12 **Abstract**

13 LIDAR technology has been rapidly advancing over the past several decades. It can be used to
14 measure a variety of atmospheric constituents at very high temporal and spatial resolutions.
15 While the number of LIDARs continues to increase worldwide, there is generally a dependency
16 on an operator, particularly for high-powered LIDAR systems. Environment and Climate
17 Change Canada (ECCC) has recently developed a fully autonomous, mobile LIDAR system
18 called AMOLITE (Autonomous Mobile Ozone LIDAR Instrument for Tropospheric
19 Experiments) to simultaneously measure the vertical profile of tropospheric ozone, aerosol and
20 water vapor (night time only) from near ground to altitudes reaching ten to fifteen kilometers.
21 This current system uses a dual laser, dual LIDAR design housed in a single climate-controlled
22 trailer. Ozone profiles are measured by the Differential Absorption LIDAR (DIAL) technique
23 using a single 1 m Raman cell filled with CO₂. The DIAL wavelengths of 287 nm and 299 nm
24 are generated as the second and third Stokes lines resulting from stimulated Raman scattering
25 of the cell pumped using the fourth harmonic of a Nd:YAG laser (266nm). The aerosol LIDAR
26 transmits three wavelengths simultaneously (355 nm, 532 nm and 1064 nm) employing a
27 detector designed to measure the three backscatter channels, two nitrogen Raman channels (387
28 nm and 607 nm), and one cross-polarization channel at 355 nm. In addition, we added a water
29 vapor channel arising from the Raman-shifted 355nm output (407nm) to provide nighttime
30 water vapor profiles. AMOLITE participated in a validation experiment alongside four other

1 ozone DIAL systems before being deployed to the ECCC Oski-ôtin ground site in the Alberta
2 Oil Sands region in November 2016. Ozone was found to increase throughout the troposphere
3 by as much as a factor of 2 from stratospheric intrusions. The dry stratospheric air within the
4 intrusion was measured to be less than 0.2 g/kg. A biomass burning event that impacted the
5 region over an eight-day period produced LIDAR ratios of 35 to 65 sr at 355 nm and 40 to 100
6 sr at 532. Over the same period the Angstrom exponent decreased from 1.56 ± 0.2 to $1.35 \pm$
7 0.2 between the 2 to 4 km smoke region.

8

1 **1 Introduction**

2 Tropospheric ozone, aerosols and water vapor are important atmospheric constituents affecting
3 air quality and climate. Ozone is a short-lived climate pollutant (SLCP) and air pollutant that
4 can have detrimental impacts on human health (Malley et al., 2015, Lippmann, 1991),
5 agriculture (McKee, 1994) and ecosystems (Ashmore, 2005) when present at high enough
6 concentrations. Tropospheric ozone is photo-chemically produced primarily from nitrogen
7 oxides and volatile organic compounds (VOCs) from anthropogenic sources, biogenically
8 produced from forest fires (Aggarwal et al., 2017 and Trickl et al., 2015) and can be enhanced
9 through stratospheric/tropospheric transport (STT) events (Ancellet et al., 1991, Langford et
10 al., 1996, Leblanc et al., 2011 and Stohl et al., 1999). Both of these latter sources can have
11 significant impacts on ozone concentration although typically their impacts vary within the
12 vertical distribution of the troposphere. The advantage of ozone DIAL is the ability to measure
13 this vertical column with high enough temporal resolution to understand atmospheric mixing
14 and exchange processes. Along with ozone, the vertical distribution of aerosols and water vapor
15 can also vary considerably throughout the troposphere.

16 Aerosols or particulate matter are tiny particles suspended in the air which contribute to the
17 radiative budget, are a tracer for pollution transport and impact visibility, cloud formation and
18 air quality. They affect the earth's climate by interacting with the sun and earth's radiation
19 (Ramanathan, 2001) and by modifying clouds (Feingold et al., 2003 and Twomey, 1977) and
20 depending on their size and the meteorological conditions can travel over great distances around
21 the globe (Uno et al., 2009). In high enough concentrations these particles can have dramatic
22 effects on visibility (Li et al., 2016 and Singh, 2017) and cause respiratory problems,
23 particularly in those suffering from lung conditions such as asthma. This has been the
24 motivation for several countries to adopt an air quality index (Kousha et al., 2015) to alert the
25 public to respiratory dangers during pollution events. Aerosol backscatter LIDAR systems are
26 uniquely capable of providing the vertical profile of tropospheric aerosols at very high temporal
27 and spatial resolutions and are therefore, ideal instruments to study the transport and optical
28 properties of aerosols. While the vertical distribution of ozone and aerosols can be highly
29 variable throughout the troposphere, water vapor tends to have the highest concentration closest
30 to the surface and throughout the mixed layer.

31 Water vapor plays a pivotal role in climate change and atmospheric stability by directly
32 influencing many atmospheric processes such as cloud formation (Pruppacher and Klett, 1997)

1 and photochemical atmospheric reactions (Yamamoto et al., 1966 and Grant, 1991).
2 Furthermore, tropospheric water vapor is a catalyst to many atmospheric chemical reactions by
3 functioning as a solvent for chemical products of natural and anthropogenic activities (Grant,
4 1991). Also, as the primary greenhouse gas, with strong infrared absorption in the 100-600 cm⁻¹
5 spectral region, water vapor helps to maintain the earth's radiation balance by absorbing and
6 emitting infrared radiation (Twomey, 1991, Clough et al., 1992 and Sinha and Harries, 1995).
7 The high spatial and temporal variability of water vapor throughout the atmosphere makes it an
8 ideal candidate for LIDAR measurements (Vogelmann et al., 2015).

9 The purpose of this paper is to describe a vertical profile measurement system that measures
10 ozone, aerosols and water vapor simultaneously. By employing three different LIDAR
11 techniques - Mie backscatter LIDAR, water vapor Raman LIDAR and ozone DIAL - in one
12 observation platform we are able to explore a synergistic approach to advance our
13 understanding of the trace gas distribution in the lower atmosphere with the eventual goal of
14 supporting development to improve air quality forecasts, diagnostic models and satellite
15 measurements. There are only a few sites that currently exist where all three LIDAR techniques
16 are operated: Garmisch-Partenkirchen (Trickl et al., 2015), Maïdo observatory Reunion Island
17 (Baray et al., 2013) and Observatoire de Haute-Provence (OHP) (Bock et al., 2013, Khaykin et
18 al., 2017 and Gaudel et al., 2015). Several of these sites are high altitude sites that began as
19 stratospheric observatories.

