introduction**

47 Aerosol particles have important climate and health effects because they can scatter
48 sunlight, form clouds by acting as the cloud condensation nuclei (CCN), alter visibility, and
49 affect human health (Hallquist et al., 2009; Jimenez et al., 2009). Recent studies have confirmed
50 that organic aerosols, which comprise approximately half of the total submicron aerosol mass in
51 the atmosphere, can change from liquid to glassy state at ambient humidity levels and
52 temperatures (Zobrist et al., 2008; Virtanen et al., 2010; Zhang et al., 2015). The effect of
53 temperature may be especially important when aerosol particles are lifted into the free
54 troposphere, where the temperature change can rapidly alter their phase from liquid to glass
55 (Koop et al., 2011). The physical state of the aerosol strongly influences air quality and aerosol
56 climate effects. Evidence suggests that secondary organic aerosols, formed through oxidation of
57 gas phase organic compounds, have much lower vaporization rates than previously assumed,
58 which changes the reactivity of the gas phase species as well as their fate in the atmosphere. For
59 example, in the glassy state, the water vapor uptake by the SOA is greatly reduced, limiting the
60 ability of particles to nucleate liquid water and thus hampering the formation of liquid cloud
61 droplets (Shiraiwa et al., 2011). However, there is evidence that glassy SOAs are effective ice
62 nucleation agents. Their ability to nucleate ice crystals to form Cirrus clouds in the upper
63 troposphere may be particularly important given the key role of these clouds in global warming
64 (Wilson et al., 2012; Berkemeier et al., 2014). Lack of adequate data describing these processes
65 contribute to the high uncertainty of atmospheric aerosol impact on climate change (Shiraiwa et
66 al., 2017).

67 The importance of organic aerosols phase state in the evaluation of their climate effects
68 has motivated several studies in this field. However, these studies are difficult to perform and the

69 data obtained so far are limited. Renbaum-Wolff et al. (2013) studied the phase state and
70 viscosity of the water-soluble part of α -pinene SOA at several humidity levels and phase
71 separation effects. Zhang et al. (2015) characterized the viscosity of α -pinene SOA across a wide
72 range of RHs. Rothfuss and Petters (2017) studied the viscosities of various types of SOAs up to
73 10^6 Pa under sub-freezing temperature regimes. There have also been a few studies exploring the
74 glass transition temperature of atmospherically relevant organic compounds by using differential
75 scanning calorimetry (Koop et al., 2011; Dette et al., 2014).

76 Despite past studies, very little information is available on how organic aerosols become
77 glass as temperature, the rate of cooling, and heating changes. Such information is required to
78 model the aerosol phase when aerosols are transported from one region of the atmosphere to
79 another (Murray et al., 2010; Wilson et al., 2012). In an early 2011 study Koop and co-workers
80 performed experiments that led them to estimate glass transition temperature (T_g) values of 268-
81 290K for a range of surrogate biogenic SOA compounds by utilizing the differential scanning
82 calorimetry (DSC) method. The results show that oxidation and/or oligomerization reactions
83 leading to higher oxygen to carbon ratios (O:C), yielded higher T_g values. Dette et al. (2014)
84 used the “metastable aerosol by the low temperature evaporation of solvent” (MARBLES)
85 technique to provide information on the glass-to liquid transition temperatures of pure organic
86 compounds and organic-inorganic binary mixtures. Their results show that the glass transition
87 temperatures of these mixtures can be accurately described by the Gordon-Taylor equation, the
88 equation describing the glass transition of binary mixtures. However, to evaluate the impact of
89 SOA and its possible phase transitions on climate and air quality issues, the current techniques
90 need to be improved in order to adapt to the atmospheric aerosol sampling requirements.

91 The small particle size and relatively low concentration of SOA in the atmosphere make

92 it difficult to measure atmospheric SOA glass transitions using conventional methods. First, a
93 reliable measurement of glass transitions with currently used techniques requires a relatively
94 large mass, typically milligram levels of the compound, while reasonable field collection
95 methods yield organic aerosols in the femtogram mass range (Dette et al., 2014; Dette and Koop,
96 2015). Second, it is difficult to collect suspended aerosols and transfer them to the analysis
97 apparatus without contaminating the sample with trace water. Trace amounts of water absorbed
98 by SOA can substantially alter glass transition properties (Bateman et al., 2015; Price et al.,
99 2015; Rothfuss and Petters, 2017; Shiraiwa et al., 2017). To circumvent these difficulties, we
100 have adapted a new technique for measuring glass forming properties of atmospherically relevant
101 organic compounds. The technique combines broadband dielectric spectroscopy (BDS) utilizing
102 interdigitated electrodes (IDE) (Chen et al., 2012) with organic aerosol sample deposition using
103 electrostatic precipitation (Liu et al., 2013).

