12 **ABSTRACT**

13 Passive air sampling of gaseous mercury (Hg) requires a high level of accuracy to discriminate  
14 small differences in atmospheric concentrations. Meteorological parameters have the potential  
15 to decrease this accuracy by impacting the sampling rate (*SR*), i.e., the volume of air that is  
16 effectively stripped of gaseous mercury per unit of time. We measured the *SR* of a recently  
17 calibrated passive air sampler for gaseous Hg in the laboratory under varying wind speeds  
18 (wind-still – 6 m s<sup>-1</sup>), temperatures (-15 – 35 °C), and relative humidities (44 – 80%). While  
19 relative humidity has no impact on *SR*, *SR* increases slightly with both wind speed (0.003 m<sup>3</sup>  
20 day<sup>-1</sup> increase in *SR* or 2.5% of the previously calibrated *SR* for every m s<sup>-1</sup> increase for wind  
21 speeds > 1 m s<sup>-1</sup>, typical of outdoor deployments) and temperature (0.001 m<sup>3</sup> day<sup>-1</sup> increase in  
22 *SR* or 0.7% for every 1 °C increase). The temperature dependence can be fully explained by the  
23 effect of temperature on the molecular diffusivity of gaseous mercury in air. Although these  
24 effects are relatively small, accuracy can be improved by adjusting *SR*s using measured or  
25 estimated temperature and wind speed data at or near sampling sites. We also assessed the  
26 possibility of reusing Radiello® diffusive barriers previously used in the passive air samplers. The  
27 mean rate of gaseous Hg uptake was not significantly different between new and previously  
28 used diffusive barriers in both lab and outdoor deployments, irrespective of the applied  
29 cleaning procedure. No memory effect from Radiellos® previously deployed in a high Hg  
30 atmosphere was observed. However, a loss in replicate precision for the dirtiest Radiellos® in  
31 the indoor experiment suggests that cleaning is advisable prior to reuse.

## 34 1. INTRODUCTION

35 Fine spatial resolution measurements of atmospheric contaminants are difficult and expensive,  
36 especially at remote locations and in developing countries. By allowing for simultaneous, cost-  
37 effective measurements at a multitude of sites, passive air samplers (PASs) are useful,  
38 complementary monitoring tools in atmospheric science. PASs can be deployed in high  
39 numbers, at sites away from sources of electricity, and in locations where the costs and logistics  
40 of active sampler deployments can be prohibitive (McLagan et al., 2016a). In order for a PAS to  
41 yield volumetric air concentration data, a sampling rate (*SR*), i.e., the volume of air that is  
42 effectively stripped of the contaminant of concern per unit of time, needs to be derived. This is  
43 done either in calibration experiments that deploy the PAS concurrently with reliable active  
44 sampling techniques or theoretically based on an understanding of the processes controlling  
45 mass transfer from atmosphere to PAS sorbent (Armitage et al., 2013; Gustin et al., 2011; Skov  
46 et al., 2007). Any uncertainty and bias in the *SR* is directly propagated to the volumetric air  
47 concentration derived from a PAS. Accordingly, a reliable PAS requires that the impact of  
48 various factors influencing the *SR* is, in order of preference, either eliminated, minimized or  
49 quantifiable and predictable.

50 A common conceptual model of uptake in PASs assumes a stagnant air layer or air-side  
51 boundary layer (ASBL) around the sorbent, through which contaminant transfer occurs solely by  
52 molecular diffusion (McLagan et al., 2016a; Shoeib and Harner, 2002). Wind decreases the  
53 thickness of the ASBL which in turn increases the *SR* (Bartkow et al., 2005; Moeckel et al., 2009;  
54 Pennequin-Cardinal et al., 2005). Diffusive barriers aim to reduce the influence of wind by  
55 standardizing the molecular diffusion distance to the sorbent and thereby ensuring that the  
56 diffusive component of contaminant transfer is the rate limiting step (Huang et al., 2014;  
57 Lozano et al., 2009; McLagan et al., 2016a). For PASs with diffusive barriers the ASBL is shifted  
58 from the outside of the sorbent to the outside of the diffusive barrier (McLagan et al., 2016b).  
59 While a diffusive barrier thus reduces the relative contribution of the ASBL to the overall  
60 diffusion distance, it cannot entirely mitigate *SR* variability caused by wind (Pennequin-Cardinal  
61 et al., 2005; Plaisance et al., 2002; Skov et al., 2007). Protective shields around the sorbent or

62 diffusive barrier are often employed to further reduce the influence of wind by reducing the  
63 face velocities at these surfaces. However, like diffusive barriers, they too are not likely to  
64 completely eliminate the influence of wind on the thickness of the ASBL (Huang et al., 2014).

65 Temperature has the potential to affect *SR* in two ways: (i) changing the rate of gas phase  
66 diffusion of the contaminant due to the temperature dependence of molecular diffusion  
67 coefficients (Armitage et al., 2013; Huang et al., 2014; Lozano et al., 2009); and (ii) shifting the  
68 partitioning equilibria between the sorbent and the gas phase (Armitage et al., 2013; Lozano et  
69 al., 2009; McLagan et al., 2016a). Relative humidity (RH) may affect *SRs* by influencing the  
70 sorptive properties of certain sorbents for target analytes (Huang et al., 2014). Other factors  
71 that may affect the sorption of contaminants to PAS sorbents include passivation of sorbents  
72 (interfering compounds blocking sorbent uptake sites or stripping analytes through reaction)  
73 (Brown et al., 2012; Gustin et al., 2011), degradation of the sorbent over time (Brown et al.,  
74 2011; McLagan et al., 2016a), and uptake of the contaminant to the sampler housing or  
75 diffusive barrier (Gustin et al., 2011; Huang et al., 2014; McLagan et al., 2016a).