20 The accomplishment here was to develop such a platform to be mobile and to run autonomously
21 providing near continuous observations (except during precipitation events), even in remote
22 areas. Environment and Climate Change Canada (ECCC) has designed and built a fully
23 autonomous, mobile LIDAR system, based on the backbone of an earlier system design
24 (Strawbridge, 2013), named AMOLITE (Autonomous Mobile Ozone LIDAR Instrument for
25 Tropospheric Experiments) to measure the vertical profile of tropospheric ozone, aerosol and
26 water vapor simultaneously. To verify the system's performance AMOLITE participated in a
27 validation campaign known as the Southern California Ozone Observation Project (SCOOP) at
28 the Jet Propulsion Laboratory's Table Mountain Facility in Wrightwood, CA during August,
29 2016. This study brought together five of the six tropospheric ozone LIDARs that form the
30 Tropospheric Ozone LIDAR Network – TOLNet (- [http://www-air.larc.nasa.gov/
31 missions/TOLNet/](http://www-air.larc.nasa.gov/missions/TOLNet/)). In addition to the five LIDARs, ozone sonde balloons were launched
32 throughout the study period. This campaign provided an excellent opportunity to evaluate the

1 ozone profiles produced by AMOLITE. For details of the inter-comparison refer to a separate
2 publication (manuscript in preparation). LIDAR networks (ndacc-lidar.org,
3 mplnet.gsfc.nasa.gov, Papayannis et al., 2008 and Sugimoto et al., 2009) are very important
4 scientific tools that allow the collective benefit of increased geographical coverage (Langford
5 et al., 2018 and Trickl et al., 2016) and can often provide valuable climatological data
6 (Granados-Munoz et al., 2016, Khaykin et al., 2017 and Gaudel et al., 2015). The existence of
7 networks like TOLNet will help to address the need for more ozone profilers in the troposphere
8 as reported in the recent Tropospheric Ozone Assessment Report (TOAR) by Gaudel et al.,
9 (2018).

10 After the validation campaign, AMOLITE was shipped back to Canada where it was made
11 ready for deployment to the oil sands region. The first AMOLITE ozone and water vapor
12 profiles at the Oski-ôtin ground site in Fort McKay, Alberta, were acquired on 3 November
13 2016. In addition to the LIDAR measurements, operation of a windRASS (wind radio-acoustic
14 sounding system – model MFAS, Scintec, Rottenburg, Germany) provides the local
15 meteorological wind fields at 10m vertical resolution from 40 m to typically 500m above
16 ground, directly determining the upwind sources near ground level and aloft over the site.
17 These remote sensors provide a coherent 3D picture of the transport processes impacting the
18 ground site and the region nearby. Also housed in a trailer on site is a chemistry observing
19 platform called CAM1 that has an extensive suite of ground-based instrumentation that
20 continuously measures a variety of gaseous and particulate pollutants. The purpose of this site
21 is to identify the predominant sources impacting the region and the main local-scale
22 atmospheric processes influencing pollutant transport, transformation and deposition. This
23 information will be used to improve our knowledge of what is being emitted and the processes
24 in the atmosphere that affect where the pollutants move and deposit.

25 The focus of this paper will be on the additional development required to add the ozone and
26 water vapor capability to the previous autonomous aerosol LIDAR design developed by ECCC,
27 followed by a brief section on the validation and verification of the instrument and processing
28 algorithms. The fourth section will describe a few case studies acquired throughout the first
29 year of operation at the Oski-ôtin ground site in Fort McKay. The final section will draw
30 conclusions and discuss some future improvements that are currently underway for AMOLITE.

31

1 2 LIDAR technique

2 The AMOLITE instrument uses three different LIDAR techniques to measure different
3 atmospheric constituents: a Mie backscatter LIDAR to measure the vertical profile of aerosol
4 at three different wavelengths, a Differential Absorption LIDAR (DIAL) to measure the vertical
5 ozone profile and a Raman LIDAR to measure the water vapor profile. The Mie backscatter
6 aerosol lidar technique used in AMOLITE, has already been described in detail by Strawbridge,
7 2013. Here we briefly describe the DIAL and Raman LIDAR techniques used for the systems
8 in AMOLITE.

9 2.1 Ozone DIAL Technique

10 Using the DIAL technique, it is possible to retrieve ozone mixing ratios from the backscatter
11 profiles. The technique essentially uses the differential absorption of ozone at two different
12 wavelengths that are relatively close together to minimize aerosol effects, but far enough apart
13 to have a sufficiently large difference in their ozone absorption cross sections. Consequently,
14 the ozone calculation uses the two-wavelength solution of the lidar equation given below
15 (Kovalev et al., 1994):

$$16 \quad N(z) = \frac{-1}{2(\alpha_{on} - \alpha_{off})} \left[\frac{d}{dz} \left[\ln \frac{P_{on}(z)}{P_{off}(z)} - \ln \frac{\beta_{on}(z)}{\beta_{off}(z)} \right] + 2\Delta\sigma(z) + 2 \sum_i \Delta\alpha_i n_i(z) \right] \quad (1) \quad \text{where}$$

17 $\alpha_{on} - \alpha_{off}$ is the differential ozone absorption cross section, $\frac{P_{on}(z)}{P_{off}(z)}$ is the signal ratio, $\frac{\beta_{on}(z)}{\beta_{off}(z)}$
18 is the ratio of the backscatter coefficient at the “on” and “off” wavelengths and $2\Delta\sigma(z)$ is the
19 total two-way extinction coefficient differential, $\Delta\alpha_i$ is the differential cross section of the
20 interfering trace gas and $n_i(z)$ is the number density profile of the interfering trace gas. In our
21 system, 287 nm represents the “on” wavelength and 299 nm represents the “off” wavelength.
22 It is possible to express the backscatter contribution overall to the ozone calculation at the on
23 and off wavelengths based solely on the ratio between the aerosol and molecular backscatter,
24 $B^*(z)$, at some reference wavelength. This is represented by

$$25 \quad \frac{d}{dz} \left\{ \ln \left[\frac{\beta_{on}(z)}{\beta_{off}(z)} \right] \right\} = \frac{d}{dz} \left\{ \ln \left[\frac{1 + B^*(z, \lambda_{ref}) \left(\frac{\lambda_{on}}{\lambda_{ref}} \right)^{4-v}}{1 + B^*(z, \lambda_{ref}) \left(\frac{\lambda_{off}}{\lambda_{ref}} \right)^{4-v}} \right] \right\} \quad (2)$$

26 Where v is the Angstrom exponent representing the wavelength dependence of aerosol Mie
27 backscatter and in our case the reference wavelength is 355 nm. The difficulty arises in

1 determining the Angstrom exponent in regions where the aerosol concentrations are lower and
 2 with enough precision to provide an accurate correction. This point is illustrated for a forest
 3 fire case shown in Section 4.3.

