Abstract. This paper presents the retrieval algorithm for the operational Ozone Monitoring Instrument (OMI) total bromine monoxide (BrO) data product (OMBRO) developed at the Smithsonian Astrophysical Observatory (SAO), and shows some validation with correlative measurements and retrieval results. The algorithm is based on direct nonlinear least squares fitting of radiances from the spectral range 319.0-347.5 nm. Radiances are modeled from the solar irradiance, attenuated by contributions from BrO and interfering gases, and including rotational Raman scattering, additive and multiplicative closure polynomials, correction for Nyquist undersampling, and the average fitting residual spectrum. The retrieval uses albedo- and wavelength-dependent air mass factors (AMFs), which have been pre-computed using a single mostly stratospheric BrO profile. The BrO cross sections are multiplied by the wavelength-dependent AMFs before fitting so that the vertical column densities (VCDs) are retrieved directly. The fitting uncertainties of BrO VCDs typically vary between 4 and 7×10^{12} molecules cm^{-2} ($\sim 10\text{-}20\%$ of the measured BrO VCDs). The retrievals agree well with GOME-2 observations at simultaneous nadir overpasses and ground-based zenith-sky measurements at Harestua, Norway, with mean biases less than $0.12 \pm 0.76 \times 10^{13}$ molecules cm^{-2} ($3.2 \pm 16.3\%$). Global distribution and seasonal variation of OMI BrO are generally consistent with previous satellite observations. The retrievals show enhancement of BrO at US Great Salt Lake. It also shows significant BrO enhancement from the eruption of the Eyjafjallajökull volcano, although the BrO retrievals can be affected under high SO₂ loading conditions by the sub-optimum choice of SO₂ cross sections.

1 Introduction

Bromine monoxide (BrO) is a halogen oxide, predominantly located in the stratosphere and upper troposphere where, like chlorine monoxide (ClO), it is a catalytic element in the destruction of stratospheric ozone (von Glasow *et al.*, 2004; Salawitch *et al.*, 2005), but with higher efficiency per molecule. Sources of tropospheric BrO include bromine release (“explosions”) during the Polar Spring (Hollwedel *et al.*, 2004; Salawitch *et al.*, 2010), volcanic eruption (Bobrowski *et al.*, 2003; Chance, 2006; Theys *et al.*, 2009;), salt lakes (Hörmann *et al.*, 2016) and stratospheric transport (Salawitch *et al.*, 2010). Global BrO measurements from space were first proposed for the Scanning Imaging Absorption Spectrometer for Atmospheric Cartography (SCIAMACHY) instrument (Chance *et al.*, 1991) and were first demonstrated with Global Ozone Monitoring Experiment (GOME-1) measurements (Chance, 1998; Platt and Wagner, 1998; Richter *et al.*, 1998), and since with SCIAMACHY nadir (Kühl *et al.*, 2008) and Global Ozone Monitoring Experiment 2 (GOME-2) measurements (Theys *et al.*, 2011). Initial observations of BrO by OMI were first reported in Kurosu *et. al.* (2004). Polar Spring BrO enhancements are known to be associated with boundary layer ozone depletion (*cf.* Salawitch *et al.*, 2010). OMI measurements of BrO have been used together with chemical and dynamical modeling to investigate stratospheric versus tropospheric enhancements of atmospheric BrO at high northern latitudes (Salawitch *et al.*, 2010). OMI BrO retrieval using the Differential Optical Absorption Spectroscopy (DOAS) method has been used to study the seasonal variations of tropospheric bromine monoxide over the Rann of Kutch salt marsh (Hörmann *et al.* 2016). The Arctic Research of the Composition of the Troposphere from Aircraft and Satellites (ARCTAS) campaign (Choi *et al.*, 2012) found consistency between BrO column densities calculated from Chemical Ionization Mass Spectrometer (CIMS) measurements with the tropospheric BrO columns derived from OMI. BrO has been observed from the ground in Harestua, Norway (Hendrick *et al.*, 2007), Lauder, New Zealand (Schofield *et al.*, 2004a, 2004b), Antarctica (Schofield *et al.*, 2006), and Barrow, Alaska (Simpson *et al.*, 2005). The purpose of this paper is to describe the OMI BrO operational algorithm and the data product, compare it with ground-based and other satellite measurements and briefly analyze its spatiotemporal characteristics. This paper is organized as follows: Section 2 describes the OMI instrument and the data product. Section 3 gives a detailed description of the operational algorithm including algorithm and product history, spectral fitting, AMF calculations, destriping, fitting uncertainties, and a known

issue. Section 4 presents results and discussion including comparison with GOME-2 and ground-based zenith-sky measurements at Harestua, Norway, global distribution and seasonality, and enhanced BrO from the U.S. Great Salt Lake and Iceland's Eyjafjallajökull volcano. Section 5 concludes this study.

5 2 OMI instrument and OMBRO data product

2.1 OMI instrument

OMI was launched on the NASA Earth Observing System (EOS) Aura satellite into a sun-synchronous orbit on 15 July 2004. It is a push-broom imaging spectrometer that observes solar backscattered radiation in the visible and ultraviolet from 270-500 nm in three channels (UV1: 10 270-310 nm, UV2: 310-365 nm, visible: 350-500 nm) at spectral resolution of 0.42-0.63 nm and spatial resolution in the normal (global sampling) mode ranging from $13 \times 24 \text{ km}^2$ at direct nadir to about $28 \times 150 \text{ km}^2$ at the swath edges. The global mode (GM) has 60 ground pixels with a total cross-track swath of 2600 km. There are also spatial and spectral zoom modes with twice finer across-track spatial resolution at nadir. The spatial zoom mode is employed every 32 days 15 (Leveld *et al.*, 2006): data from this mode are spatially rebinned to global-mode sampling sizes, known as the rebinned spatial zoom mode. The spatial zoom mode (SZM), like the global mode (GM), has 60 cross-track pixels. These are re-binned to 30, to form "the rebinned spatial zoom mode" (RSZM) which is equivalent in pixel size to the GM data, but with reduced spatial coverage.

20

Since June 2007, certain cross-track positions of OMI data have been affected by the row anomaly: some loose thermal insulating material likely appeared in front of the instrument's entrance slit, which can block and scatter the light thus causing errors in level 1b data and subsequently the level 2 retrievals (Kroon *et al.*, 2011). Initially, the row anomaly only affected a 25 few positions and the effect was small. But since January 2009, the anomaly has become more serious, spreading to $\sim 1/3$ of the positions and retrievals at those positions are not recommended for scientific use. A flagging field termed XtrackQualityFlags has been introduced in the OMI level 1b data to indicate whether an OMI pixel is affected by this instrument anomaly.