76 Mercury is a persistent, bioaccumulative, and toxic contaminant of global concern that has  
77 come under greater international scrutiny with the adoption of the Minamata Convention  
78 (UNEP, 2013). A key stipulation under Article 19 of the convention “Research, Development and  
79 Monitoring” is the requirement of participating parties to improve current monitoring networks  
80 (UNEP, 2013). A PAS for measuring atmospheric Hg could play an important role in this context,  
81 if it can be shown to be suitable for monitoring long-term background concentrations,  
82 concentration gradients in and around Hg sources, and personal exposure levels (McLagan et  
83 al., 2016a). Gaseous elemental Hg (GEM) is generally the dominant form of atmospheric Hg  
84 (typically making up >95%), due to its high atmospheric residence time of ~1 year (Driscoll et  
85 al., 2013; Pirrone et al., 2010; Selin, 2009), especially at sites remote from combustion sources  
86 (McLagan et al., 2016a; Peterson et al., 2009; Rutter et al., 2009). The long atmospheric  
87 residence time of GEM results in fairly uniform background concentrations within each  
88 hemisphere, with much of the global atmosphere having levels within <25% of the hemispheric  
89 average (Gustin et al., 2011). PASs capable of discriminating such small concentration variability

90 require high accuracy and precision, i.e. *SRs* need to be well characterized and repeatable.  
91 Existing *PASs* for gaseous mercury have struggled to achieve the accuracy and precision  
92 necessary for background monitoring due to inadequate detection limits or highly variable *SRs*  
93 (Huang et al., 2014; McLagan et al., 2016a).

94 We recently introduced a *PAS* for gaseous Hg with a precision based uncertainty of  $2 \pm 1\%$  that  
95 uses an activated carbon sorbent and a Radiello® diffusive barrier (McLagan et al., 2016b).  
96 While it is believed that the sampler takes up predominantly GEM, we cannot rule out the  
97 possibility for gaseous oxidized Hg to also pass through the diffusive barrier (McLagan et al.,  
98 2016b). We therefore use the term gaseous Hg to define the target analyte. An earlier  
99 calibration of this *PAS* at one outdoor location yielded a *SR* of  $0.121 \text{ m}^3 \text{ day}^{-1}$  (McLagan et al.,  
100 2016b). Here we report on a series of laboratory experiments that quantified the effect of wind  
101 speed, temperature, and RH on the *SR* of that sampler. We additionally explored the possibility  
102 of reusing the Radiello® diffusive barrier in multiple deployments in order to further reduce the  
103 costs associated with the sampler's use. During deployment, the inside of the Radiello® can  
104 become covered in sorbent dust. It is also possible that atmospheric components, e.g.  
105 atmospheric particulate matter and oxidants, sorb to or react with the diffusive barrier during  
106 deployment. Thus, in addition to meteorological impacts on the *PAS's SR*, we also explored the  
107 effect of prior use and cleaning of the diffusive barrier on the uptake of Hg in the *PAS*.

## 108 2. METHODS

### 109 2.1 Sampler Design

110 The sampler consists of a porous stainless steel mesh cylinder, filled with ~0.7 g of sulphur-  
111 impregnated activated carbon sorbent (HGR-AC; Calgon Carbon Corp.), which is inserted into a  
112 Radiello® radial diffusive body (Sigma Aldrich), which itself is placed inside a polyethylene-  
113 terephthalate protective jar. During deployments the opening of the jar, covered with a  
114 polypropylene (PP) mesh screen, is facing down. After sampling the jar is sealed with a PP cap  
115 and PTFE tape for transport and storage. McLagan et al. (2016b) provide more detail on the *PAS*  
116 design.

## 117 2.2 Study Design

118 2.2.1 *WIND*. PAS in four different configurations were exposed to different wind conditions in  
119 the laboratory at the University of Toronto Scarborough: (1) regular, white Radiello® with  
120 windshield, (2) white Radiello® without windshield, (3) thick-walled, less porous, yellow  
121 Radiello® with windshield, and (4) yellow Radiello® without windshield. Adopting the  
122 experimental setup of Zhang et al. (2013), electronic fans (Delta Electronics Inc., model number:  
123 BFC1212B) were employed to generate wind for each individual sampler. The angle of wind  
124 incidence was always 90°, i.e. we simulated wind that is blowing parallel to the surface. Wind  
125 speeds of 1, 1.5, 2, 3, 4, 5, and 6 m s<sup>-1</sup> were achieved by manipulating the distance between  
126 PASs and fan (see Fig. S1 and Fig. S2). Wind speeds for each individual PAS were measured  
127 every 5 seconds with a hot-wire Anemometer/Thermometer (Traceable®, VWR International)  
128 for five minutes before and five minutes after each deployment. As such, average wind speeds  
129 of individual samplers within each wind speed treatment varied slightly (Fig. 1). “Wind-still”  
130 experiments without fans were performed for comparison (with wind speed assumed to be  
131 0.05 m s<sup>-1</sup>).