4 **2.2 . Water Vapor Raman Technique**

5 During the early stages of the optical detector design for the aerosol LIDAR, it was determined
 6 that with the addition of a few optics (see Figure 2), that requires very little additional space in
 7 the detector design, it would be possible to measure nighttime water vapor using the Raman
 8 technique on the 355 nm laser wavelength. This would be particularly valuable when
 9 identifying STT events where the dry stratospheric air can be easily identified by the water
 10 vapor LIDAR measurements. Raman scattering is an inelastic quantum-mechanical scattering
 11 process, in which the wavelength of the incident radiation is shifted as a result of the interaction
 12 of the photons with target molecules. The Raman wavelength shift, related to the exciting laser
 13 wavelength (λ_L), is proportional to the distinct ro-vibrational energy levels and provides a
 14 unique fingerprint for each molecule. The Raman scattering process can either involve energy
 15 absorption by the molecule, producing Stokes Raman scattered light with less energy (longer
 16 wavelength) or energy transferred to the molecule, producing anti-Stokes Raman scattered light
 17 with more energy (shorter wavelength). Most atmospheric species are vibrationally active;
 18 resulting in a net Raman shift to longer wavelengths ($\lambda_r > \lambda_L$), which indicates that atmospheric
 19 target molecules gain energy from the radiation field. The most probable Raman shifts for N_2
 20 and H_2O are at 2330.7 cm^{-1} and 3652.0 cm^{-1} , respectively (Whiteman et al., 1992).

21 The ratio between the water vapor and nitrogen Raman signals, yields a mathematical
 22 expression for the dependence of Raman signals ratio on water vapor and nitrogen molecular
 23 density (N_{H_2O} and N_{N_2}), namely

$$\frac{P(z, \lambda_I, \lambda_{H_2O})}{P(z, \lambda_I, \lambda_{N_2})} \propto R \frac{N_{H_2O}}{N_{N_2}} \frac{[d\sigma_{H_2O}/d\Omega]}{[d\sigma_{N_2}/d\Omega]} \exp\left\{-\int_0^z [\alpha(\lambda_{H_2O}, z') - \alpha(\lambda_{N_2}, z')] dz'\right\} \quad (3)$$

26 where R is the proportionality constant dependent on the instrument specifications. This
 27 equation ignores the temperature-dependent functions required for very narrow bandwidth
 28 filters, typically used for daytime operation (see Whiteman, 2003).

1 The water vapor mixing ratio (WVMR denoted as $w(z)$) in grams of water vapor per kilogram
 2 of dry air) as a function of vertical altitude (z) is proportional to the ratio of the number density
 3 of water vapor to nitrogen, and is given by (Goldsmith et al., 1998):

$$4 \quad w(z) = \frac{MW_{H_2O} N_{H_2O}(z)}{MW_{DryAir} N_{DryAir}(z)} \approx \frac{MW_{H_2O} N_{H_2O}(z)}{MW_{DryAir} N_{N_2}(z)/0.78} \approx 0.485 \frac{N_{H_2O}(z)}{N_{N_2}(z)} \quad (4)$$

5 The WVMR equation above can be related to experimentally recorded Raman lidar signals, SG,
 6 by comparing equations. (3) and (4), leading to the following expression,

$$7 \quad w(z) = D \frac{SG_{H_2O}}{SG_{N_2}} \quad (5)$$

8 where D (in g/kg) is a constant depending on instrumental specifications, ratio between N_2 and
 9 H_2O backscattering cross sections, N_2 mixing ratio, and Raman lidar signals extinction due to
 10 the aerosols and air molecules (Dionisi et al., 2009). The D constant is commonly evaluated by
 11 comparison with independent measurement (radiosonde) of water vapor mixing ratio ($w(z)$).

12

13 **3 AMOLITE system design**

14 **3.1 Trailer Design and Infrastructure**

15 The current system described here builds upon the successes of the autonomous aerosol
 16 LIDARS built over the past decade by ECCC (Strawbridge, 2013). AMOLITE uses a
 17 synergistic approach which combines a dual laser (for redundancy), dual LIDAR design
 18 (tropospheric ozone DIAL (Differential Absorption LIDAR and aerosol LIDAR) housed in the
 19 same trailer. In order to accommodate two LIDAR systems, the trailer needed to have a slightly
 20 larger interior footprint of 2.1 m by 4.3 m feet long. A picture of AMOLITE, operating in full
 21 autonomous mode, deployed on a field experiment is shown in Figure 1a. The external
 22 infrastructure of the trailer was very similar to previous designs utilizing a meteorological
 23 tower, precipitation sensor enabled hatch cover, modified vertically-pointing radar interlock
 24 system and the other safety equipment required for operation of a class IV laser. The main
 25 differences in the design were the addition of a second radome to provide safety radar
 26 redundancy, larger hatch opening to allow the operation of two LIDAR receivers
 27 simultaneously and a greatly improved heating and cooling system. The second radar system
 28 allows one to remotely change between radar sources in the event that a system failure occurs.

1 We found that these radomes would typically last between 2 and 4 years. However, when a
2 failure occurs the LIDAR system is shut down for safety reasons until a site visit can be arranged
3 and a new radar system installed. The addition of a second radar reduced system downtime and
4 operational costs. The larger hatch not only is necessary for dual-LIDAR operation, but was
5 also modified to allow the wiper system to operate while the hatch is either open or closed. It
6 was also designed to accommodate exterior blower fans to prevent the accumulation of insects
7 on the window attracted by the UV laser light. The most significant upgrade was the addition
8 of two Mitsubishi Mr. Slim ducted units capable of delivering between 6000 and 24000 BTU
9 of cooling as well as heat units mounted in the duct allowing an operational range of -40C to
10 +40C. The ducting allows for better distribution of cool and warm air, maintaining a much
11 more thermally stable environment throughout all the seasons of operation. The internal
12 infrastructure of the trailer followed the early design of rack-mounted components and a single
13 optical bench. The optical bench layout (see Figure 1b) was large enough to mount both LIDAR
14 systems including the two laser sources per LIDAR. The details of the optical bench layout are
15 discussed in Section 3.2 and 3.3. The main improvements of the trailer infrastructure were the
16 inclusion of a battery-operated propane furnace and charger capable of maintaining trailer heat
17 for at least 48 hours in the event of a power failure. This is particular important should there
18 be a power failure during the winter season, which can leave the trailer without heat for hours
19 at a time causing the laser coolant to freeze, resulting in severe damage to the lasers. The other
20 major change was the analog to digital computer card with a modular Advantech ADAM I/O
21 system with greater flexibility and robustness. These improvements to the trailer infrastructure
22 provided a more stable, reliable environment for improved data quality and uptime.