104 BDS is one of the most widely used techniques for measuring the dynamics and glass
105 transition of liquid and semi-solids (Dette et al., 2014; Richert, 2014). In the usual arrangement,
106 dielectric spectroscopy instruments consist of two parallel metallic plates with the sample filling
107 the space between the plates. As was stated, the traditional dielectric method usually requires
108 mass in the milligram range to perform the measurement (Richert, 2014). Such high mass
109 loading cannot be reasonably attained with aerosol collected under normal atmospheric
110 conditions. A relatively new technique, using interdigitated electrodes (IDE), which requires
111 only one surface for samples and requires mass only in the femtogram range (Chen et al., 2012),
112 is suitable for atmospheric aerosol phase studies. A thin film is deposited on the IDE first, then
113 the dielectric spectra are recorded to characterize the glass transition of aerosol particles at
114 variable cooling or heating rates.

115 The purpose of this study is to demonstrate the new IDE-BDS analysis technique by
116 presenting results of SOA surrogates glass transition studies using this technique. In section 2
117 below, we first describe the experimental setup including aerosol generation, thin film deposition
118 on the IDE, temperature conditioning chamber, and the BDS measurement system. Then data
119 analysis, including glass transition determination, is discussed in section 3. Section 4 includes
120 discussion of the advantages of the IDE-BDS method, as well as caveats associated with its
121 current implementation.

122 **2. Experimental Setup**

123 A schematic diagram of the experimental setup is shown in Figure 1. The setup is
124 conveniently divided into four parts: 1. Aerosol sample generation, 2. Thin film formation via
125 electrostatic precipitation on the Interdigitated electrodes (IDE) with associated humidity control
126 3. Temperature conditioning chamber and 4. Broadband Dielectric Spectroscopy measurement
127 system.

128 **2.1 Aerosol generation.**

129 Two types of aerosol generation systems are used in our experiments. The first is a home-
130 made self-nucleation generation device used for producing liquid glycerol aerosol samples.
131 About 0.5 gram of the glycerol is placed at the bottom of a round flask and the temperature of the
132 flask is heated to 20°C below the boiling temperature of the organic liquid. A condenser is
133 connected to the top of the flask to cool the temperature of that region. A flow of 2 liters per
134 minute (Lpm) flow dry air passes through the condenser and brings the aerosol particles to the
135 region where the aerosols are precipitated onto the IDE.

136 The second method utilizes a commercial unit (TSI, 3076) to generate atomized citric
137 acid aerosols. About 0.5 gram of citric acid is dissolved in 100 mL of high purity water to form

138 the atomizing solution. About 30 psi pressure of dry air is applied on one end of the atomizer to
139 generate a constant 3 Lpm aerosol-containing flow to the second part of the system, which is the
140 thin film generation system that will be described below.

141 **2.2 Interdigitated electrode (IDE) and thin film formation.**

142 An IDE (NIB003744, MS-01/60, NETZSCH Instrument North America) is used in this
143 study as a substrate for measuring the dielectric constants of organic materials. The IDE consists
144 of two thin electrodes that are interdigitated together like entwined finger tips, as shown in
145 Figure 2. Each interdigitated pair serves as a small capacitor for dielectric analysis. The thin
146 electrodes are made from platinum (Pt) and are arrayed on a quartz substrate. The electrodes
147 utilized in this study are spaced 1 μm apart and are able to withstand temperatures up to 200 $^{\circ}\text{C}$.
148 The combination of multiple interdigitated pairs of electrodes greatly enhances the sensitivity of
149 the technique compared to a single pair of electrodes that would have been used.

150 An electrostatic deposition method is used to deposit organic films on the IDE (Liu et al.,
151 2013). The electrostatic precipitator has one inlet and one outlet. A stream of aerosolized
152 oxygenated organic liquid droplets to be studied is passed through an inlet with a high voltage
153 corona discharger (-5000V) so that all the droplets are negatively charged to varying degrees.
154 The flow is directed above the substrate held at +3000 V within the precipitator. Due to opposite
155 charges, the charged particles are electrostatically deposited onto the substrate, gradually
156 merging together to form thin films. The remaining flow is then withdrawn from the precipitator
157 and flows through a HEPA filter connected to a pump. The flow rate through the precipitator is
158 maintained between 1.7-1.9 Lpm. Depending on the amount of aerosols being deposited onto the
159 surface, the deposition can remain either remain as discrete aerosol droplets, or at higher droplet
160 depositions, can form a uniform thin film, as shown in Figure 2.