132 While experiments with white Radiellos (configuration 1 and 2) generally lasted one week,  
133 additional experiments lasting two, three, and four weeks were performed at selected wind  
134 speeds (3 and 6 m s<sup>-1</sup>). Experiments with yellow Radiellos (configurations 3 and 4) lasted two  
135 weeks (the lower *SR* of yellow Radiello® requires longer deployment times to reach detection  
136 limits) and were only performed at wind speeds of 3 and 6 m s<sup>-1</sup>, as well as without fans.  
137 Additionally, a 3 months uptake experiment under wind-still conditions was performed in order  
138 to obtain a precise *SR* of the PAS with a white Radiello deployed indoors with a protective  
139 shield. Eighteen samplers were deployed at the same time and triplicates were removed after  
140 15, 28, 46, 56, 70 and 84 days. The earlier indoor calibration experiment described in McLagan  
141 et al. (2016b) had been performed without a windshield.

142 Temperature and RH, monitored before, after, and periodically during each individual  
143 experiment, ranged from 21.9 – 24.2 °C and from 32 – 53%. While there was some variation in

144 the gaseous Hg concentration as recorded by the Tekran 2537A between deployments, the  
145 average concentration across all wind experiments was  $1.9 \pm 0.3 \text{ ng m}^{-3}$ .

146 **2.2.2 TEMPERATURE & RELATIVE HUMIDITY.** The regular PAS configuration (configuration 1)  
147 was exposed to eight different combinations of temperature and RH (Table 1) for two weeks  
148 periods in climate controlled walk-in chambers located at the Biotron Facility of Western  
149 University in London, Ontario. Each experiment was replicated five times. Samplers were  
150 attached to metal shelving units near the centre of the chambers where a continuous flow of  
151 air from the outflow of the climate control units of  $1.1 - 2.3 \text{ m s}^{-1}$  was observed using the hot-  
152 wire Anemometer over a two minute period at the completion of each experiment. The  
153 average actively measured gaseous Hg concentration across all temperature and RH  
154 experiments was  $2.2 \pm 0.9 \text{ ng m}^{-3}$ .

155 **Table 1: Combinations of temperature and relative humidity during the eight experiments performed**  
156 **in climate-controlled chambers**

|           |           |         |          |          |          |          |          |          |
|-----------|-----------|---------|----------|----------|----------|----------|----------|----------|
| Temp (°C) | -15.0±0.1 | 5.0±0.0 | 12.5±0.1 | 19.9±0.0 | 20.0±0.1 | 20.0±0.1 | 27.5±0.0 | 35.0±0.0 |
| RH%       | 68±1      | 77±1    | 76±2     | 44±5     | 60±1     | 80±0     | 60±1     | 45±3     |

157

158 **2.2.3 RADIELLO® REUSE.** The potential impacts of sorbent dust accumulation or atmospheric  
159 contamination during prolonged deployment periods on sampling rates and therefore on the  
160 ability to reuse the Radiello® diffusive barriers are unknown. Currently, new diffusive barriers  
161 are used for each deployment. In this experiment, previously used Radiellos® were redeployed  
162 after different cleaning procedures were applied. Six cleaning treatments were applied: *new*  
163 (unused Radiellos®), *uncleaned* (unaltered after previous deployments), *physical* (physical  
164 agitation with funnel brushes and compressed air blow down), *soap* (Citranox® detergent,  
165 cleaning brushes, and deionized water, compressed air blow down, deionized water rinse and  
166 sonication and air drying), *acid* (six hour soak in 20% HNO<sub>3</sub> bath, deionized water rinse,  
167 compressed air blow down, deionized water rinse and sonication and air drying), and *heat-acid*  
168 (six hour soak in 20% HNO<sub>3</sub> bath at 40 °C, deionized water rinse, compressed air blow down,  
169 deionized water rinse and sonication and air drying). Prior to cleaning, diffusive bodies were

170 categorized based on the extent of visible dust coating using a 5 point scale (0 – new, 1 – very  
171 low, 2 – low, 3 – moderate, 4 – high, and 5 – very high). To the extent this was possible with a  
172 limited stock of previously deployed Radiellos<sup>®</sup>, we evenly distributed Radiellos<sup>®</sup> of variable  
173 dust coating among the treatments (see Table S1 for details). We also tested Radiellos<sup>®</sup>  
174 previously deployed in contaminated environments with very high gaseous Hg concentrations  
175 (~100 – 10000 ng m<sup>-3</sup>) to assess whether such deployments led to a memory effect whereby  
176 sorbed Hg is released from the diffusive body during subsequent uses. All samplers from this  
177 *memory* treatment contained moderate dust coating and were not cleaned.

178 Five replicate samplers for each of the 7 treatments were deployed for a period of two weeks in  
179 a laboratory with slightly elevated Hg concentrations (previously measured as ~5-10 ng m<sup>-3</sup>) at  
180 the University of Toronto Scarborough. Additionally, five different replicate samplers for each  
181 of the three treatments *new*, *uncleaned*, and *soap* were exposed for 34 days outdoors on the  
182 campus of the University of Toronto Scarborough (43.78714 °N, 79.19049 °W). In this case, all  
183 previously used Radiellos<sup>®</sup> were heavily dust coated (category 4 or 5, see Table S2 for details).  
184 In both the indoor and outdoor experiment all samplers were deployed concurrently.  
185 Therefore, no active gaseous Hg measurements were necessary and the mass of sorbed Hg  
186 could be directly compared and was used in data analysis.

187 **2.2.4 ACTIVE GASEOUS MERCURY MEASUREMENTS.** A Tekran 2537A (Tekran Instruments Corp.)  
188 was used to measure the gaseous Hg concentrations at 5 min intervals throughout all wind,  
189 temperature and RH experiments. A sampling inlet that combined a 2 m Teflon tube connected  
190 to a 0.2 µm PTFE filter was used (detailed setup is given in: (Cole and Steffen, 2010; Steffen et  
191 al., 2008)). Auto-calibrations were made using the internal Hg permeation unit every 25 hrs and  
192 these were verified through manual injections from a Tekran 2505 Mercury Vapor Primary  
193 Calibration Unit (Tekran Instruments Corp.) before and after each set of experiments. Quality  
194 control and assurance of the Tekran 2537A data sets followed the Environment Canada  
195 Research Data Management and Quality Control system (Steffen et al., 2012).