23 **3.2 Aerosol LIDAR design**

24 Since the aerosol LIDAR design described in Strawbridge, 2013 was the backbone of this new
25 system only the changes will be discussed. The main differences are adding a laser for
26 redundancy and adding an additional transmitted wavelength (355 nm) which in turn added the
27 ability to acquire more particle information and a water vapor channel arising from the Raman
28 shifted 355 nm output (407 nm) to provide night time water vapor profiles. The second identical
29 laser, a Continuum Inlite III Nd:YAG operating at 20 Hz (see Figure 1b), shares the same
30 steering mirror (see Figure 2) as the primary laser and can therefore be engaged remotely by a
31 computer-controlled interface. The folding mirrors and steering mirror are triple-coated (anti-
32 reflection coating at 355 nm, 532 nm and 1064 nm) 50 by 6 mm flat with a high damage

1 threshold, manufactured by Blue Ridge Optics, mounted in a Thorlabs mount with encoded
2 Thorlab actuators to permit remote alignment if necessary. A schematic of the aerosol LIDAR
3 in Figure 2 shows the transmitter beam path and receiver design. The receiver was designed to
4 image the aperture on the photomultiplier tube rather than the field stop. This is necessary to
5 avoid signal modulations due to the inhomogeneous sensitivity of the cathode. The Continuum
6 laser has an output energy of at least 65 mJ at 355 nm, 65 mJ at 532 nm and 100 mJ at 1064
7 nm. The seven-channel receiver (see Figure 2) measures the backscatter at each of the emitted
8 wavelengths as well as the depolarization at 355 nm, the nitrogen Raman channels at 387 nm
9 and 607 nm and the water vapor Raman channel at 407 nm. All of the channels, except the
10 1064 nm channel, use LICEL photomultiplier tubes coupled into a LICEL analog/photon
11 counting transient recorder to increase the dynamic range. The 1064 nm channel is focused
12 onto a Perkin Elmer C30956E avalanche photodiode (APD). The APD incorporates a
13 logarithmic amplifier (25mV rms noise), made by Optech Inc., to increase dynamic range. The
14 amplifier was calibrated prior to the experiment via a transfer function, to convert the signal to
15 a linear scale, in addition to second-order corrections provided by Optech Inc. The signal is
16 directed into a 14-bit, Gage Compuscope computer card. The 1064 nm channel is generally
17 used for qualitative information only because of issues such as APD sag and higher noise
18 background. Both the LICEL transient recorder and Gage computer card were externally
19 triggered by the same Stanford Research delay generator. The collected data is averaged to
20 produce aerosol profiles from 100 m to 15 km agl every minute and water vapor profiles from
21 100 m to 10 km agl every 5 minutes.

22 **3.3 Ozone DIAL design**

23 The ozone DIAL system optical bench layout and detector design is shown in Figure 3. A dual
24 laser design is also used for redundancy and can be engaged remotely by a user-controlled
25 translation stage that moves the folding mirror in and out of the optical axis of the transmitter.
26 The folding mirrors have an anti-reflection coating at 266 nm. The lasers are Continuum Inlite
27 III Nd:YAG operating at 20 Hz with an output energy specification of 45 mJ at 266nm. The
28 laser pumps a 1 m long CO₂-filled Raman cell (Nakazato et al., 2007) manufactured by Light
29 Age. The two 45° mirrors together provide enough adjustment to align the laser beam to the optical
30 axis of the Raman cell. The multi-wavelength output from the Raman cell is directed zenith by
31 a steering mirror that is broadband coated from 266 nm to 320 nm. This 50 mm optic mounted
32 in a Thorlabs mount with encoded Thorlab actuators has a user-controlled interface to permit

1 remote alignment if necessary. The differential pair chosen for the DIAL is the second and
2 third Stokes lines from the Raman conversion, namely 287 nm and 299 nm. The two
3 wavelengths are separated out via the detector block where the signals from the LICEL
4 photomultiplier tubes are directed into a LICEL analog/photon counting transient recorder.
5 Again, the optical design imaged the aperture onto the photomultiplier tube for the same reason
6 discussed in section 3.2. A slight delay is imposed on the DIAL Stanford Research delay
7 generator to minimize cross-talk between the two LIDAR systems. The single telescope design
8 is capable of measuring ozone as low as 400 m above ground level (agl) to altitudes reaching
9 15 km during the night every 5 minutes. It operates 24 hours a day, seven days a week, except
10 during precipitation events. The system is operated remotely and the data are updated hourly to
11 a website providing near real-time capability.

12 **3.4 AMOLITE Ozone DIAL Algorithm and its Validation**

13 The raw data for AMOLITE is acquired every minute with a vertical resolution of 3.75 m. The
14 data is then averaged (10 minutes for color-coded plots and sometimes longer for individual
15 profiles) and processed using a boxcar filter to produce a simple smoothing of the raw data,
16 followed by a second-order Savitzky-Golay convolution to compute the derivative with respect
17 to altitude of the signal ratio and $\frac{\beta_{on}(z)}{\beta_{off}(z)}$. Although the Savitsky-Golay approach may cause
18 issues at the top of the stratospheric ozone profiles (Godin et al., 1999) it does not have as much
19 of a negative impact for tropospheric ozone due to the vertical structure of ozone typically
20 increasing at the top of the profile. This is primarily due to the signal-to-noise ratio being large
21 enough at most altitudes. Alternate, more sophisticated filters are being considered (Leblanc et
22 al., 2016a) and may be implemented in future data versions, but for now all TOLNet LIDARs
23 are using the same approach. The boxcar smoothing used on AMOLITE data is a simple first
24 pass noise removal technique where a centered smoothing window is moved along the lidar
25 signal profile and the average value across the window is calculated for each altitude. The
26 averaged values then become the resulting smoothed profile. The size of the smoothing
27 window starts at 10 bins and increases slightly with altitude (eg. window is 150 at 12 km) to
28 compensate for the higher signal-to-noise ratio encountered at increased range. The ozone data
29 is also dead-time corrected using a value of 4 ns. The background correction was determined
30 by using the average background value calculated over a 10 km range starting at 35 km. For
31 the Rayleigh extinction term we used the formulation described by Equation 2.25 from Kovalev

1 and Eichinger, 2004. Also, the variable ozone cross sections, at the AMOLITE wavelengths,
2 were introduced using the Brion-Daumont-Malicet (BDM) values found in Weber et al., 2016.
3 The BDM values were interpolated onto a 0.01 nm x 0.1 K grid.