OMI measures ozone and other trace gases, aerosols, clouds, and surface properties. Products developed at the SAO include operational BrO, chlorine dioxide (OCIO), and formaldehyde (H₂CO; González Abad *et al.*, 2015) that are archived at NASA Goddard Earth Sciences (GES) Data and Information Services Center (DISC), and offline (“pre-operational”) ozone profile and tropospheric ozone (O₃) (Liu *et al.*, 2010; Huang *et al.*, 2017a,b), glyoxal (C₂H₂O₂) (Chan Miller *et al.*, 2014, 2016) and water vapor (H₂O) (Wang *et al.*, 2014, 2016) that are available at the Aura validation data center (AVDC). All the products except for the ozone profile product are produced using nonlinear least-squares (NLLS) fitting methods based on those previously developed at the SAO for the analysis of measurements from the GOME (now GOME-1) (Chance, 1998; Chance, *et al.*, 2000) and SCIAMACHY instruments (Burrows and Chance, 1991; Chance *et al.*, 1991; Martin *et al.*, 2006).

2.2 OMBRO data product

The current operational BrO product, OMBRO version 3.0.5, contains BrO vertical column densities (VCDs), slant column densities (SCDs), effective air mass factors (AMFs) and ancillary information retrieved from calibrated radiance and irradiance spectra in OMI GM and RSZM level 1b data product. Each BrO product file contains a single orbit of data, from pole to pole, for the sunlit portion of the orbit. The data product from 26 August 2004 through the present is available at GES DISC. Data used in this study cover the period from 1 January 2005 to 31 December 2014.

3 Retrieval algorithm

3.1 Algorithm and product history

OMBRO Version 1.0 was released on 1 February 2007, based on a spectral fitting window of 338–357 nm. Version 2.0 was released on 13 April 2008. It included major adjustments for Collection 3 Level 1b data, improved destriping measures, change of the fitting window to 340–357.5 nm, improvements to radiance wavelength calibration, and several improvements for processing near-real-time data. In both Versions 1 and 2, total BrO VCDs were retrieved in two steps: first performing spectral fitting using the basic optical absorption spectroscopy (BOAS) method to derive SCDs from OMI radiance spectra, and then converting from SCDs to VCDs by

dividing AMFs. This is similar to current SAO H₂CO, H₂O and C₂H₂O₂ as mentioned previously. The latest Version 3.0.5, released on 28 April 2011, includes major algorithm changes: the fitting window was moved to 319.0–347.5 nm, and BrO cross sections are multiplied by wavelength-dependent AMFs, which are a function of albedo, before fitting, for a
5 direct retrieval of BrO VCDs. SCDs are similarly retrieved in a separate step by fitting BrO cross sections that have not been multiplied with wavelength-dependent AMFs, and an effective AMF = SCD/VCD is computed. Diagnostic cloud information from the OMCLDO2 product (Acarreta *et al.*, 2004) was added, and the row-anomaly indicating flags XtrackQualityFlags were carried over from the level 1b product.

10

The current algorithm is described in detail in the rest of this section, with spectral fitting in Section 3.2, AMF calculation prior to spectral fitting in Section 3.3, the post-processing of de-stripping to remove cross-track dependent biases in Section 3.4, the fitting uncertainties in Section 3.5, and one known issue regarding the used SO₂ cross sections in Section 3.6.

15 **3.2 Spectral fitting**

Most aspects of the algorithm physics for the direct fitting of radiances by the BOAS method were developed previously at SAO for analysis of GOME and SCIAMACHY satellite spectra (Chance, 1998, Chance *et al.*, 2000, OMI, 2002; Martin *et al.*, 2006) and in the various algorithm descriptions of other SAO OMI products (Wang *et al.*, 2014; Chan Miller *et al.*, 2014; Gonzalez
20 Abad *et al.*, 2015). Unlike the often-used DOAS fitting method (Platt, 1994), radiances are not ratioed to irradiances, logarithms are not taken, and no high-pass filtering is applied.

The spectral fitting in the SAO OMI BrO retrieval is based on a Gauss-Newton NLLS fitting procedure, the CERN ELSUNC procedure (Lindström and Wedin, 1987), which provides for
25 bounded NLLS fitting. Processing begins with wavelength calibration for both irradiance and radiance. In each case the wavelength registration for the selected fitting window is determined independently for each cross-track position by cross-correlation of OMI spectra with a high spectral resolution solar irradiance (Caspar and Chance, 1997; Chance, 1998; Chance and Kurucz, 2010) using the preflight instrument slit functions (Dirksen *et al.*, 2006). To improve
30 cross-track stripe correction (Section 3.4) and reduce the noise in the solar irradiance data, the

OMI irradiance spectra are composites derived from a principal component analysis of three years of individual OMI irradiance measurements (2005-2007). Radiance wavelength calibration is performed for a representative scan line of radiance measurements (usually in the middle of the orbit) to determine a common wavelength grid for reference spectra.

5

Following wavelength correction, an undersampling correction spectrum is computed to partially correct for spectral undersampling (lack of Nyquist sampling: Chance, 1998; Slijkhuis *et al.*, 1999; Chance *et al.*, 2005). The calculation of the corrections for the undersampling is accomplished by convolving the preflight slit functions with the high-resolution solar spectrum 10 and differencing its fully-sampled and undersampled representations (Chance *et al.*, 2005).

Fitting is then performed for all scan lines in the OMI swath granule. In each stage, the fitting is performed individually for the 60 cross-track pixels of a block of 100 OMI across-track swath lines along the flight direction (30 cross-track pixels for the RSZM) according to Eq. (1):

$$15 \quad I = \{(aI_0 + \sum_i \alpha_i A_i) e^{-\sum_j \beta_j B_j} + \sum_k \gamma_k C_k\} Poly_{scale} + Poly_{baseline}, \quad (1)$$

where I_0 is the solar irradiance (used in our operational BrO retrieval) or radiance reference measurement, I is the Earthshine radiance (detected at satellite), a is albedo, α_i , β_j , γ_k , are the coefficients to the reference spectra of A_i , B_j , C_k , (for example, trace gas cross sections, Ring effect, vibrational Raman, undersampling correction, common mode, *etc.*) of model constituents.

20 The reference spectra are derived separately for each cross-track position from original high-resolution cross sections convolved with the corresponding OMI slit functions after correcting for the solar I_0 effect (Aliwell *et al.*, 2002). Figure 1 shows the trace gas cross sections and Ring spectra used in the current operational algorithm. The black lines are the original high-resolution reference spectra, and the red line shows the corresponding spectra convolved with OMI slit 25 function, which are used in the fitting.

For improved numerical stability, radiances and irradiances are divided by their respective averages over the fitting window, renormalizing them to values of ~1. BrO is fitted in the spectral window 319.0–347.5 nm, within the UV-2 channel of the OMI instrument. The switch

from the previous fitting window of 340–357.5 nm to this shorter and wider fitting window is to reduce fitting uncertainty by including more BrO spectral structures as shown in Fig. 1.