196 2.2.5 SAMPLING RATE CALCULATION.  $SRs$  ( $m^3 \text{ day}^{-1}$ ) were calculated using:

$$197 \quad SR = \frac{m}{(C t)} \quad (1)$$

198 where  $m$  is the mass of sorbed mercury (ng),  $C$  is the concentration of gaseous Hg measured by  
199 the Tekran 2537A ( $ng \text{ m}^{-3}$ ), and  $t$  is the deployment time of the PAS (days). With the exception  
200 of the 3-months experiment, the  $SRs$  were derived from single point calibrations using Eq. (1).  
201  $SRs$  derived from a single deployment have a higher uncertainty than  $SRs$  derived from  
202 experiments involving multiple simultaneous deployments of variable length, such as those  
203 described in McLagan et al. (2016b). This uncertainty is further increased when deployment  
204 times are short and gaseous Hg concentrations are low, as  $m$  will be closer to quantification  
205 limits. To nevertheless constrain the uncertainties from the experiments described here, we  
206 performed a high number of replications. In the wind experiments, true replication was not  
207 possible, as wind speed varied slightly between each deployment. While they cannot be called  
208 replicates, we performed a very large number of individual experiments, which allowed for the  
209 derivation of a robust relationship between  $SR$  and wind speed. Additionally, the variable length  
210 of the experiments at selected wind speeds not only added to the number of data points, but  
211 also allowed us to assess if there was any effect of deployment time on  $SR$ .

### 212 2.3 Analyses

213 Total Hg (THg) in the activated carbon sorbent was quantified using thermal combustion,  
214 amalgamation, and atomic absorption spectroscopy in oxygen ( $O_2$ ) carrier gas (USEPA Method  
215 7473) using an AMA254 (Leco Instruments Ltd.) (USEPA, 2007). Because the sorbent in a PAS  
216 cannot be assumed to take up Hg homogeneously, the entire carbon from each PAS was  
217 analyzed in two aliquots of up to 0.45 g each. In order to increase the lifetime of AMA254  
218 catalyst tubes while processing samples with high sulphur content, catalyst tubes were  
219 amended with 5 g of sodium carbonate ( $Na_2CO_3$ ) and  $\sim 0.15$  g of  $Na_2CO_3$  was added directly to  
220 each sample boat (McLagan et al., submitted). Samples were dried for 30 seconds at 200 °C and  
221 thermally decomposed at 750 °C for 330 seconds, while gaseous elemental Hg was trapped on  
222 the gold amalgamator. After combustion the system was purged for 60 seconds to ensure all

223 pyrolysis gases were removed from the catalyst. Throughout the analysis the catalyst was  
224 heated to 550 °C. After purging, the amalgamator was heated to 900 °C for 12 seconds to  
225 release the trapped Hg into the cuvette where absorption at 253.65 nm was measured by dual  
226 detector cells for both low and high absolute amounts of Hg.

227 The instrument was calibrated by adding varying amounts of Hg liquid standard for AAS ( $1000 \pm$   
228  $5 \text{ mg l}^{-1}$ ; in 10% w/w HCl; Inorganic Ventures) to  $\sim 0.22 \text{ g}$  of clean (unexposed) HGR-AC.  $\sim 0.15 \text{ g}$   
229 of  $\text{Na}_2\text{CO}_3$  was added on top of the liquid standard and HGR-AC. In all experiments absolute  
230 amounts of Hg were less than 20 ng and the high cell was therefore not required for  
231 quantification. The low cell calibration included standards of 0, 0.1, 0.25, 0.5, 1, 2.5, 5, 10, 15,  
232 and 20 ng of Hg (uncertainty in autopipette is  $1 \pm 0.004 \text{ ng}$ ) fitted with a linear relationship.

#### 233 **2.4 Quality Assurance and Control**

234 Both analytical and field blanks were included in all experiments. Analytical blanks represented  
235 analyses of clean HGR-AC with mean concentration of  $0.3 \pm 0.2 \text{ ng g}^{-1}$  of HGR-AC (n=14). Field  
236 blanks, taken both at the start and end of each experiment, were taken to the site, opened,  
237 deployed, and then immediately taken down, sealed and stored for analysis. The mean field  
238 blank concentration for the wind experiments (n=7), the temperature/RH experiments (n=5),  
239 and the Radiello® reuse experiments (n=4) were  $0.5 \pm 0.2 \text{ ng g}^{-1}$ ,  $0.58 \pm 0.15 \text{ ng g}^{-1}$  and  $0.38 \pm$   
240  $0.08 \text{ ng g}^{-1}$  of HGR-AC, respectively. All results are blank adjusted by subtracting the mean field  
241 blank concentration for each experiment multiplied by the mass of HGR-AC in that sample.