4 The ozone data was not corrected for SO₂ interference. There are only a few times during all
5 the time periods presented in this paper where the ground level concentration of SO₂ was above
6 5 ppbv. These events generally only lasted an hour or two and were thought to be associated
7 with the industrial plumes. Unfortunately, we did not have vertical profile information for SO₂
8 which can be highly variable in the lower troposphere and so these data were screened out of
9 the ozone plots. The clouds and regions of high aerosol concentration were also screened out
10 of the ozone plots. Discussions are underway within TOLNet to reach a consensus on how to
11 correct the ozone DIAL profiles when aerosols are present.

12 When undergoing a system validation, it is important to compare the final ozone profiles
13 between DIAL systems and determine whether the differences are instrumental and/or
14 algorithm dependent. As a result, AMOLITE's ozone algorithm was tested against a
15 standardized algorithm developed for the SCOOP validation campaign. The first step required
16 a data importer to be written that could read the simulated data into the AMOLITE algorithm.
17 The simulated data included both the simulated LIDAR data and simulated sonde profiles. Next
18 a boxcar smoothing that is applied to the AMOLITE data was turned off as there is no equivalent
19 in the standardized algorithm. The algorithm testing began by turning off the dead-time
20 correction (saturation), background correction, Savitzky-Golay smoothing, Rayleigh extinction
21 correction and variable ozone absorption cross sections (constant values were used for both
22 wavelengths), leaving only the bare bones ozone calculation. The concept was to use the
23 simulated input in both the AMOLITE and standardized algorithms, comparing the results to
24 the original simulated ozone profile with each algorithm. With all of the above terms turned
25 off, the results matched perfectly after ensuring all unit conversions were done correctly and
26 verified both algorithms were using the same resolution functions. The next test involved using
27 a different simulated ozone profile with saturation turned on. Comparing this to both algorithms
28 with dead-time correction set to 4 ns gave confidence that the algorithms were both handling
29 the saturation effects correctly. The next test involved turning off all the terms except the
30 Rayleigh extinction correction and testing this new simulated ozone product against both the
31 algorithms. Once it was established that both algorithms were calculating the Rayleigh profile
32 from the simulated sonde input, the output matched with less than a 0.05% bias, acceptable and

1 not unexpected from math rounding errors. Proceeding to the next test, all terms were turned
2 off except for the variable ozone absorption cross sections. Here it was important to make sure
3 the wavelengths of the system were taken to sufficient accuracy to minimize errors in the values
4 picked from the standardized look-up table. In our case the wavelength values were set to the
5 AMOLITE DIAL wavelengths of 287.20 and 299.14 nm. Once again with a successful
6 outcome the final test was to turn on random (Poisson) noise and added sky background to the
7 simulated ozone profile. For this final test all the terms were turned off except the background
8 correction and a second-order Savitzky-Golay convolution applied yielding a final result within
9 0.2%. The end result of this testing gave us confidence that the AMOLITE ozone algorithm
10 was performing flawlessly. Details of the results and comparisons to the other TOLNet LIDAR
11 systems will be presented in the SCOOP validation paper (manuscript in preparation).

12 **3.5 AMOLITE Instrument Validation and Calibration**

13 The performance of the ozone LIDAR was evaluated through an inter-comparison study with
14 four other tropospheric ozone LIDARs, all of which are part of TOLNet (Tropospheric Ozone
15 LIDAR Network). The campaign named SCOOP (Southern California Ozone Observation
16 Project) took place at the JPL Table Mountain Facility in Wrightwood, California. This
17 provided an opportunity to compare AMOLITE ozone profiles between other LIDAR
18 instruments and 14 ozone sondes launched during the study. The vertical resolution of the
19 ozone LIDAR was chosen to be range dependent to provide sufficient detail in the lower
20 troposphere as well as providing ozone profile information to altitudes reaching the tropopause
21 where the return signal is significantly weaker. Figure 4 shows the effective range dependent
22 resolution obtained using the algorithm developed by Leblanc et al., 2016a. The left y-axis
23 shows the effective resolution during SCOOP in meters above sea level that was applied to the
24 AMOLITE ozone data in Figure 5. Figure 5a represents a 30-minute average of the LIDAR
25 data starting from the time of the sonde launch at 401 UTC on 10 August 2016 and Figure 5b
26 is also a 30-minute average at 2103 UTC on 16 August 2016. These two profiles were shown
27 to represent the typical results contrasting the range of the ozone DIAL during nighttime and
28 daytime operation. Typically, the DIAL measurements at night will reach a range of over 10
29 km agl and dip to 7 km agl around midday when the solar background is high. The agreement
30 between AMOLITE and the ozone sonde on both days is very good, with the LIDAR generally
31 staying within approximately 10-20% of the ozone sonde values and no obvious bias throughout
32 the profile. There are a few regions, notably around layer transitions, where the difference

1 reaches 50%. This is often due to the difference in vertical resolution of the two instruments.
2 Note the sonde data is plotted at the highest vertical resolution available. It is also important to
3 note that the geophysical separation of the sonde at altitudes of 12 km above sea level is 20-30
4 km for these cases, which can easily account for the larger differences between the sonde and
5 LIDAR as the altitude increases. On some days during the study the LIDAR/sonde agreement
6 varied significantly, particularly at the higher altitudes, due to the large geophysical separation
7 of the two measurements. This is shown in Figure 6 which represents the average of all 14
8 LIDAR/sonde comparisons. The middle panel clearly shows that up to 8 km the lidar agrees to
9 within 5% of the sonde, with larger differences aloft where there are fewer number of
10 coincidences and the geophysical separation with the sonde increases.

11 The entire SCOOP campaign is captured in the false color ozone DIAL plot shown in Figure 7.
12 AMOLITE was the only fully autonomous LIDAR operating during SCOOP. The advantages
13 of a fully autonomous LIDAR system are easily recognized in its ability to capture a continuous
14 dataset throughout the complete diurnal cycle while capturing the dynamics and mixing of long-
15 term events. The ozone DIAL is reaching the lower stratosphere, enabling observations of
16 STT events. The signal-to-noise was affected 11-14 August when there was an air conditioner
17 failure. The outside temperature was reaching over 30 C and the single remaining air
18 conditioner was unable to keep up with the cooling demand of two LIDARs operating
19 simultaneously. A decision was made to turn off the aerosol/water vapor LIDAR for the
20 remainder of the study to focus on the ozone inter-comparison.

21 The two color-coded plots in Figure 8 show the advantage of coincident measurements of ozone
22 and water vapor. In this case a stratospheric intrusion which starts just after 1200 UTC on 10
23 August, descends to approximately 4 km above sea level and persists for over three days. The
24 water vapor plot (see Figure 8b), even though it represents night time measurements only,
25 clearly shows the very dry air coincident with the high ozone concentrations of the stratospheric
26 intrusion. The water vapor measurements below 4 km on 10 August show very dry air (and
27 high ozone values) which may also represent a prior stratospheric intrusion, followed by a more
28 defined boundary layer with an increase in water vapor, more typical of boundary layer air.
29 The water vapor channel was calibrated as described by Al Basheer et al., 2015 using the
30 SCOOP radiosonde data.