The rotational Raman scattering (Chance and Spurr, 1997; Chance and Kurucz, 2010) and
5 undersampling correction spectra, A_i , are first added to the albedo-adjusted solar irradiance aI_0 , with coefficients α_i as shown in Eq. 1. Radiances I are then modeled as the this quantity attenuated by absorption from BrO, O₃, NO₂, H₂CO, and SO₂ with coefficients β_j fitted to the reference spectra B_j as shown in Eq. 1. A common mode spectrum C_k , computed on line, is added by fitting coefficient γ_k after the Beer-Lambert law contribution terms. An initial fit of several
10 hundred pixels per cross-track position determines the common mode spectra (one spectrum per cross-track position, between 30°N and 30°S) as the average of the fitting residuals. The common mode spectra include any instrument effects that are uncorrelated to molecular scattering and absorption. This is done to reduce the fitting root-mean-square (RMS) residuals, and the overall uncertainties. These are then applied as reference spectra in fitting of the entire orbit. The fitting
15 additionally contains additive (*Polybaseline*) and multiplicative closure polynomials (*Poly_{scale}*), parameters for spectral shift and, potentially, squeeze (not normally used). The operational parameters are provided in Table 1.

3.3 Air mass factors

20 Due to significant variation in ozone absorption and Rayleigh scattering in the new fitting window, AMFs vary with wavelength by 10–15% as shown in Fig. 2, particularly at larger solar and viewing zenith angles, which makes it difficult to identify a single representative AMF *ad hoc*. The wavelength dependent AMFs are introduced to take into account for such strong variation within the BrO fitting window, and are applied pre-fit to the BrO cross sections, and the
25 spectral fit retrieves VCDs directly. This direct fitting approach is a major departure from the commonly employed 2-step fitting procedure (OMI, 2002). It was first developed for retrievals of trace gases from SCIAMACHY radiances in the shortwave infrared (Buchwitz *et al.*, 2000) and has been demonstrated for total O₃ and SO₂ retrievals from GOME/SCIAMACHY measurements in the ultraviolet (Bracher *et al.*, 2005; Coldewey-Egbers *et al.*, 2005; Weber *et*
30 *al.*, 2005; Lee *et al.*, 2008).

The albedo- and wavelength-dependent AMFs were pre-computed with the Linearized Discrete Ordinate Radiative Transfer code (LIDORT, Spurr, 2006) using a single mostly stratospheric BrO profile (Fig. 3). The BrO profile, based on the model of Yung *et al.* (1980), has ~30% BrO
5 below 15 km, ~10% BrO below 10 km, and ~2% BrO below 5 km. For conditions with enhanced BrO in the lower troposphere, using this profile will overestimate the AMFs and therefore underestimate the BrO VCDs. Surface albedos are based on a geographically varying monthly mean climatology derived from OMI (Kleipool *et al.*, 2008). Although AMFs based on this BrO profile only slightly depend on surface albedo, albedo effects can be significant over highly
10 reflective snow/ice surfaces, reducing VCDs by 5-10%.

In order to provide the AMF in the data product for consistency with previous versions based on a two-step approach, a second fitting of all OMI spectra is performed with unmodified BrO cross sections, which yields SCDs. An effective AMF can then be computed as $AMF = SCD/VCD$.
15

The green line in Fig. 3 shows the modified BrO cross section after multiplication with the wavelength-dependent AMF (albedo = 0.05, SZA = 5.0°, and VZA = 2.5°). The wavelength-dependence in AMF is visible from the varying differences near BrO absorption peaks and the right wings at different wavelengths. The correlation of the unmodified BrO cross sections with
20 the rest of the molecules fitted is small (typically less than 0.12), except with H₂CO (0.43). However, it is safe to assume that in most polar regions with enhanced BrO there are no high concentrations of formaldehyde. It will be worthwhile for future studies to assess the interference of H₂CO under high H₂CO and background BrO conditions. In addition, the AMF wavelength dependence increases with the increase of solar and viewing zenith angles and surface albedo,
25 which increases the correlation between modified BrO cross sections and O₃ cross sections. However, the correlation with O₃ becomes noticeable (~0.10) only at solar zenith angles above ~80°.

3.4 Destriping

OMI L1b data exhibit small differences with cross-track position, due to differences in the dead/bad pixel masks (cross-track positions are mapped to physically separate areas on the CCD), dark current correction, and radiometric calibration, which lead to cross-track stripes in 5 Level 2 product (Veihelmann and Kleipool, 2006). Our destriping algorithm employs several methods to reduce cross-track striping of the BrO columns. First, we screen outliers in the fitting residuals. This method, originally developed to mitigate the effect of the South Atlantic Anomaly in SAO OMI BrO, H₂CO, and OCIO data products, is now also being employed for GOME-2 (Richter *et al.*, 2011). Screening outliers is done through computing the median, r_{med} , and the 10 standard deviation σ of residual spectra $r(\lambda)$ and in subsequent refitting excluding any spectral points for which $r(\lambda) \geq |r_{med} \pm 3\sigma|$. This can be done repeatedly for every ground pixel, which makes the processing slow. However, we do it once for a reference scan line, recording the positions of the bad pixels, and excluding them by default in each subsequent fit. Second, after the completion of the spectral fitting process for all ground pixels in the granule, a post- 15 processing cross-track bias correction is performed: an average cross-track pattern is calculated from the along-track averages of all BrO VCDs for each cross-track position within a $\pm 30^\circ$ latitude band around the equator, to which a low-order polynomial is fitted. The differences between the cross-track pattern and the fitted polynomial is then applied as a cross-track VCD correction (or “smoothing”) factor. The smoothed VCDs are provided in a separate data field, 20 *ColumnAmountDestriped*. Smoothed SCDs are derived in an analogous fashion and are also included in the data product.

3.5 Fitting uncertainties

Estimated fitting uncertainties are given as $\sigma_i = \sqrt{C_{ii}}$ where C is the covariance matrix of the 25 standard errors. This definition is strictly true only when the errors are normally distributed. In the case where the level 1 data product uncertainties are not reliable estimates of the actual uncertainties, spectral data are given unity weight over the fitting window, and the 1σ fitting error in parameter i is determined as

$$\sigma_i = \varepsilon_{rms} \sqrt{\frac{c_{ii} \times n_{points}}{n_{points} - n_{varied}}} \quad (2)$$

where ε_{rms} is the root mean square of the fitting residuals, $npoints$ is the number of points in the fitting window, and $nvaried$ is the number of parameters varied during the fitting.

The BrO VCD retrieval uncertainties listed in the data product only include spectral fitting
5 errors. Error sources from AMFs (*i.e.*, BrO climatology), atmospheric composition and state
(pressure/temperature vertical profiles, total ozone column, *etc.*) and other sources of VCD
uncertainty are not included. The fitting uncertainties for single measurements of the BrO VCDs
typically vary between 4×10^{12} and 7×10^{12} molecules cm^{-2} , consistently throughout the data
record. The uncertainties vary with cross-track positions, from $\sim 7 \times 10^{12}$ at nadir positions to
10 $\sim 4 \times 10^{12}$ at edge positions due to the increase of photon path length through the stratosphere.
Relatively, the VCD uncertainties typically range between 10-20% of individual BrO VCDs, but
could be as low as 5% over BrO hotspots. This is roughly 2-3 times worse than what was
achieved from GOME-1 data. Uncertainties in the AMF, used to convert slant to vertical
15 columns, are estimated to be 10% or less except when there is substantially enhanced
tropospheric BrO. Hence the total uncertainties of the BrO vertical columns typically range
within 15-30%.