242 Analytical precision was monitored throughout the experiments (approximately every 10-15  
243 instrumental runs) by analyzing 5 or 10 ng Hg liquid Standards for AAS added to  $\sim 0.22 \text{ g}$  of HGR-  
244 AC. Recoveries for precision testing were  $100.1 \pm 1.6$  (n=62),  $100.0 \pm 1.3$  (n=24), and  $100.0 \pm 1.3$   
245 (n=21) % for the wind, temperature/RH, and reuse experiments, respectively. Recovery was  
246 monitored throughout the experiments (approximately every 10-15 runs) by analyzing a high  
247 sulphur, bituminous coal standard reference material, NIST 2685c (S = 5 wt%; National Institute  
248 of Standards and Technology), or our own in-house reference material, RM-HGR-AC1  
249 (powdered HGR-AC loaded with Hg by exposure to air for four months then homogenized; 23.1

250  $\pm 0.8 \text{ ng g}^{-1}$  based on 198 analytical runs). Recoveries of NIST 2685c were  $101 \pm 3$  (n=35),  $102 \pm$   
251  $3$  (n=14), and  $99 \pm 4$  (n=10) % for the wind, temperature/RH, and reuse experiments,  
252 respectively. Recoveries of RM-HGR-AC1 were  $98 \pm 3$  (n=43),  $97 \pm 2$  (n=13), and  $96 \pm 2$  (n=10) %  
253 for the wind, temperature/RH, and reuse experiments, respectively. All statistical tests were  
254 either performed by hand or using R v3.3.2 (R Foundation for Statistical Computing).

### 255 3. RESULTS AND DISCUSSION

#### 256 3.1 Wind

257 The effect of wind speed on *SR* varied considerably across the four tested PAS configurations  
258 (Fig. 1). The greatest effect was observed for white Radiello® without windshield (configuration  
259 2), which is a configuration that is unlikely to be used in practice. A positive linear relationship  
260 across the tested wind speed range (wind still to  $6 \text{ m s}^{-1}$ ) had a slope indicative of a  $0.022 \text{ m}^3$   
261  $\text{day}^{-1}$  (or 18% of the calibrated *SR*) increase in *SR* for every  $1 \text{ m s}^{-1}$  increase in wind speed (Fig.  
262 1). Previous investigators, using the white Radiello® (without protective shield) to monitor  
263 varying atmospheric contaminants, fitted logarithmic (Pennequin-Cardinal et al., 2005;  
264 Plaisance, 2011; Skov et al., 2007) or quadratic (Plaisance et al., 2004) relationships to data  
265 describing the effect of wind speed on *SR*. The *SR* was most sensitive at lower wind speeds.  
266 However, due to the limited number or range of measured wind speeds, or high data  
267 uncertainty, a linear relationship fits some of these data equally well (McLagan et al., 2016a).

268 The addition of the windshield (configuration 1), which is the current method of practice,  
269 reduced the effect of wind speed on the *SR*, particularly at higher wind speeds. The best fit of  
270 the data was a logarithmic relationship (linear fit:  $R^2 = 0.66$ ) in which *SR* was most sensitive to  
271 wind speed between 0 and  $1 \text{ m s}^{-1}$  (Fig. 1). While average wind speeds of less than  $1 \text{ m s}^{-1}$  are  
272 common for indoor deployments, outdoors average wind speeds typically exceed  $1 \text{ m s}^{-1}$  (98.3%  
273 of data from  $0^\circ 10'$  resolution global data set of monthly averaged wind speeds at 10 m above  
274 ground level between 1961 and 1990 (New et al., 2002)). When we consider only the data  $>1 \text{ m}$   
275  $\text{s}^{-1}$  we observe a slight, but significant, positive linear relationship between *SR* and wind speed  
276 ( $p=0.006$ ) corresponding to a  $0.003 \text{ m}^3 \text{ day}^{-1}$  (or 2.5% or the previously calibrated *SR*) increase

277 in *SR* for every  $\text{m s}^{-1}$  increase in wind speed (Fig. 1). Neither configuration with the thicker,  
 278 yellow Radiello® led to a significant effect of wind speed on *SR* (Fig. 1). With the protective  
 279 shield in place the *SR* was approximately 10% lower than without the protective shield.  
 280 Plaisance (2011) also noted a negligible effect of wind speed on *SR* using a yellow Radiello® PAS  
 281 without any protective shield when monitoring benzene.

283 **Figure 1: The effect of wind speed on the sampling rate of four different configurations of a passive air**  
 284 **sampler for gaseous mercury. Configuration 1: White Radiello®, with protective shield (1 week: ■, 2**  
 285 **week: ■, 3 week: ■, and 4 week: ■ deployments); Configuration 2: White Radiello®, without**  
 286 **protective shield (1 week: ◆, 2 week: ◆, 3 week: ◆, and 4 week: ◆ deployments); Configuration 3:**  
 287 **Yellow Radiello®, with protective shield (■); Configuration 4: White Radiello®, without protective**  
 288 **shield (◆). Sampling rate, wind speed relationships are based on all data for each configuration**  
 289 **irrespective of deployment length.**

290 The importance of a diffusive barrier is illustrated by the very strong effect of wind speed on  
 291 the *SR* of another PAS for gaseous Hg that also utilizes an activated carbon sorbent, but has no

292 diffusive barrier: the  $SR$  increased by  $0.126 \text{ m}^3 \text{ day}^{-1}$  (or 97% of the calibrated  $SR$ ) for every  $\text{m s}^{-1}$   
293 increase in wind speed (Guo et al., 2014; Zhang et al., 2012). This information and the results  
294 here demonstrate the merit of employing both diffusive barriers and protective shield in  
295 reducing the effect of wind speed on  $SR$ . The diffusive path length of the PAS has three  
296 components: (1) the ASBL, (2) the diffusive barrier (adjusted for the porosity of the diffusive  
297 barrier), and (3) the internal airspace of the Radiello® (McLagan et al., 2016b). Employing a  
298 thicker, less porous diffusive barrier (yellow Radiello®) increases the diffusive path length of the  
299 diffusive barrier component, in turn reducing the  $SR$ . By reducing turbulence on the outside of  
300 the diffusive barrier, the protective shield essentially increases the thickness of the ASBL  
301 (McLagan et al., 2016b), leading to a reduction in  $SR$ .