31

32

1 **3.6 AMOLITE Ozone Uncertainty**

2 An uncertainty in the ozone concentration from AMOLITE can be calculated mathematically
3 for several components. For consistency with other DIAL systems within TOLNet, the
4 uncertainty calculation was based on the paper by Leblanc et al., 2016b. For a detailed
5 description of the mathematical formulations please refer to that paper. In brief, the total
6 uncertainty determined for AMOLITE (eg. See Figures 5 and 6) was based on six different
7 components: uncertainty due to detector noise, uncertainty due to saturation, uncertainty due
8 to the Rayleigh cross-section, uncertainty due to the background calculation, uncertainty due to
9 the ozone cross-section, and uncertainty due to the air number density. To calculate these
10 uncertainties, one must also make estimates of dead time error (estimate 10%), the Rayleigh
11 error (estimate 1%), the sonde pressure uncertainty (estimate 20 Pa) and the temperature
12 uncertainty (estimate 0.3K). The AMOLITE uncertainty calculations, for each individual
13 uncertainty, successfully compared to the standardized algorithm uncertainty for a test profile.
14 The altitude at which the AMOLITE ozone profiles get truncated is based on a total uncertainty
15 threshold value chosen to be 15 % based on AMOLITE/sonde comparisons. There is no
16 threshold value set for the ozone false color plots. This can sometimes provide additional
17 context for the existence of layers, particularly at higher altitudes.

18

19 **4 AMOLITE: Oski-ôtin Measurements**

20 After the SCOOP campaign, AMOLITE was transported back to ECCC's Centre For
21 Atmospheric Research Experiments where the air conditioning unit was repaired and routine
22 maintenance was done on the instrument to prepare it for deployment to the oil sands region in
23 northern Alberta. AMOLITE started collecting the full suite of data products on 3 November
24 2016. The instrument has run fully autonomous, collecting a year's worth of consecutive data
25 except for a couple of weeks in July when the instrument was down for a service visit due to a
26 laser failure, and two shorter periods of time for routine maintenance requirements. During the
27 first year of operation, the autonomous ozone, aerosol and water vapor LIDAR measurements
28 provided a near continuous dataset, observing the impact of many atmospheric processes and
29 transport over a range of scales and altitudes. The following sections give examples of three
30 selected periods throughout the year showing the impact of long-range transport events,
31 atmospheric dynamics and local industrial sources as well as seasonal variability.

1 **4.1 6-13 November 2016**

2 Stratospheric intrusions were frequently observed throughout the year, with sometimes three
3 or four occurrences per week. In recent years, there has been more understanding about the
4 mechanism that enables these STT events (Langford et al., 2018). However, there is still very
5 little data on the frequency and magnitude of these events and their impact on the tropospheric
6 ozone budget. For example, Figure 9 shows three false-color plots of ozone, water vapor and
7 aerosol backscatter ratio for the bottom 10 km of the atmosphere from 6-13 November 2016.
8 During this week-long period two stratospheric intrusions were observed (and evidence that a
9 third started on the 13 November). The white areas on the ozone plot, represent cloudy regions
10 where the DIAL system is unable to retrieve ozone values. These white areas correlate very
11 well with the cloud regions displayed in the aerosol backscatter ratio plot. The water vapor plot
12 shows dry air (less than 0.2 g/kg) coincident with the higher ozone concentrations of the
13 stratospheric air reaching down into the moist regions more typical of the lower atmosphere.
14 During most of the stratospheric intrusions over the Oski-ôtin site, it was noted that although
15 the free tropospheric ozone levels were increased significantly, the ozone intrusion does not
16 always penetrate the boundary layer and increase surface values.

17 A series of ozone vertical profiles during the stratospheric intrusion between 9-11 November is
18 plotted in Figure 10. This plot shows the ozone concentration before the intrusion (red line)
19 where the typical background value of approximately 30 ppbv is present in the lowest 4 km.
20 As time progresses, one can clearly see the high ozone concentration, reaching 120 ppbv on 10
21 November at 0000 UTC, from the stratospheric transport descending down to lower and lower
22 altitudes. The impact increased the tropospheric budget by almost a factor of 2. Figure 11
23 shows only the lowest 4 km of the ozone plot compared to the ground level observations of
24 ozone and NO_x. There is reasonably good agreement between the ground level measurements
25 and the DIAL measurements around 600m (the lowest few LIDAR bins can be unreliable as
26 they are strongly dependent on the alignment and temperature fluctuations inside the trailer). It
27 is also important to consider the height of the boundary layer (see Figure 12a) which during the
28 winter time can be significantly lower. The ozone/NO_x relationship in Figure 11b is not the
29 typical diurnal relationship that can be observed, in part due to the stratospheric intrusion event,
30 but also due to industrial plume sources impacting the site. For several hours on 7, 8 and 9
31 November the ozone values approach 0. There is an increase in ozone during the daytime hours
32 (solar day is approximately 1400 to 0000 UTC during this period), but also an increase during

1 the night time on 10, 11 and 12 November when the stratospheric intrusion occurred. Figure
2 12 shows the aerosol LIDAR plot for the lowest 4 km along with various chemical and
3 particulate tracers from CAM1. The aerosol LIDAR plot gets down to approximately 100
4 above ground level, which during the winter months is necessary to observe the boundary layer
5 and plume dynamics. There is a good correspondence between the increase in aerosol shown
6 by the LIDAR and the PM_{2.5} trace over the entire period. The increase in particle concentration
7 is linked to the presence of the plume impacting the site. For example, on the 7-9 November
8 and the night of 10 November the aerosol LIDAR observations show an increase in
9 concentration in the lowest 750 m (see Figure 12a) typically of industrial plume sources. As
10 the plume impacts the ground directly, there is a substantial bump in the PM_{2.5} concentration.
11 Figures 12c and 12d also indicate that the air is from an industrial source where the CO₂, CO,
12 CH₄ and sulfur compound concentrations are high. This is the first example where the vertical
13 context given by the LIDAR aids in the understanding of the ground-based measurements.

14

15 **4.2 29-31 August 2017**

16 Another occurrence that can change the ozone budget is forest fires (Jaffe and Wigder, 2012).
17 During the period of 29-31 August, smoke from a forest fire was advected into the region as
18 shown in the MODIS (Moderate Resolution Imaging Spectroradiometer) true color image
19 acquired from the Terra satellite on the 31 August 2017 (see Figure 13). The ozone plot shown
20 in Figure 14a presents a significant amount of ozone in the free troposphere. The enhanced
21 ozone signature on 29 August is from a stratospheric intrusion whereas the enhanced ozone on
22 30 and 31 August is a result of forest fire smoke. The extent of the forest fire smoke is shown
23 by the large aerosol burden in Figure 14b coincident with the ozone as well as the depolarization
24 ratio plot in Figure 14c, showing a value of about 5%, consistent with other smoke plume
25 measurements (Aggarwal et al., 2017).