3.6 Known issue in the used SO_2 cross sections

During the comparisons and investigations of volcanic eruption scenarios (Section 4.4), it was
20 discovered that the currently implemented SO_2 molecular absorption cross sections (Vandaele *et
al.*, 1994) are a sub-optimum choice (see Fig. 4). Compared to more recent laboratory
measurements (Hermans *et al.*, 2009; Vandaele *et al.*, 2009), the original SO_2 cross sections
implemented in OMBRO do not extend over the full BrO fitting window and exhibit the wrong
behavior longward of 324 nm, overestimating the recent one by up to a factor of 3. As the
25 correlation between BrO and both SO_2 cross sections are very small (-0.03 for the current SO_2
and 0.11 for the latest SO_2 cross sections) over the spectral range of SO_2 cross sections,
interference by SO_2 in BrO retrievals is usually not an issue at average atmospheric SO_2
concentrations, but strong volcanic eruptions will render even small SO_2 absorption features past
333 nm significant. Around 334 nm, the Vandaele *et al.* (2009) data show an SO_2 feature that
30 correlates with BrO absorption when SO_2 concentrations are significantly enhanced. As a

consequence of this spectral correlation, SO₂ may be partially aliased as BrO, since the implemented SO₂ cross sections cannot account for it. Section 4.4 presents an example from the 2010 Eyjafjallajökull eruption to show that the BrO retrieval can be affected by the choice of SO₂ cross sections. The next version of the OMBRO public release will be produced using the 5 updated SO₂ absorption cross sections. Until then, caution is advised when using the OMI BrO product during elevated SO₂ conditions.

4 Results and discussions

4.1 Comparisons with GOME-2 and ground-based observations

To validate the OMBRO product, we first compared OMI BrO VCDs with BIRA/GOME-2 BrO 10 observations (Theys *et al.*, 2011). GOME-2 and OMI have different orbits: descending orbit with a local equator crossing time (ECT) of 9:30 am for GOME-2 and afternoon ascending orbit with an ECT of 1:45 pm for OMI. To minimize the effects of diurnal variation especially under high solar zenith angles (e.g., McLinden *et al.*, 2006; Sioris *et al.*, 2006) on the comparison, we conduct the comparison using simultaneous nadir overpasses (SNOs) within 2 minutes between 15 GOME-2 and OMI predicted by NOAA National Calibration Center's SNO prediction tool (<https://ncc.nesdis.noaa.gov/SNOPredictions>). Due to different orbits, all these SNOs occur at high latitudes around 75°S/N. OMI data are averaged within $\pm 2^\circ$ longitude/latitude around SNO locations while GOME-2 data are based on individual measurements at SNO locations. Figure 5 shows the time series of comparison of OMI/GOME-2 BrO from February 2007 through 20 November 2008. The temporal variation of GOME-2 BrO at the SNO locations is very well captured by OMI BrO. Figure 6 is a scatter plot comparison between OMI and GOME-2 BrO. OMI BrO shows excellent agreement with GOME-2 BrO with a correlation of 0.86, and a mean bias of $0.074 \pm 0.70 \times 10^{13}$ molecules cm⁻² (mean relative bias of $2.16 \pm 12.43\%$, with respect to individual GOME-2 BrO). Considering very different retrieval algorithms including different 25 cross sections and BrO profiles, such a good agreement is remarkable. GOME-2 retrievals use the BrO cross sections of Fleischmann *et al.* (2004) while our BrO retrievals use the BrO cross sections of Wilmouth *et al.* (1999). According to the sensitivity studies by Hendrick *et al.* (2009), using the Fleischmann cross section increases the BrO by ~10%. So, accounting for different cross sections, OMI BrO overestimates the GOME-2 BrO by ~10%. In addition, the

GOME-2 algorithm uses a residual technique to estimate tropospheric BrO from measured BrO SCDs by subtracting a dynamic estimate of stratospheric BrO climatology driven by O₃ and NO₂ concentrations and by using two different tropospheric BrO profiles depending on surface albedo conditions. This is very different from the approach of using a single BrO profile on the OMI 5 BrO algorithm, and can contribute to some of the BrO differences. Furthermore, additional algorithm uncertainties in both algorithms and different spatial sampling can also cause some differences.

We also used ground-based zenith-sky measurements of total column BrO at Harestua, Norway 10 (Hendrick *et al.*, 2007) to validate the OMI BrO. We compared daily mean total BrO at Harestua with the mean OMI BrO from individual footprints that contain the location of Harestua site. Figure 7 shows the time series of the comparison between OMI total BrO and Harestua total, stratospheric, and tropospheric BrO from February 2005 through August 2011 with the scatter 15 plot of comparing total BrO shown in Fig. 8. Ground-based total/stratospheric BrO shows an obvious seasonality with high values in the winter/spring and low values in the summer/fall. Such seasonality is well captured by the OMI BrO. OMI BrO shows a reasonable good agreement with Harestua BrO with a moderate correlation of 0.46 and a small mean bias of 0.12±0.76×10¹³ molecules cm⁻² (mean relative bias of 3.18±16.30%, with respect to individual Harestua BrO) slightly larger than the values for validation with GOME-2 BrO. From the 20 Harestua data, tropospheric BrO typically consists of 15–30% of the total BrO, larger than what we have assumed in the troposphere. The use of single BrO profile in the OMI BrO algorithm will likely underestimate the actual BrO. Accounting for the uncertainty due to profile shape, OMI BrO will have a larger positive bias relative to Harestua measurements, which can be caused by other algorithm uncertainties and the spatiotemporal differences between OMI and 25 Harestua BrO.

4.2 Global distribution of BrO VCDs

Figure 9 presents the global distribution of monthly mean BrO VCDs for selected months (January, March, June, and September) to show the BrO seasonality for three different years 30 (2006, 2007 and 2012). BrO typically increases with latitude, with minimal values in the tropics

($\sim 2 \times 10^{13}$ molecules cm^{-2}) and maximum values ($\sim 10^{14}$ molecules cm^{-2}) around polar regions especially in the northern hemisphere winter/spring. In the tropics, BrO shows little seasonality.