161 **2.3 Temperature conditioning chamber.**

162 The IDE substrate coated with organic material is then transported to the temperature
163 conditioning chamber using a tweezer. The temperature conditioning chamber consists of a
164 stainless steel cap and a heating/cooling surface using either a liquid nitrogen cooler or a heating
165 furnace. The sample temperature can be controlled from $\sim -150^{\circ}\text{C}$ to $+200^{\circ}\text{C}$. Details of the
166 chamber are shown in Figure 1. The cooling rate can be varied from 1 K/min to 25 K/min. The
167 chamber is flushed with dry nitrogen gas to reduce the relative humidity (RH) prior to
168 temperature conditioning. A K type thermocouple is located on top of a reference cell inside the
169 conditioning chamber, to monitor sample temperature. The typical cooling cycle starts around 20
170 $^{\circ}\text{C}$ and ends at about -140°C , while the heating cycle starts at -140°C and ends at 30°C . The
171 cooling and heating cycle are adjusted with the desired cooling/heating rates between 2 K/min
172 and 10 K/min.

173 **2.4 Broadband Dielectric Spectroscopy (BDS) measurement system.**

174 The BDS instrument used in this study is manufactured by NETZSCH Inc. (DEA 288
175 model). A periodic signal from the instrument is applied to the IDE electrodes. The frequency of
176 the signal ranges from 10^{-3} Hz to 1 MHz. The data acquisition part of the instrument then
177 measures the impedance, Z_{sample} , of the sample as a function of the applied frequency. The
178 impedance measurement yields the capacitance of the sample on top of the IDE. By measuring
179 the impedance of the uncoated and organic-coated IDE, three IDE capacitances can be obtained,
180 i.e., when the IDE is uncoated Z_{empty} , when it is coated with organic compounds, Z_{coated} , and the
181 geometric capacitance of the IDE without any substrate, Z_{geo} . Approximate values of the real and
182 imaginary part of the sample permittivity, ϵ_{sample} , can be obtained using Eq. (1) (Chen et al.,
183 2012)

$$184 \quad \varepsilon_{sample} = 1 + \frac{Z_{loaded} - Z_{empty}}{Z_{geo}} \quad (1)$$

185 For demonstration and data comparison purposes, we have used glycerol (99%, Sigma
 186 Aldrich, St. Louis, MO, USA) as the test compound for homogeneous nucleation and citric acid
 187 (99%, Sigma Aldrich, St. Louis, MO, USA) as the surrogate organic aerosol generated by
 188 atomizing solutions. For atomizing solutions, the surrogate compound is mixed with high purity
 189 water. All reagents were used as provided without further purification.

190 3. Data Analysis

191 3.1 Calculating Relaxation Time τ

192 The thin film on the IDE is usually cooled at a selected cooling rate and then heated back to 30
 193 °C. After a cooling-heating cycle, the dielectric constant at each temperature measured, $\varepsilon(\omega)$, is
 194 recorded by instrument. The relaxation time, τ , can be obtained by curve fitting the Havriliak-
 195 Negami equation of the real and imaginary parts ($\varepsilon'(\omega)$ and $\varepsilon''(\omega)$, respectively) with the
 196 frequency ω , as shown in Figure 3 and S1 (Chen et al., 2012). The detailed equation of $\varepsilon'(\omega)$
 197 and $\varepsilon''(\omega)$ are shown in Eqns. (S1) and (2). At each temperature, the dielectric spectra often
 198 show peaks at specific frequencies, designated as dielectric relaxation peaks. Different peaks
 199 give different τ values after fitting Eq. (2) into the data points.

$$200 \quad \varepsilon''(\omega) = \Delta\varepsilon \left(1 + 2(\omega\tau)^\alpha \cos\left(\frac{\pi\alpha}{2}\right) + (\omega\tau)^{2\alpha} \right)^{-\beta/2} \sin(\beta\varphi) \quad (2)$$

$$201 \quad \text{with } \Delta\varepsilon = \varepsilon_s - \varepsilon_\infty, \quad \varphi = \arctan\left(\frac{(\omega\tau)^\alpha \sin\left(\frac{\pi\alpha}{2}\right)}{1 + (\omega\tau)^\alpha \cos\left(\frac{\pi\alpha}{2}\right)}\right)$$

202 where ε_s is the permittivity at lower frequency, ε_∞ is the permittivity at the high frequency limit,
 203 α, β are fitting parameters, and τ is the characteristic relaxation time of the medium
 204 (Adrjanowicz et al., 2009; Chen et al., 2012).

205 Log τ is then plotted as a function of the invert of the temperature to further examine how
206 relaxation time changes as a function of temperature. The error bar represents twice the standard
207 deviation of the fitting result. The resulting curve can be used to calculate the glass transition
208 temperature of the compound, as described in section 3.2.