26 The diurnal cycle of ozone over three days are shown in Figure 15b with increased ozone due
27 to the smoke impacting the surface around 00 UTC 31 August, from what we hypothesize to be
28 enhancement from the forest fire. In Figure 15a a series of ozone traces at different altitudes
29 from the DIAL measurements are plotted against the ground ozone values. In this plot the
30 ozone aloft tracks the ground level ozone quite well until the ozone enhanced air from the forest
31 fire smoke begins to descend over the site. The noisy ozone values around the 1000m level are

1 a result of an error in ozone when the aerosol concentrations were very high (see Figure 14 (a)
2 and (b) around 1500 UTC to 1700 UTC on 31 August). There is also evidence that the smoke
3 impacted the surface from 00 UTC – 1800 UTC on August 31st shown in Figure 15c-15e where
4 an increase in H₂S, PM_{2.5} and CO also occur. An alternative way to plot aerosol LIDAR data
5 is to plot extinction coefficients instead of backscatter coefficients. Since we are measuring the
6 nitrogen Raman channel during the night time, we can calculate the backscatter coefficient,
7 extinction coefficient and extinction-to-backscatter ratio also known as the S ratio. The S ratio
8 is a useful quantity for determining the air type (see Strawbridge, 2013). The three-panel plot
9 in Figure 16 shows the 355 nm backscatter coefficient, extinction coefficient and S ratio for
10 300 UTC to 1200 UTC (night time) on 31 August 2017 using 10-minute average data. The
11 near field overlap is corrected and the data are plotted in kilometers above mean sea level (msl),
12 primarily because the atmospheric density obtained from sonde data is also relative to msl. The
13 white noisy regions aloft on the extreme left and right are artifacts due to the increase in sky
14 background. The backscatter coefficient plot reveals the dynamic nature of the smoke plume
15 between 1 to 5 km and a cirrus cloud layer between 8.5 to 11 km. The extinction coefficient
16 plot is useful because one can directly relate it to aerosol optical depth by integrating along the
17 altitude range. The S ratio plotted as a 10-minute average shows extraordinary detail within
18 the smoke plume with values ranging approximately from 40 to 65 sr. These values are
19 consistent with the value of 45 to 65 sr reported by Barbosa et al. (2014) and are consistent with
20 several other observations provided in Table 3 of Ortiz-Amezcuca et al. (2017). Figure 16 also
21 shows the boundary layer aerosols with an S ratio of 20 to 35 sr, indicative of larger particles
22 in the moist boundary layer air (see water vapor plot in Figure 14d) and 10 to 15 sr in the cirrus
23 cloud. Figure 17 shows a one-hour average taken between 800 UTC and 900 UTC. For highly
24 variable conditions such as a forest fire plume, the one-hour average may result in
25 underestimating the maximum S value. It is also very difficult to measure the S value in the
26 free troposphere when there is very little aerosol present, such as in this case. Those values will
27 be very noisy and have been discriminated out of the dataset shown here.

28 **4.3 4-9 September 2017**

29 The ozone plot for 4-9 September 2017 (see Figure 18a) shows several processes occurring
30 throughout the entire altitude range. There is a stratospheric intrusion on 4 September that
31 extends into 5 September (see dry air in Figure 18d). The increased ozone in the free
32 troposphere from 6-9 September is due to the forest fire activity being advected back into the

1 region. The forest fire smoke is clearly visible in the aerosol backscatter plot (see Figure 18b)
2 and the depolarization ratio plot (see Figure 18c). There is also a fairly dominant feature
3 between 800 m – 2200 m where the ozone values reach very close to 0. There are also time
4 periods where these near 0 ozone features appear to reach closer to ground level (1200 UTC on
5 each day during the 4-7 September period).. This is also shown in Figure 19a where the ozone
6 values from the DIAL at 500 m, 700 m and 900 m are plotted against the ground level ozone.
7 The very low surface ozone around 1200 UTC on 7 September remains low well up into the
8 lower troposphere. The ozone data around 1200 UTC on 8 September are an artifact due to the
9 very high aerosol loading and have been removed. The surface ozone levels (see Figure 19b)
10 on 4 September ranged from a low of 10 ppbv around 1200 UTC to 20 ppbv. Figure 20 shows
11 the winds were primarily coming from the north, where there are fewer industrial sources to
12 impact the ground site. However, on 5 September the winds are coming from the south where
13 the industrial sources are impacting the site as shown by the increase in NO_x (see Figure 19b),
14 sulphates (see Figure 19c), PM_{2.5} (see Figure 19d) and CO₂ (see Figure 19e).

15 The ground level ozone increased to 70 ppbv around 1800 UTC on 7 September and dropped
16 to 50 ppbv around 300 UTC on 8 September which was mostly due to the southerly wind (see
17 Figure 20) bringing the industrial plumes to the ground site. The DIAL ozone shows ozone
18 levels reaching 80 ppbv within 500 m of the surface. There is also an increase in SO₄ and CH₄
19 during this time period. The diurnal ozone cycle is very well established throughout this entire
20 study period, except when the elevated ozone from the forest fire smoke is mixed down to the
21 surface starting around 600 UTC on 8 September (note the increase in NO₂, but no NO). The
22 increase in ground level ozone throughout the night time reaches values of up to 35 ppbv. There
23 is also a steep increase in PM_{2.5} levels (from 25 to 50 μgm⁻³) and CO around 1500 UTC on 8
24 September coincident with the LIDAR backscatter ratio plot shown in Figure 18b indicative of
25 an increased concentration of the biomass burning plume impacting the ground site. The wind
26 has also shifted from a southerly flow to eventually a northerly flow. The resultant ozone at the
27 ground is a mixture of local chemistry and ozone rich air transported into the region.