But at higher latitudes especially polar regions, BrO displays evident seasonality and the seasonality is different between northern and southern hemispheres. In the northern hemisphere,

5 BrO values are larger in the winter/spring and smaller in the summer/fall, and the enhancement is more widespread during the spring. In the southern hemisphere, BrO values are larger in southern hemispheric spring and summer (i.e., September and January) and smaller in the winter. Such global distribution and seasonal variation are generally consistent with previous satellite measurements (*cf.* Chance, 1998; http://bro.aeronomie.be/level3_monthly.php?cmd=map). BrO
10 in the tropics shows consistent zonal distributions with lower values over land and in the intertropical convergence zone. This might be related to the impacts of clouds on the retrievals (e.g., BrO below thick clouds cannot be measured, there are uncertainties in the AMF calculation under cloudy conditions) and will be investigated in detail in future studies. The global distribution and seasonal variation are consistent from year to year, but the distributions from
15 different years disclose some interannual variation. For example, BrO values in 2007 are smaller in January but are larger in March compared to those in 2006. Although OMI data since 2009 have been seriously affected by the row anomaly at certain cross-track positions, the monthly mean data derived from good cross-track positions are hardly affected by the row anomaly as shown from the very similar global distribution and seasonality in 2012.

20 4.3 Great Salt Lake BrO

Salt lake BrO was first measured from space by OMI, from the Great Salt Lake and the Dead Sea (Chance, 2006). Elevated BrO over the Dead Sea was earlier observed during an aircraft campaign (Matveev *et al.*, 2001). Seasonal variations of tropospheric bromine monoxide over the Rann of Kutch salt marsh have been observed using OMI from an independent research BrO
25 product (Hörmann *et al.* 2016). The active bromine compound release is due to the reaction between atmospheric oxidants with salt reservoirs. Figure 10 shows an example of monthly mean BrO over the U.S. Great Salt Lake in February 2013. BrO enhancement of $\sim 5-10 \times 10^{12}$ molecules cm^{-2} over background values is clearly shown right over this salt lake. BrO over other salt lakes and the spatiotemporal distribution of BrO over various salt lakes will be investigated in further
30 studies.

4.4 Observations of BrO from the Eyjafjallajökull volcano

The first volcanic BrO measured from space was from the Ambrym volcano, measured by OMI (Chance, 2006). Theys *et al.* (2009) reported on GOME-2 detection of volcanic BrO emission after the Kasatochi eruption. Bobrowski *et al.* (2003) made the first ground-based observations 5 of BrO and SO₂ abundances in the plume of the Soufrière Hills volcano (Montserrat) by multi-axis DOAS (MAX-DOAS). BrO and SO₂ abundances as functions of the distance from the source were measured by MAX-DOAS in the volcanic plumes of Mt. Etna in Sicily, Italy and Villarica in Chile (Bobrowski *et al.*, 2007). The BrO/SO₂ ratio in the plume of Nyiragongo and Etna was also studied (Bobrowski *et al.*, 2015).

10

The top panels of Fig. 11 show daily average operational BrO VCDs from the eruption of the Eyjafjallajökull volcano on May 5 and 17, 2010, respectively. Enhanced BrO values of $> 8.0 \times 10^{13}$ are detected in the vicinity of this volcano (e.g., plume extending southeast ward from the volcano on May 5 and, high BrO over Iceland on May 17). Some of these enhanced BrO 15 values correspond to the locations of enhanced SO₂ as shown from the NASA global SO₂ monitoring website (<https://so2.gsfc.nasa.gov/>). This enhancement of BrO is not related to the seasonal variation of BrO as no such BrO enhancement is detected over Eyjafjallajökull during May 5-17, 2011 (a year after the eruption), with BrO values of only up to $\sim 5.3 \times 10^{13}$ molecules cm⁻² (not shown). The bottom panels of Fig. 11 show the same BrO retrievals except with the 20 latest SO₂ cross sections by Vanaele et al. (2009). Using the improved SO₂ cross sections increase the BrO over a broader area on both days, supporting that the choice of SO₂ cross sections can affect the BrO retrievals as discussed in Section 3.6. However, BrO enhancement around the volcano can still clearly be seen with the improved SO₂ cross sections. This suggests 25 that this BrO enhancement is not due to aliasing of SO₂ as BrO, but real BrO from the volcanic eruption.

5 Conclusions

This paper described the current operational OMI BrO retrieval algorithm developed at SAO and the corresponding V3.05 OMI total BrO (OMBRO) product in detail. The OMI BrO retrieval algorithm is based on nonlinear least-squares direct fitting of radiance spectra in the spectral

range 319.0–347.5 nm to obtain vertical column densities (VCDs) directly in one step. Compared to previous versions of two-step algorithms, the fitting window was moved to shorter wavelengths and the spectral range was increased to reduce the fitting uncertainty. Because air mass factors (AMFs) vary significantly with wavelengths as a result of significant variation of
5 ozone absorption, the wavelength and surface albedo dependent AMF, which is precomputed with the Linearized Discrete Ordinate Radiative Transfer (LIDORT) code using a single mostly stratospheric BrO profile, is applied pre-fit to BrO cross sections for direct fitting of VCDs. Prior to the spectral fitting of BrO, wavelength calibration is performed for both irradiance and radiance at each cross-track position and reference spectra are properly prepared at the radiance
10 wavelength grid. Then radiances are modeled from the measured solar irradiance, accounting for rotational Raman scattering, undersampling, attenuation from BrO and interfering gases, and including additive and multiplicative closure polynomials, and the average fitting residual spectrum. To maintain consistency with previous versions, a second fitting of all OMI spectra is performed with unmodified BrO cross sections to derive SCDs and the effective AMFs. Then a
15 destriping step is employed to reduce the cross-track dependent stripes.

The uncertainties of BrO VCDs included in the data product include only spectral fitting uncertainties, which typically vary between 4 and 7×10^{12} molecules cm⁻² (10–20% of BrO VCDs, could be as low as 5% over BrO hotspots), consistent throughout the data record. The
20 uncertainties vary with cross-track positions, from $\sim 7 \times 10^{12}$ at nadir positions to $\sim 4 \times 10^{12}$ at edge positions. The use of single stratospheric BrO profile is another source of uncertainty, overestimating AMFs and therefore underestimating BrO VCDs for conditions with enhanced BrO in the lower troposphere. In addition, the used SO₂ cross sections are a sub-optimum choice and can cause errors in the retrievals under high SO₂ concentrations.