209 **3.2 Glass Transition Determination**

210 The glass transition temperature is defined as the temperature where a compound changes
211 from liquid to glass. Several methods have been used to indirectly determine the glass transition
212 temperatures. A common way to calculate the glass transition temperature using BDS is to
213 measure relevant parameters and to calculate the dielectric relaxation τ described in section 3.1
214 at several equilibrium temperatures T , and then plot $\log \tau$ as a function of $1000/T$. The data points
215 are fitted by using Vogel-Fulcher-Tammann (VFT) formula (Vogel, 1921; Fulcher, 1925;
216 Tammann and Hesse, 1926). The glass transition is customarily defined as the temperature where
217 $\tau = 100$ s in the fitted curve (Chen et al., 2012; Richert, 2014). The result usually agrees with the
218 differential scanning calorimetry (DSC) measurement within a few degrees (Richert, 2014).
219 However the method is limited, because not all compounds become glass as $\tau = 100$ s.
220 Furthermore, this method does not take into account kinetic effects on glass transition,
221 specifically the effect of cooling and heating rates (Elmatad et al., 2009, 2010; Keys et al., 2013;
222 Limmer and Chandler, 2014; Hudson, 2016), as glass transition temperature changes with
223 cooling and heating rates.

224 The following method, used in our studies, takes into account the effect of cooling rate on
225 the glass transition. As a compound is cooled and transitions from a liquid to a supercooled
226 liquid it exhibits super Arrhenius behavior described in Elmatad et al.(2009). As temperature
227 further decreases, the supercooled liquid becomes glass-like, which exhibits Arrhenius behavior.

228 The temperature where the supercooled liquid changes to glass is the glass transition temperature
229 of the compound at the specific cooling rate studied. As the sample is continuously cooled at a
230 specific cooling rate, the dielectric relaxation peaks can be generated as a function of the sample
231 temperature. The experimentally obtained data are plotted in the form $\log \tau$ vs $1/T$. The data
232 obtained at the higher temperature range are fitted to the super-Arrhenius function and the data
233 obtained at the lower temperature range are fitted to the Arrhenius function. As shown in Figure
234 4, the kinetically controlled glass transition temperature (or the true glass transition temperature)
235 is the temperature at the intercept of the two functions. The traditional method determines the
236 glass transition temperature as shown in dashed lines where $\tau = 100$ s. Depending on the
237 compound, the true glass transition temperature may not be the same as the glass transition
238 temperature determined by using $\tau = 100$ s, as shown in section 4 below. The error bar of the
239 glass transition temperature is estimated based on varying the fitting parameters of the super
240 Arrhenius curve and Arrhenius line within a one-sigma range.

241 For glycerol, measurements of glass transitions were performed at three cooling rates: 2
242 K/min, 5 K/min, and 10 K/min. At each cooling rate the compound is cooled from approximately
243 300 K to 125 K, while the dielectric peaks are measured simultaneously as a function of
244 temperature. The organic film is thin enough so that its temperature reaches equilibrium with the
245 cooling/heating medium, reducing the errors caused by heat transfer within the sample itself.
246 Such measurements are difficult to perform with conventional techniques due to slow heat
247 transfer in large mass samples, which often leads to inaccurate results. The effect of cooling rates
248 on glass transition measurements will be discussed in the following section.

249 4 Results and Discussion

250 4.1 Glass transition temperature of selected organic compounds

251 Aerosols are generated by two methods in this study, and in each method, we measured
252 the glass transition of a compound that has been studied in the literature. Glycerol and citric acid
253 particles were generated through the homogeneous nucleation method and atomizer method,
254 respectively. The measured dielectric spectra of glycerol and citric acid show distinct dielectric
255 relaxation rates at different frequencies as the temperature changes. This is a confirmation of the
256 expected behavior.

257 As is shown in Table 1, our kinetically controlled glass transition data agree well with
258 previously measured literature values of glycerol (Zondervan et al., 2007; Chen et al., 2012;
259 Amann-Winkel et al., 2013). For citric acid, our kinetically controlled glass transition result
260 fitted using Eq. (S2) agrees reasonably well (within 10% error) with two literature results (Lu
261 and Zografí, 1997; Bodsworth et al., 2010). The third literature data (Murray, 2008) is based on
262 extrapolation of experimental fitting result and is about 16% lower than the value obtained from
263 this study. The differences can be explained by the following reasons: (1) As described above,
264 our method measured the kinetically controlled glass transition temperature at a given cooling
265 rate, i.e., the transition of the long range intermolecular movements of the sample to determine
266 the glass transition temperature. If the more conventional method, i.e. fitting the super-Arrhenius
267 curve to obtain the glass transition temperature when $\tau=100$ s, is applied to the data, as shown in
268 Figure 5, the obtained glass transition temperature would be 281 ± 3 K, which is within 1%
269 difference compared with the two nearest literature values. Therefore, the difference herein is
270 due to including the kinetically controlled process in glass transition. Based on the theory
271 described by Chandler and co-authors (Elmatad et al., 2009; Keys et al., 2013; Hudson, 2016),