302 Because the samplers were not exposed to exactly the same wind speeds, it is not possible to  
303 construct uptake curves from the experiments with variable deployment length. It is, however,  
304 possible to test whether the measured  $SR$ s depend on the length of the single point  
305 calibrations. The relationship between deployment length and  $SR$  was not significant ( $p > 0.05$ ),  
306 irrespective of the applied wind speed (wind-still,  $\sim 3 \text{ m s}^{-1}$ , and  $\sim 6 \text{ m s}^{-1}$ ) or configuration (1 and  
307 2); see Fig. S3 for details. This confirms that the  $SR$ s derived from short one-week deployments  
308 were neither biased high or low.

309 The 3-month uptake experiment under wind-still conditions produced a  $SR$  of  $0.106 \pm 0.009 \text{ m}^3$   
310  $\text{day}^{-1}$  when calculated as the average of single point calibrations (see Fig. S4 for uptake curve).  
311 The slope of the regression of  $m$  against  $C \cdot t$  (McLagan et al., 2016b; Restrepo et al., 2015) gave  
312 a very similar  $SR$  of  $0.109 \pm 0.009 \text{ m}^3 \text{ day}^{-1}$ . Because the latter method is thought to give a  
313 slightly more reliable  $SR$  (McLagan et al., 2016b; Restrepo et al., 2015), we suggest to use this  
314  $SR$  for indoor deployments of the PAS using the white Radiello and a windshield (configuration  
315 1). This  $SR$  is 9.9% lower than the  $SR$  obtained in an earlier outdoor calibration study, despite  
316 the higher temperature ( $\sim 23^\circ\text{C}$ ) indoors than outdoors (mean temperature across all  
317 deployments:  $7.6^\circ\text{C}$ ). Additionally, the replicate precision of samplers from this uptake  
318 experiment for the wind-still data with the protective shield ( $11 \pm 8\%$ ) was significantly poorer  
319 ( $p < 0.001$ ) than in the outdoor calibration study with the same sampler setup ( $2 \pm 1.3\%$ ; mean

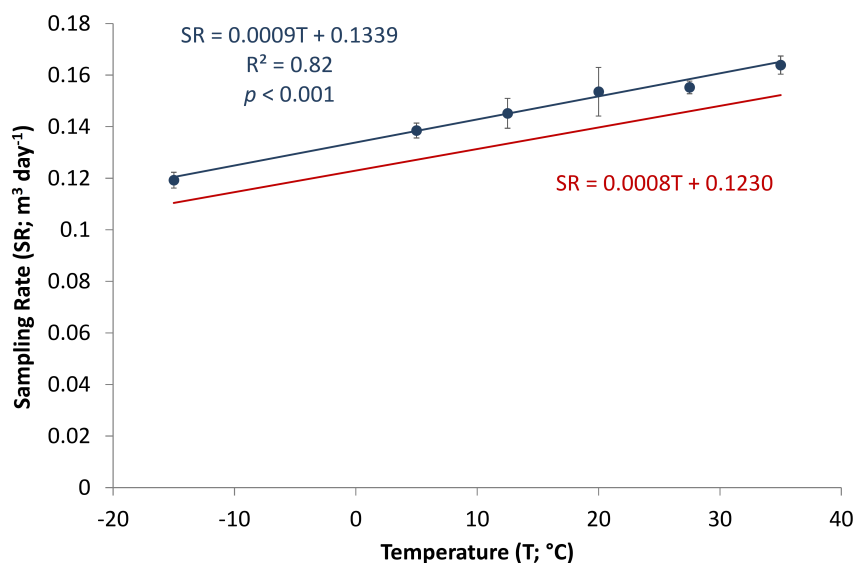

320 wind speed  $1.89 \text{ m s}^{-1}$  (McLagan et al., 2016b). Both the lower *SR* and the greater uncertainty  
321 of the *SR* are consistent with the effect of wind observed for this configuration (green markers  
322 in Fig. 1): At the low wind speeds of indoor deployments ( $< 1 \text{ m s}^{-1}$ ), the *SR* is expected to be  
323 both lower and more sensitive to changes in wind speed. Although, conditions for this  
324 experiment were labelled “wind-still”, in reality any activity within the laboratory (movement of  
325 lab personnel, opening and closing of doors, etc.) will result in small variations in wind speeds  
326 around the PAS within the range where the *SR* is most sensitive to such variations (Zhang et al.,  
327 2013).

### 328 **3.2 Temperature and relative humidity**

329 Relative humidity, tested at 44, 60, and 80% and a stable temperature of  $20 \text{ }^{\circ}\text{C}$ , had no  
330 significant effect on *SR* ( $p = 0.080$ ; see Fig. S5). It is therefore appropriate to analyze the effect  
331 of temperature on *SR* despite small variations in RH at different temperature levels. We  
332 observed a significant, positive, linear relationship between *SR* and temperature ( $p < 0.001$ ; Fig.  
333 2) corresponding to a  $0.001 \text{ m}^3 \text{ day}^{-1}$  increase in *SR* for every  $1 \text{ }^{\circ}\text{C}$  increase in temperature (or  
334 0.7% of the calibrated *SR*). This relationship remained linear across the tested range from  $-15$  to  
335  $35 \text{ }^{\circ}\text{C}$ .