25

We compared OMI BrO VCDs with BIRA/GOME-2 BrO observations at locations of simultaneous nadir overpasses. OMI BrO shows excellent agreement with GOME-2 BrO with a correlation of 0.86, and a mean bias of $0.074 \pm 0.703 \times 10^{13}$ molecules cm⁻² (mean relative bias of $2.16 \pm 12.43\%$). We also compared OMI BrO with ground-based zenith-sky measurements of
30 total BrO at Harestua, Norway. This BrO seasonality in Harestua total BrO is well captured by the OMI BrO and OMI BrO shows a reasonable good agreement with a moderate correlation of

0.46 and a small mean bias of $0.12 \pm 0.76 \times 10^{13}$ molecules cm^{-2} (mean relative bias of $3.18 \pm 16.30\%$). The global distribution and seasonal variation of OMI BrO are generally consistent with previous satellite measurements. There are small values in the tropics with no much seasonality, and large values at high latitudes with distinct seasonality. And the seasonality
5 is different between the northern and southern hemisphere, with larger values in the hemispheric winter/spring (spring/summer) and smaller values in summer/fall (winter) for the northern (southern) hemisphere. This spatiotemporal variation is generally consistent from year to year and is hardly affected by the row anomaly, but does show some interannual variation. The retrievals show enhanced BrO of $5-10 \times 10^{12}$ molecules cm^{-2} over U.S. Great Salt Lake, and also
10 significant enhancement from the eruption of Eyjafjallajökull volcano despite BrO retrievals under high SO_2 conditions can be affected by the current use of a sub-optimal choice of SO_2 cross sections.

For the next version, we will update the SO_2 cross sections, test the inclusion of $\text{O}_2\text{-O}_2$ cross
15 sections, optimize the spectral fitting including investigating and mitigating the interference of H_2CO on BrO retrieval. We will also improve the AMF calculation accounting for clouds and ozone and consider the use of model-based climatological BrO profiles. The second step of spectral fitting to derive SCDs and effective AMFs will be removed as the effective AMFs can be derived from wavelength dependent AMFs.

5 **Table 1. Fitting window and parameters used to derive BrO vertical column densities**

Parameter	Description/value
Fitting window	319.0 - 347.5 nm
Baseline polynomial	4th order
Scaling polynomial	4th order
Instrument slit function	Hyper-parameterization of pre-flight measurements, Dirksen <i>et al.</i> , 2006
Wavelength calibration	Spectral shift (no squeeze)
Solar reference spectrum	Chance and Kurucz, 2010
BrO cross sections	Wilmouth <i>et al.</i> , 1999, 228K
H ₂ CO cross sections	Chance and Orphal, 2011, 300K
O ₃ cross sections	Malicet <i>et al.</i> , 1995, 218K, 295K
NO ₂ cross sections	Vandaele <i>et al.</i> , 1998, 220K
SO ₂ cross sections	Vandaele <i>et al.</i> , 1994, 295K ¹ Hermans <i>et al.</i> , 2009; Vandaele <i>et al.</i> , 2009, 295K ²
OCIO cross sections	Kromminga <i>et al.</i> , 2003, 213K
Molecular Ring cross sections	Chance and Spurr, 1997
Undersampling correction	Computed on-line, Chance <i>et al.</i> , 2005
Residual (common mode) spectrum	Computed on-line between 30°N and 30°S

1. Used in the current operational algorithm.
2. Used for testing sensitivity to SO₂ cross sections and will be used in the next version.

Figures and Figure Captions

5

Figure 1. Cross sections used in the current operational BrO algorithm except for the lower SO₂ cross section at 298 K, which is to be used in the next version. The black lines are the original cross sections, the red lines show the cross sections convolved with OMI slit function (which is assumed to be a Gaussian with 0.42nm), and the green line is the BrO cross section after multiplication with the wavelength-dependent AMFs (albedo = 0.05, SZA = 5.0°, and VZA = 2.5°). For visualization, the cross sections are arbitrarily scaled and positioned.

10
15

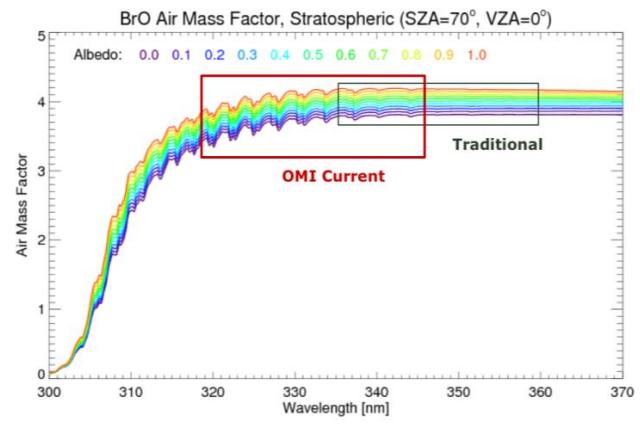

Figure 2. Wavelength- and albedo-dependent AMFs with the fixed BrO profile. The blue box shows the typical fitting window (e.g., used in our previous versions), and the red box shows the new fitting window in the current operational algorithm.

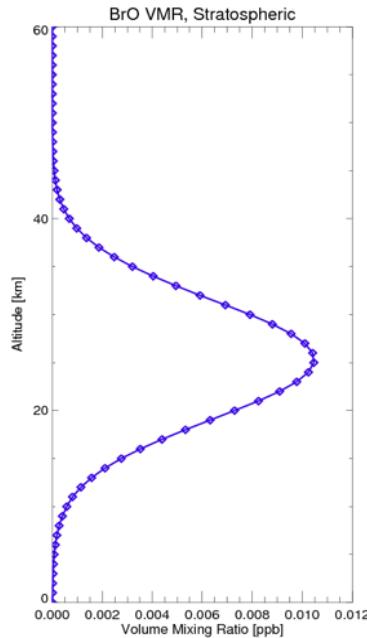

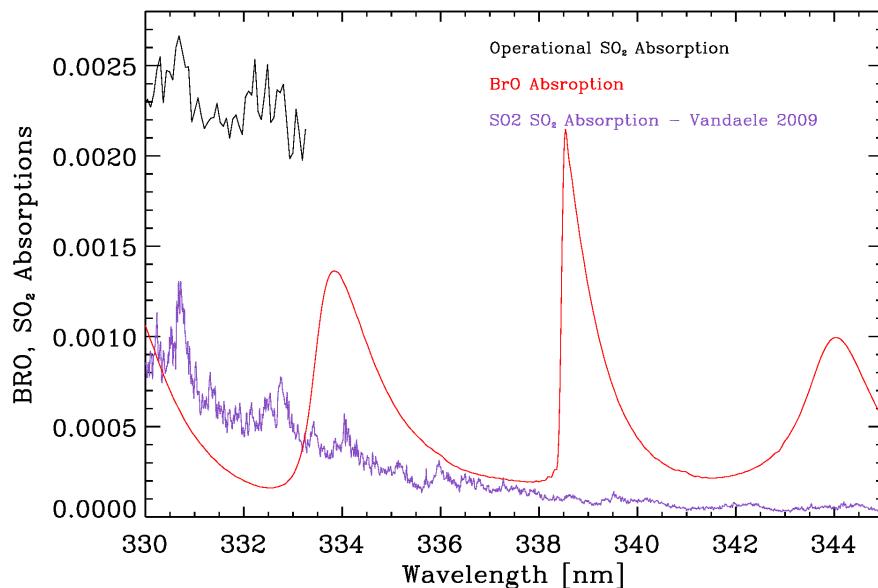

Figure 3. A mostly stratospheric vertical BrO profile used for AMFs. Total BrO, BrO < 15 km, BrO < 10 km, and BrO < 5 km are 1.55×10^{13} , 5.06×10^{12} , 1.55×10^{12} , and 2.87×10^{11} , respectively.