272 we report the citric acid glass transition temperature as 307 ± 5 K at 5 K/min cooling rate, which
273 we believe is a more accurate way of reflecting the glass transition process, as the kinetical
274 process is considered. The relevant data plot is shown in Figure 5. (2) Moreover, glass transition
275 data of citric acid are rather limited and there are differences between each study. For instance,
276 from the literature data, the differences between three reported glass transition temperatures are
277 up to 10%, which is the same value comparing our data to the other two nearest literature results.

278 Even though the reasons listed above are likely to be the primary reasons leading to
279 ~10% difference of the glass transition temperature of citric acid between our data and the
280 literature, the following factors may play a role: (1) Atomizing the citric acid solution and re-
281 depositing citric particles via electrostatic precipitation could introduce impurities during the
282 atomization process the may affect the glass transition temperatures; (2) The glass transition of
283 citric acid was measured during a warming cycle. A fast non-recordable cooling cycle at
284 20K/min was performed prior to warming in order to inhibit the citric acid crystal formation. The
285 hysteresis effect will lead to an increase of the glass transition temperature from the warming
286 cycle compared with data obtained from the cooling cycle (Wang et al., 2011); (3) Lu and
287 Zogrfaï (1997) have shown that different ways of preparing the citric acid can lead to differences
288 in glass transition measurements. The thicknesses of the thin films are equal to or less than one
289 micrometer, leading to confinement effects and differences in glass transition temperature
290 measured from bulk compounds (Park and McKenna, 2000). The results show that the thin film
291 IDE-BDS method can accurately measure the glass transition temperatures of various organic
292 compounds that are comparable to the composition of organic aerosols.

293 4.2 The influence of cooling rates on glass transition temperatures

294 One advantage of this study is the introduction of cooling and heating rates as variables
295 for glass transition temperature measurement for organic compounds. For BDS studies, a glass
296 transition temperature of a compound is often deduced by measuring the sample at a few
297 isothermal temperatures and fitting the curve of temperature and relaxation time in order to
298 identify the temperature when relaxation time corresponds to 100 s. The transitional approach
299 makes it difficult to directly compare the result with glass transition temperatures deduced from
300 DSC studies with variable cooling rates. One of the advantages of our technique is that variable
301 cooling rate measurements are performed on the thin film and the cooling rate dependent glass
302 transition temperature of glycerol is determined.

303 The influence of cooling rate on glass transition temperature was carefully examined by
304 repeating the glycerol experiment at two additional cooling rates. The resulting super Arrhenius
305 curve for each cooling rate is plotted against the Arrhenius lines of that cooling rate, as shown in
306 Figure 6. As a compound remains in the supercooled liquid stage, the relaxation time is short
307 enough that it is constantly in equilibrium with external perturbations, leading the super-
308 Arrhenius region totally reversible so it should behave the same for all cooling rates. The super
309 Arrhenius part of the data from all three different cooling rates all collapse into one single trend,
310 indicating the data collected agree well with the theory. Reference data from Elmatad et al.
311 (2009) is also plotted as the black dash line and it also agrees well with our experimental results.
312 As the cooling continues, the relaxation time gets longer until it cannot keep up with the external
313 temperature change, leading to the compound falling out equilibrium and forming a glass.
314 Therefore, a faster cooling rate often leads to a quick falling out of equilibrium and a higher glass
315 transition temperature for the compounds studied, as demonstrated in Figure 6. Based on the

316 intercept of the super-Arrhenius curve and the Arrhenius line, the glass transition temperatures
317 for 5 K/min and 10 K/min cooling are determined to be 192 ± 2 K and 194 ± 2 K. For 2 K/min
318 cooling, because an Arrhenius line does not appear within our range of measurement, the glass
319 transition temperature will likely be lower than 189 K.

320 Our results agree reasonably well with other studies for the glass transition temperatures
321 of glycerol and citric acid. However, there are a couple possible caveats for this study. One is
322 the influence of humidity during the cooling process. Even though dry nitrogen is used to flush
323 through the cooling chamber to remove any extra water vapor present prior to cooling, there is
324 still the possibility that the chamber wall surface can degas and release water vapor to the system
325 during the cooling process. The effect of water vapor on the testing materials is likely to be small,
326 but should be considered when the organic compound tested can readily absorb water at low RH
327 conditions. The other potential caveat is the influence of non-equilibrium heat transfer within the
328 thin film on glass transition temperature measurement. Because the sample is being cooled from
329 underneath, the heat transfer between the upper and lower boundaries of the film can lead to
330 uncertainties of the glass transition temperature. The organic thin films made during the
331 experiments are within the micrometer range, therefore the thermal gradient between is small
332 enough to be likely insignificant compared with other systematic errors. Moreover, theoretical
333 models to predict the glass transition of compounds with variable cooling rates are needed in
334 further studies to verify and explain these experimental measurements.