336 Temperature can affect the *SR* because of its impact on (i) the partitioning equilibrium between  
337 the sorbent and the gas phase and (ii) the diffusion coefficient (McLagan et al., 2016a;  
338 Pennequin-Cardinal et al., 2005). The uptake capacity of the HGR-AC for gaseous Hg is  
339 extremely high and we suspect that any change in the sorption equilibrium caused by changing  
340 temperatures should have a negligible effect on the *SR*. The increase in diffusivity caused by an  
341 increase in temperature is easily quantified. Fig. 2 also displays *SR* as a function of temperatures  
342 predicted with a previously described model based on Fick’s first law of diffusion (McLagan et  
343 al., 2016b). While the predicted *SRs* are  $\sim 8\%$  lower than the measured ones, the slope of the  
344 relationship between *SR* and temperature is the same (no significant difference, z-score test,  $p$   
345  $= 0.427$ ), confirming that the effect of temperature on the diffusivity of gaseous Hg is sufficient  
346 to explain the observed temperature dependence of the *SR*.

347

348 **Figure 2: The effect of temperature on the sampling rate of a passive air sampler for gaseous mercury**  
349 **as determined experimentally (blue) and as calculated using the diffusion model (red) by McLagan et**  
350 **al. (2016b). The measured and calculated temperature dependence, given by the slopes of the**  
351 **relationships, are not significantly different.**

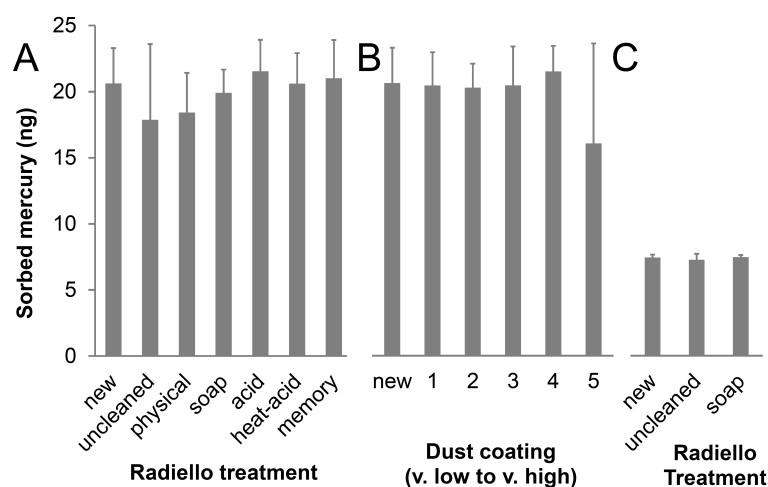

352 Earlier studies on PAS for gaseous Hg did not observe an effect of temperature on *SR*. Guo et al.  
353 (2014) found no significant effect of temperature on the *SR* of their activated carbon based PAS  
354 between -10 and 35 °C. Similarly, there was no effect of temperature on the *SR* of a PAS using a  
355 solid gold sorbent and a white Radiello® diffusive body (Skov et al., 2007). In neither case,  
356 however, was the precision of the measurement sufficient to detect the small dependence of  
357 *SR* on temperature caused by the effect of temperature on diffusivity. Such a small temperature  
358 effect can only be detected in a highly precise sampler.

### 359 3.3 Radiello® reuse

360 In the Radiello® reuse experiment conducted indoors, no significant difference in the amount of  
361 sorbed Hg was observed between *new*, *uncleaned*, or any of the cleaned Radiellos® (ANOVA, *p*  
362 = 0.467; Fig. 3(A)). Similarly, when we ignore the effect of cleaning, no significant difference in  
363 the sorbed amount of Hg was observed between Radiellos® with different degrees of dust  
364 coatings, including the new Radiellos® (ANOVA, *p* = 0.841; Fig. 3(B)). The cleaning treatments  
365 also did not differ in terms of the observed variances (Levene's Test, *p* = 0.307). However, the

366 amount of Hg taken up in Radiellos<sup>®</sup> with the most dust (category 5) had a significantly higher  
367 variance than all other treatments ( $p = 0.004$ , Levene's Test with Tukey's Honest Significant  
368 Difference post hoc test). Although the differences between all Radiello<sup>®</sup> treatments in the  
369 indoor Radiello<sup>®</sup> reusability experiments are small, the significantly higher variability observed  
370 for Radiellos<sup>®</sup> with the highest dust coating suggests some form of cleaning would be better in  
371 maintaining the high level of precision of this PAS. Effect size, using Cohen's  $d$  value (see S5),  
372 was then applied to examine differences in treatments without the use of traditional binary  
373 hypotheses testing (See Table S3). In comparison to new Radiellos<sup>®</sup> *soap*, *acid*, and *heat-acid*  
374 were the most effective treatments. While there was no significant difference in means  
375 (ANOVA;  $p = 0.548$ ) or variances (Levene's;  $p = 0.221$ ) for the outdoor experiment testing *new*,  
376 *uncleaned*, and *soap* Radiellos<sup>®</sup>, effect size analysis (see S5) confirmed that *soap* cleaning is an  
377 effective method in preparing used Radiellos<sup>®</sup> for redeployment (Fig. 4(C)).