5 **Figure 4.** Comparison of BrO absorption (red) and SO₂ absorptions under volcanic scenarios based on cross sections used in the operational algorithm (Vandaele et al., 1994) as shown in black and the recent laboratory cross sections (Vandaele et al., 2009) as shown in purple. For BrO, a SCD of 1.0×10^{14} molecules cm⁻² is assumed; for SO₂, a SCD of 15 Dobson Units (i.e., 4.03×10^{17} molecules cm⁻²) is assumed.

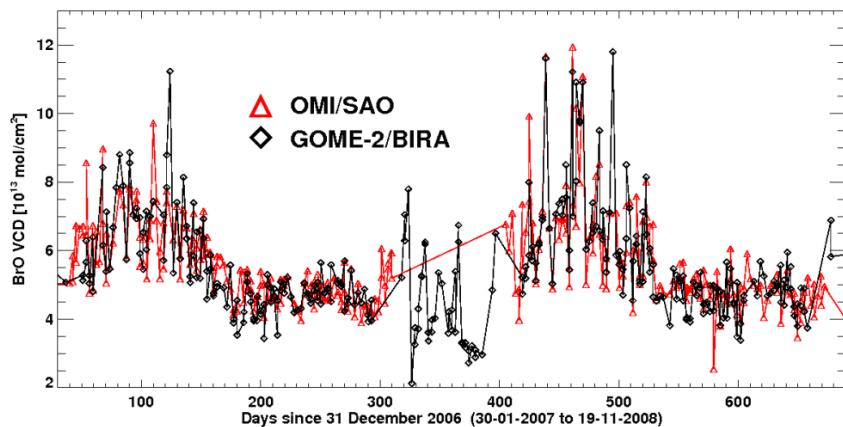

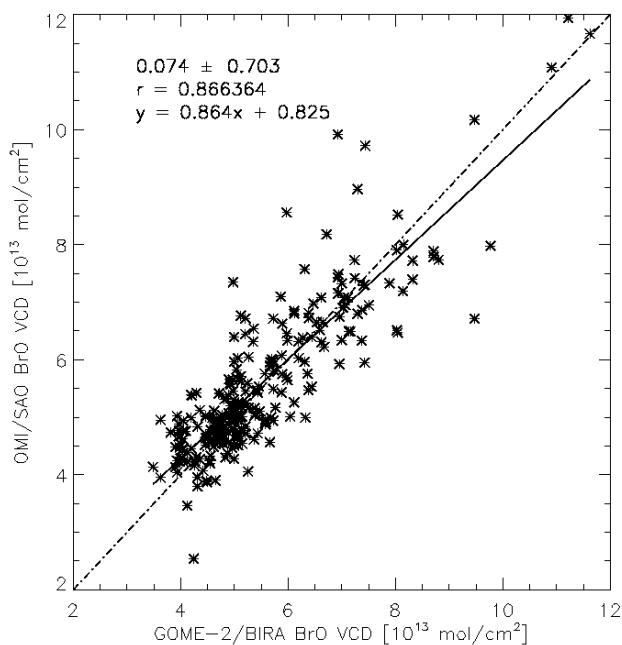

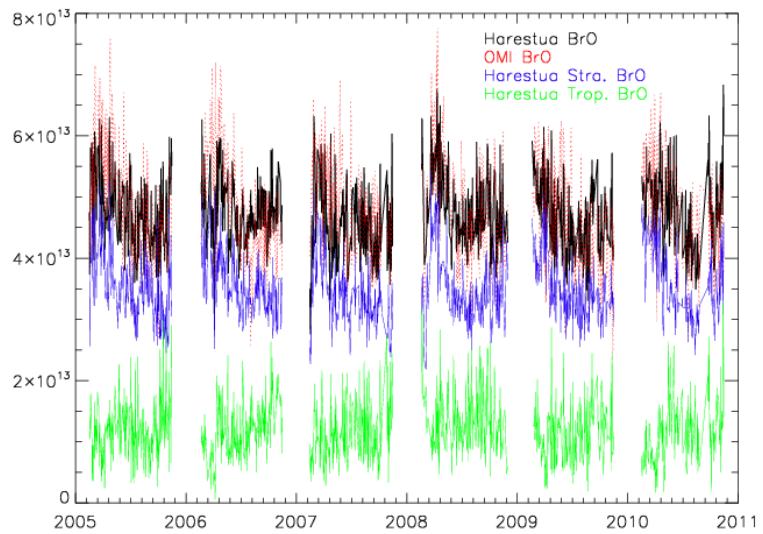

Figure 5. Time series comparison of SAO OMI (red) BrO and BIRA GOME-2 (black) BrO VCDs from February 2006 to November 2008 using simultaneous nadir overpasses (SNO) within 2 minutes between OMI and GOME-2 observations. OMI data are averaged within $\pm 2^\circ$ longitude/latitude and GOME-2 are from individual measurements.

5

10 **Figure 6.** Scatter plots of OMI and GOME-2 BrO for the data in Fig. 5 when both data are available. The legends show the mean biases and standard deviations of the differences, correlation, and the linear regression.

5 **Figure 7. Time series of comparison of ground-based zenith-sky total (black), stratospheric (blue), and tropospheric (green) BrO at Harestua, Norway and coincident SAO OMI BrO (red) from February 2005 through August 2011.**

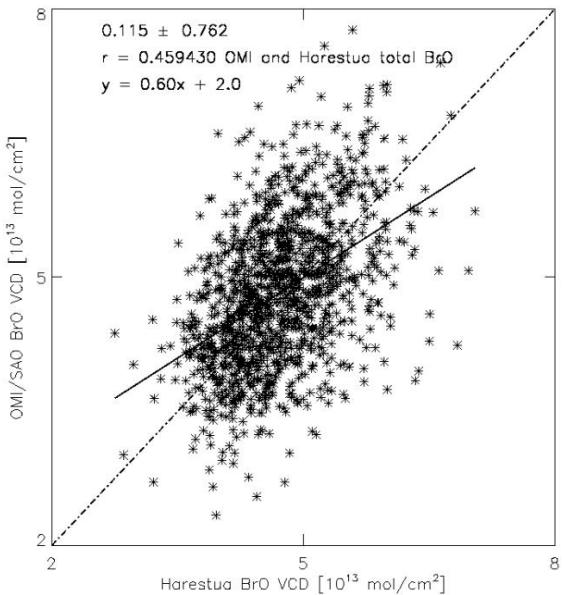

Figure 8. Scatter plots of OMI and Harestua BrO for the data in Fig. 7. The legends show the mean biases and standard deviations of the differences, correlation, and the linear regression.