335 **5 Summary**

336 In this work, we have demonstrated a novel method using interdigitated electrodes,
337 broadband dielectric spectroscopy, and electrostatic precipitation together as an efficient and
338 powerful approach studying the phase and glass transitions of organic particles under various

339 cooling rates. The method is particularly suitable for studying the glass transition of submicron
340 organic particles whose mass loading is generally too small for other kinds of glass transition
341 measurement techniques. The results from this technique agree well with published studies using
342 other methods. Future publications will report glass transition measurements for simulated SOA
343 mixtures as well as laboratory produced SOA particles.

344 The dielectric relaxation peaks of glycerol and citric acid were recorded and the
345 logarithm of characteristic relaxation time were calculated and plotted as a function of inverse
346 temperature. The super Arrhenius and Arrhenius fittings were used to determine the temperature
347 where the super-cooled liquid fell out of equilibrium to become glass, which is defined at the
348 experimental true glass transition temperature. Furthermore, cooling rates are demonstrated to
349 have an effect on the glass transition temperature. By changing the cooling rate from 2 K/min to
350 10 K/min, the glass transition temperature increases by at least 5 K for glycerol.

Table 1. Glass transition temperatures for glycerol and citric acid measured by broadband dielectric spectroscopy with thin film interdigitated electrode array

Compound	Chemical Formula	T_g (K)-Measured	T_g (K)-Literature
Glycerol	C ₃ H ₈ O ₃	<189 K (2 K/min)	190 K (Zondervan et al., 2007)
		192 ± 2 K (5 K/min)	191 K (Chen et al., 2012)
		194 ± 2 K (10 K/min)	196 K (Amann-Winkel et al., 2013)
Citric Acid	C ₆ H ₈ O ₇		281 ± 5 K (Bodsworth et al., 2010)*
		307 ± 5 K (5 K/min)	285 ± 0.2 K (Lu and Zograf, 1997)
			260 ± 10 K (Murray, 2008)**

* The data was based on modeling result. ** The data was based on fitting extrapolation result.

List of Figures

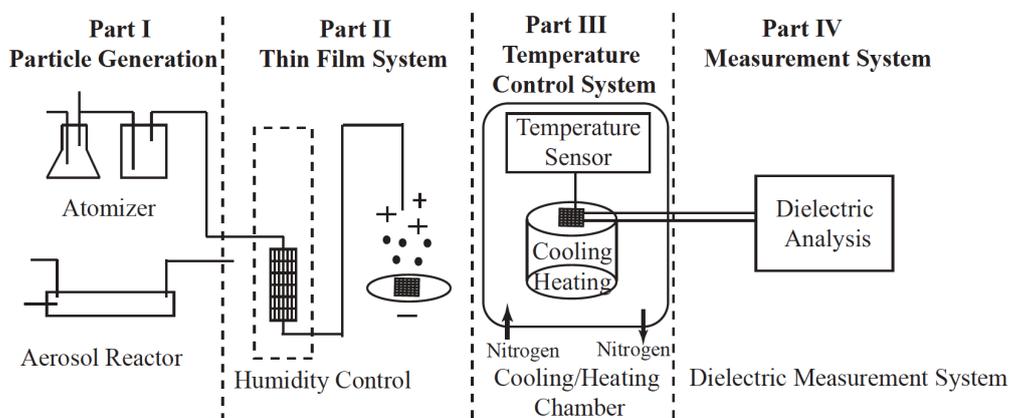

Figure 1. A schematic diagram of the experimental setup and procedure. The experimental approach consists of four parts: aerosol generation, thin film deposition using an electrostatic precipitator, the temperature control system, and the broadband dielectric spectroscopy measurement system.