378  
379 **Figure 3: Mean sorbed mercury for differing Radiello<sup>®</sup> cleaning treatments and at varying degrees of**  
380 **HGR-AC dust coating inside the Radiello<sup>®</sup> (Panel B) from indoor experiment. Cleaning treatments and**  
381 **degree of dust coating is described in Sect. 2.2.3. Panel A also includes the memory effect treatment,**  
382 **which were uncleaned Radiellos<sup>®</sup> from deployments in a high concentration environment. Panel C**  
383 **presents the mean sorbed mercury for differing Radiello<sup>®</sup> cleaning treatments from outdoor**  
384 **experiment.**

385 Uptake of Hg in uncleaned Radiellos<sup>®</sup> previously deployed in gaseous Hg concentrations 2 – 4  
386 orders of magnitude higher than the other Radiellos<sup>®</sup> (*memory* treatment) was also not  
387 significantly different from any of the other treatments in terms of mean (ANOVA:  $p = 0.499$ ) or

388 variance (Levene's:  $p = 0.307$ ; Fig. 3(A)). This implies that very little Hg was sorbed to the  
389 Radiello® and re-released during the subsequent deployment and that gaseous Hg has little  
390 affinity for the porous high-density polyethylene diffusive membrane of the Radiello®.

#### 391 4. RECOMMENDATIONS AND CONCLUSIONS

392 While the  $SR$  of the PAS in its standard configuration (white Radiello® with protective shield)  
393 was found to depend on both wind speed and temperature, the effects are both small and  
394 predictable. The accuracy of volumetric air concentrations derived from the PAS can be  
395 improved by applying adjustment factors to the  $SR$ , especially for deployments at or close to  
396 background gaseous Hg concentrations. The  $SR$  of the standard configuration PAS (white  
397 Radiello® with shield) deployed outdoors of  $0.121 \text{ m}^3 \text{ day}^{-1}$  was obtained for a mean wind  
398 speed of  $1.89 \text{ m s}^{-1}$  and a mean temperature of  $7.6^\circ\text{C}$ .<sup>15</sup> We recommend to use the increments  
399 from Fig. 1 and Fig. 2, i.e.  $0.003 \text{ m}^3 \text{ day}^{-1}$  increase in  $SR$  for every  $\text{m s}^{-1}$  increase in wind speed  
400 and  $0.001 \text{ m}^3 \text{ day}^{-1}$  increase in  $SR$  for every  $1^\circ\text{C}$  increase in temperature to adjust the  $SR$  of  
401  $0.121 \text{ m}^3 \text{ day}^{-1}$  to the average temperature and wind speed of each PAS deployment (See S6 for  
402  $SR$  adjustment equation and sample calculation).

403 The experiments here predict a  $SR$  of  $0.142 \text{ m}^3 \text{ day}^{-1}$  for an average wind speed of  $1.89 \text{ m s}^{-1}$   
404 (Fig. 1) and a  $SR$  of  $0.141 \text{ m}^3 \text{ day}^{-1}$  for an average temperature of  $7.6^\circ\text{C}$  (Fig. 2). Both these  
405 values are greater than the  $SR$  of  $0.121 \text{ m}^3 \text{ day}^{-1}$  from the calibration study (McLagan et al.,  
406 2016b). While we presently do not know the reason for this discrepancy, it may be related to  
407 the relatively short deployment periods used in the present experiments. As mentioned above,  
408 short deployment at background concentrations yield a  $SR$  with a higher uncertainty. Also,  
409 McLagan et al. (2016b) observed that  $SR$  for PAS deployed outdoors for less than 1-2 months  
410 were higher than the  $SR$  derived for the entire one-year sampling period. Despite this slight  
411 discrepancy, we note that the y-intercepts of the relationships reported here (the magnitude of  
412 the  $SR$ ) are less important than their slopes (i.e. the temperature and wind speed adjustment  
413 factors). An ongoing study measuring the uptake of gaseous Hg in PAS deployed at several  
414 locations with widely different temperature and wind speed conditions will help refine both the

415 *SR* applicable to outdoor deployments and the validity of the laboratory derived adjustment  
416 factors for temperature and wind speed reported here.

417 When designing a PAS, there is a need to strike a balance between maximizing the *SR* and  
418 minimizing the variability in the *SR* caused by factors such as wind speed, objectives that are  
419 contradictory in nature (McLagan et al., 2016a). Although using a thicker, yellow Radiello® with  
420 or without a protective shield are the methods least affected by wind, the *SR* for these methods  
421 is approximately half that of the white Radiello® with a shield. A lower *SR* translates to lower  
422 amounts of sorbed Hg, which means that longer deployments are required to reach method  
423 quantification limits (MQL). The PAS configuration with white Radiello® and windshield needs  
424 to be exposed to typical background concentrations of gaseous Hg ( $\sim 1.5 - 2 \text{ ng m}^{-3}$ ) for  
425 approximately one week to reach levels above MQL (McLagan et al., 2016b). A PAS with yellow  
426 Radiello would presumably require deployments twice as long. For either configuration, longer  
427 deployments of a month or more are likely to yield greater accuracy. Given the possibility of  
428 adjusting the *SR* for the slight effect caused by wind speeds above  $1 \text{ m s}^{-1}$  and the shorter  
429 minimum deployment times, we recommend the PAS configuration with a shielded white  
430 Radiello for most outdoor deployments. Nonetheless, there may be long deployments under  
431 highly variable winds that warrant the use of the yellow Radiello®. A full long-term calibration  
432 study outdoors would be advisable prior to using this configuration.

433 Finally, our results suggest that previously deployed Radiello® are indeed reusable as long as  
434 the Radiellos® are cleaned between deployments. Because the different cleaning methods were  
435 generally equally effective, we recommend the use of the *soap* method because of its overall  
436 ease and health, safety and waste benefits over using acids (Anastas and Warner, 1998).