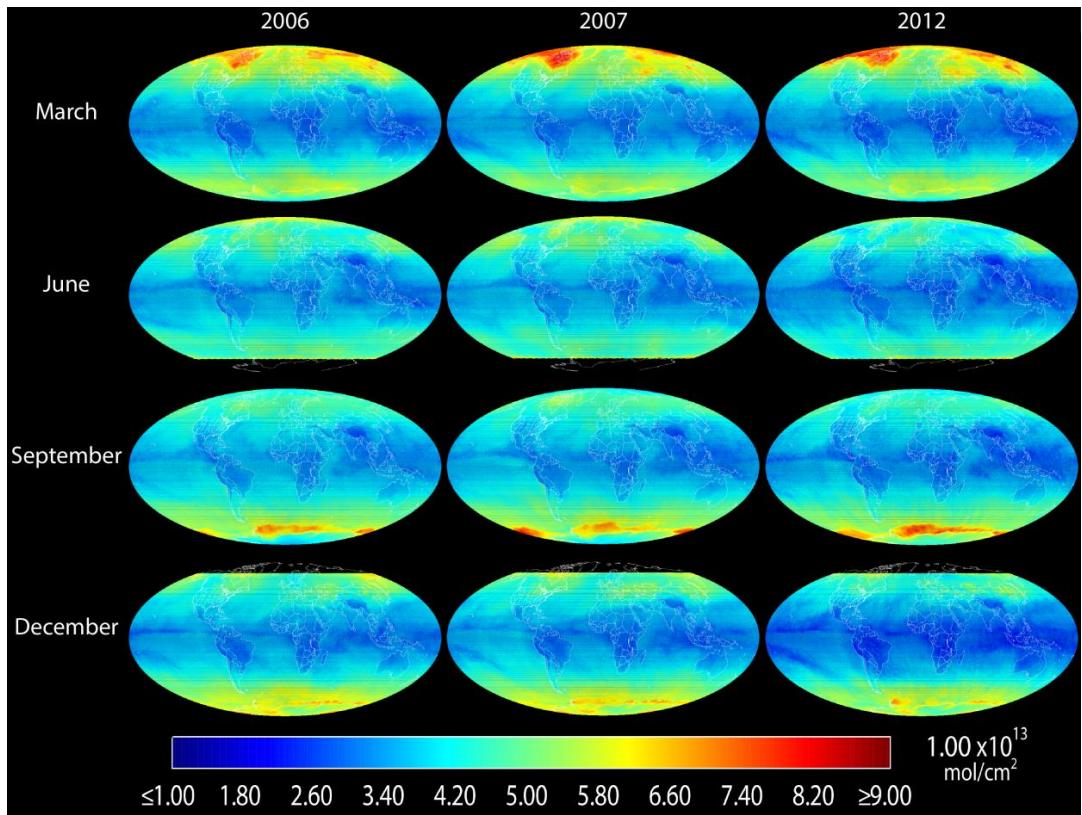

Figure 9. Global distributions of monthly mean BrO VCDs in March, June, September and December (in different rows) of 2006, 2007, and 2012 (different columns).

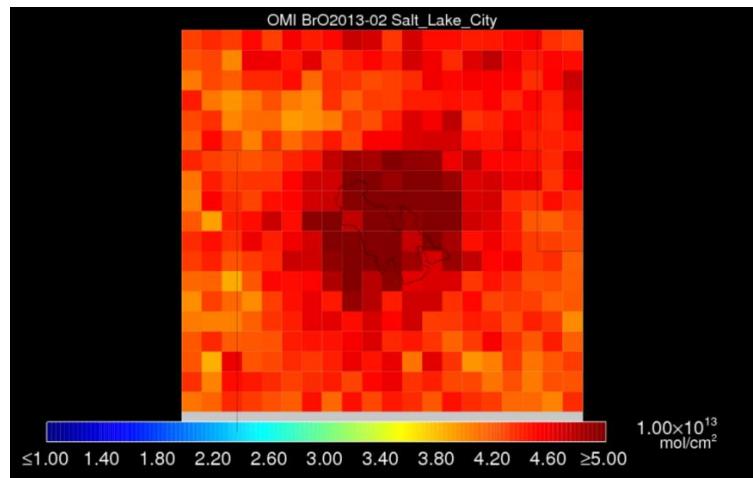

Figure 10. Monthly mean BrO VCD over the U.S. Great Salt Lake for February 2013.

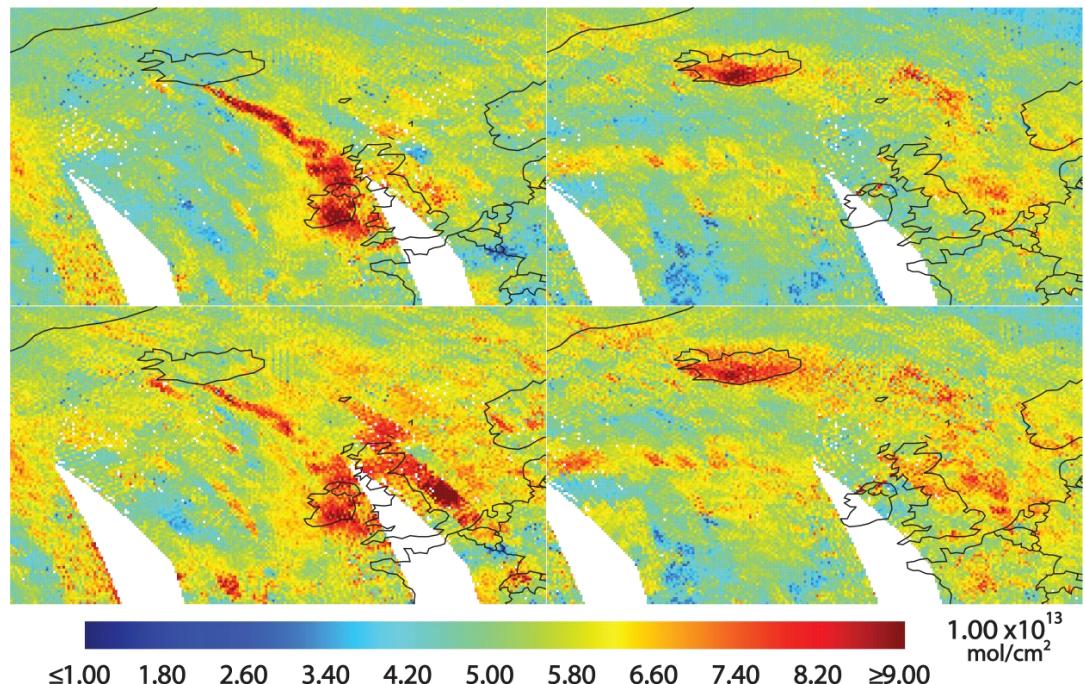

Figure 11. Daily average BrO VCDs from Eyjafjallajökull on May 5 and 17, 2010 produced using (top) the operational SO₂ cross sections and (bottom) the Vandaele et al. (2009) SO₂ cross sections.