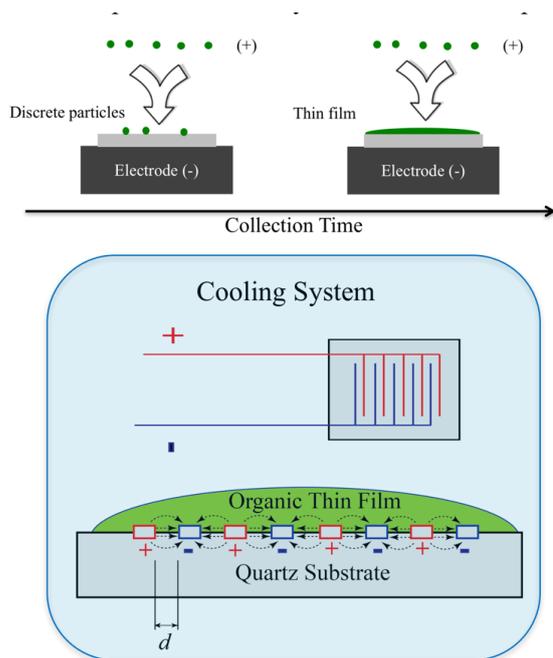

Figure 2. A schematic diagram of the key experimental setup. The upper panel shows the formation of organic thin films through electrostatic deposition. The lower panel shows the working principle of broadband dielectric spectroscopy (BDS) with an interdigitated electrode sensor. A compound is placed on an array of interdigitated electrodes with a periodic voltage, and the compound's impedance is recorded.

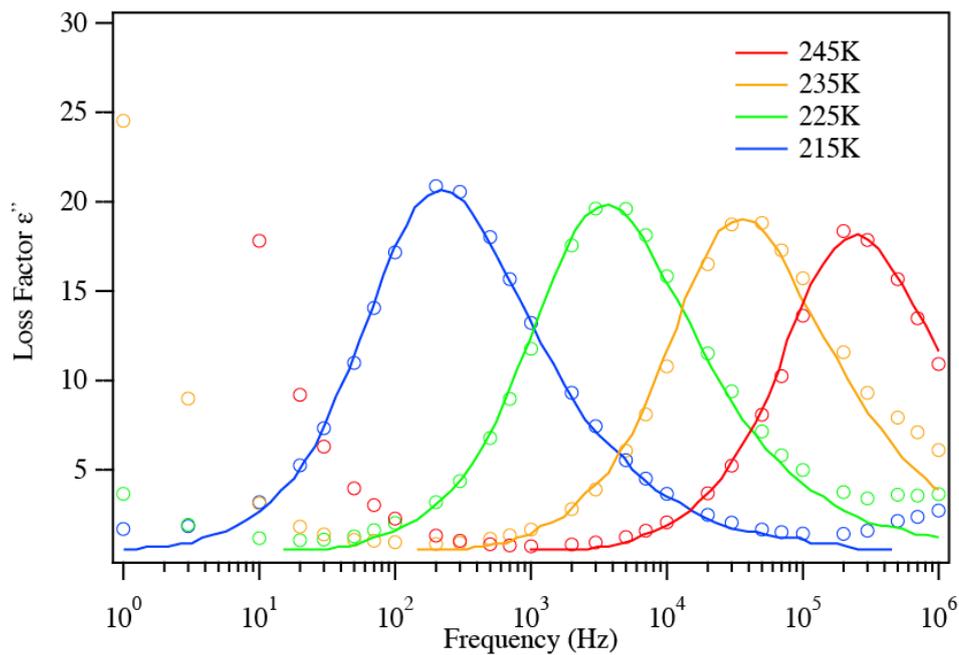

Figure 3. The dielectric relaxation spectrum of glycerol at different temperatures. The open circles are measurement experimental data and the solid lines are literature data from Chen et al. (2012). As temperature decreases, the dielectric peaks shift towards lower frequencies, indicating the relaxation timescale increases.

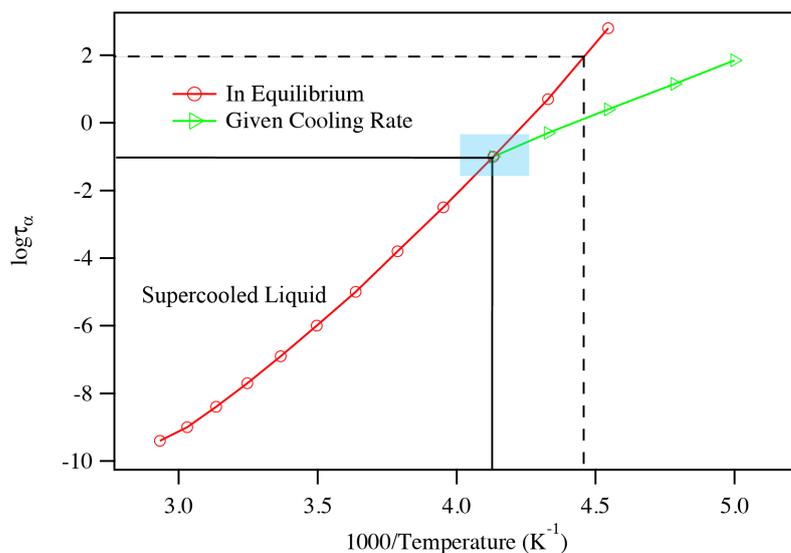

Figure 4. The logarithm of the relaxation is plotted against inverse T, i.e., $\log \tau$ vs $1000/T$. By linking the data points together, one can plot the super-Arrhenius curve (red) vs. the Arrhenius line (green). Using a consistent cooling rate, the intersection of the two regions identifies the compound's glass transition temperature, as indicated by the shaded blue region. The intersection of the two black lines represents the glass transition point. The intersection of the two black dashed lines shows the glass transition temperature determined using traditional method when $\tau=100$ s.

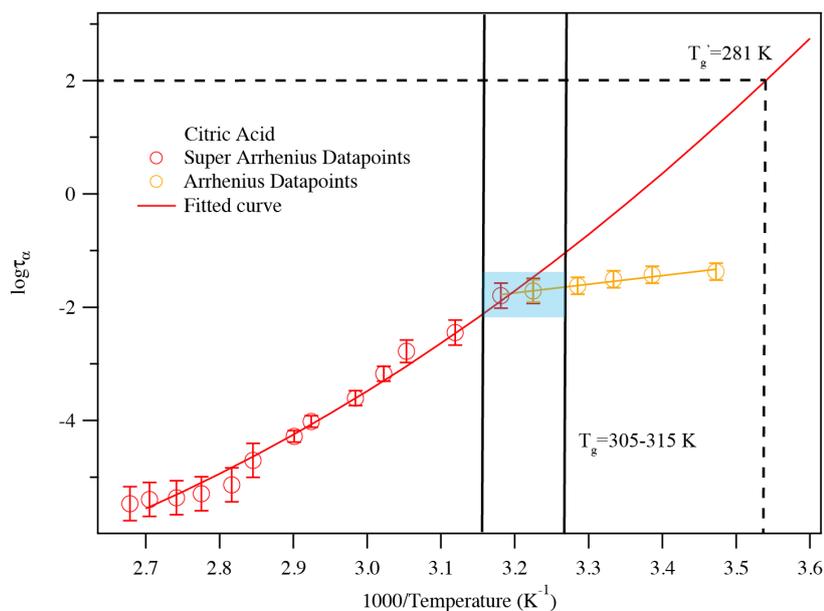

Figure 5. A plot of superimposed datapoints and curves constructed for citric acid warmed at 5K/min. The solid color lines represent the fitted curves for the super Arrhenius and Arrhenius region. The blue shaded area shows the glass transition region. The two vertical black lines associated with the blue shaded area indicate the corresponding temperature range where the super Arrhenius curve intersects with the Arrhenius line. The intersect between the two black dashed lines indicate the glass transition temperature determined using traditional method when $\tau=100$ s.

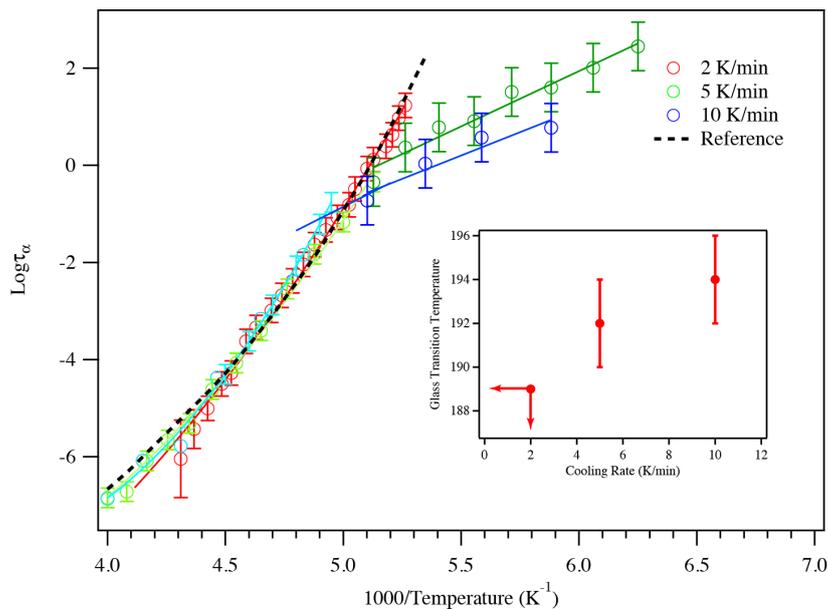

Figure 6. A plot of superimposed datapoints and curves constructed for glycerol cooled at 2K/min, 5K/min, and 10K/min. The black dashed line represents the literature data of the super-Arrhenius region from Elmatad et al. The open circles are experimental data and the solid lines are fitting results. The inset shows the glass transition temperature of glycerol as a function of cooling rates. At 2 K/min cooling, the glass transition temperature has a higher bound of 189 K.