28 A plot of the backscatter coefficient, extinction coefficient and S ratio from 7-9 September (see
29 Figure 21) shows the contrast between the smoke plume on 8 September and the boundary layer
30 aerosols and industrial plume (around 2 km on 7 September). The smoke plume S ratios are
31 slightly smaller (35 to 55 sr) compared to 31 August, likely indicative of more aged smoke (see
32 the one-hour average plot between 1000 UTC and 1100 UTC shown in Figure 22c). The

1 LIDAR ratio, S , can also be calculated for 532 nm. However, there is significantly less signal-
2 to-noise so the 10-minute average false color plots were not produced. A comparison was made
3 for a one-hour average when the smoke plumes that were present on 31 August and 8 September
4 (see Figure 23a and 23b). The S ratio for 532 nm on 31 August ranges between 40 to >100 sr
5 while on 8 September ranges between 40 to 70 sr. These values are consistent with the higher
6 532 nm S ratio values reported in Table 3 of Ortiz-Amezcu et al. (2017). The Angstrom
7 exponent (see Figure 23c and 23d) is inversely related to the average size of the particles. On
8 31 August the Angstrom exponent was 1.56 ± 0.2 between 2 to 4.2 km in contrast to $1.35 \pm$
9 0.2 between the 2 to 4 km 8 September. These values are consistent with what others have
10 reported for biomass burning (see Table 3 by Ortiz-Amezcu et al. (2017)). During this six-day
11 period it would be very difficult to understand the ground measurements without the vertical
12 context of the LIDARs.

13

14

15

16 **5 Conclusions and future work**

17 Environment Canada has successfully designed, built and deployed a fully autonomous ozone,
18 aerosol and water vapor LIDAR system called AMOLTE. The instrument participated in a
19 validation campaign with other tropospheric ozone LIDARs where the continuous operation of
20 AMOLITE provided a unique dataset showing the complete evolution of atmospheric events.
21 The instrument underwent an extensive validation in both the hardware and software algorithm
22 processing to provide confidence in the AMOLITE ozone profiles generated. A comparison
23 with ozone sondes revealed no bias in the AMOLITE ozone profile and typical difference of
24 less than 10 % throughout the altitude range. It was also shown that stratospheric intrusions
25 can have frequent and significant impact on free tropospheric and sometimes even surface
26 measurements. In some cases the ozone concentration at the surface can be increased by a
27 factor of 2. It was also shown that higher ozone levels in forest fire plumes can also impact
28 local air quality. The lidar ratio was also calculated for the forest fire plume and found to range
29 between 35 to 65 sr at 355 nm and 40 to 100 sr at 532 nm. It was also noted that over an eight-
30 day period the S ratio decreased. The average Angstrom exponent went from 1.56 on 31 August
31 to 1.35 on 8 September. The three-LIDAR system provides critical information and vertical
32 context to help interpret ground-based surface measurements. The primary motivation in

1 building AMOLITE, was to collect continuous LIDAR profiles, except during precipitation, to
2 improve our understanding of the impact and extent of long-range transport and other pollution
3 events on air quality at local, regional and national scales. Developing an autonomous LIDAR
4 facility significantly reduces the operational field costs of maintaining on site personnel. The
5 development of the instrument was possible due to recent technological advancements in laser
6 technology and internet-controlled electronics. A sophisticated control program was developed
7 to provide safe operations, extensive system controls and the storage, transmission and display
8 of the data in near real-time. One of the challenges with an autonomous multi-LIDAR system
9 is the large volume of data produced. While the quick look products that are currently produced
10 are very useful to survey data quality and periods of interest in will be necessary to develop
11 algorithms to meet the data archival needs and produce various product data levels. Some of
12 these will include automated cloud screening, aerosol corrections and possibly other derived
13 products such as boundary layer height. The implementation of these algorithms in the future
14 will provide further value for the current location as well as future observation sites.

15 Current plans are underway to add a second telescope to the ozone DIAL to allow
16 measurements closer to the surface. A couple of different designs are being investigated that
17 will fill in the gap between 100 m to 500 m. This is quite important, particularly during the
18 winter months and night time operation, when the boundary layer can often be less than 500 m
19 in height.

20

1 List of Figures:

2

3 Figure 1. (a) A picture showing AMOLITE on location during the SCOOP campaign at Table
4 Mountain in California. (b) A schematic diagram of the dual laser, dual LIDAR design of
5 AMOLITE. Both LIDAR systems are mounted on the same optical bench.

6 Figure 2. A schematic showing the transmitter and receiver of the aerosol and water vapor
7 LIDAR. A detailed optical breakout is shown for the seven-channel detector package. The
8 abbreviations are explained in a separate box in the figure.

9 Figure 3. A schematic showing the transmitter and receiver design for the DIAL ozone system.
10 The abbreviations are explained in a separate box in the figure. Note the translation stage that can
11 be moved to change which laser is used.

12 Figure 4. A plot showing the effective resolution of the DIAL ozone profiles. The MSL scale
13 was used during the SCOOP campaign and the AGL scale was used for the Oski-ôtin data.

14 Figure 5. Three-panel plots showing AMOLITE ozone profile against the sonde profile, the
15 percentage difference between the two profiles and the horizontal sonde distance from the
16 launch site for (a) 401 UTC on 10 August and (b) 2103 UTC on 16 August. Local time is UTC
17 – 7 hours.

18 Figure 6. Three-panel plot showing the average of all AMOLITE and coincident sonde profiles
19 throughout the entire SCOOP campaign. The number of coincident measurements varies with
20 altitude primarily due to the reduced altitude capability of the AMOLITE during daytime
21 operation.

22 Figure 7. False color plot of ozone from AMOLITE during the entire SCOOP campaign. The
23 white areas represent where no ozone data is available due to clouds or high daytime
24 background light.

25 Figure 8. False color plots showing (a) ozone and (b) water vapor for the same time period of
26 10-14 August 2016.

27 Figure 9. False color plots the first 10 km of the atmosphere for (a) ozone (b) water vapor and
28 (c) aerosol backscatter ratio for the period of 6-13 November 2016 at the Oski-ôtin ground site.

29 Figure 10. A plot showing ozone profiles between 9 November and 11 November as the ozone
30 rich stratospheric air descends down into the troposphere.

1 Figure 11. (a) False color plot showing of DIAL ozone from AMOLITE between 6-13
2 November and (b) surface measurements of ozone and NO_x during the same time period.

3 Figure 12. (a) False color plot of aerosol backscatter ratio for the same altitude and time period
4 as Figure 11a. CAM1 surface measurements during the same time period for (b) PM_{2.5} (c)
5 sulphates and (d) CH₄, CO, CO₂ and NO.

6 Figure 13. Terra MODIS true color composite image on 31 August 2017. Note the location of
7 the ground site.

8 Figure 14. False color LIDAR plots for 29-31 August for (a) ozone (b) backscatter ratio, (c)
9 depolarization ratio and (d) water vapor (night time only).

10 Figure 15. (a) DIAL ozone traces at different altitudes compared to surface ozone for the same
11 period as Figure 14. CAM1 surface measurements for same time period of (b) ozone and NO_x
12 (c) sulfur compounds (d) PM_{2.5} and (e) CH₄, CO, CO₂ and NO.

13 Figure 16. Three-panel plot showing the backscatter coefficient , extinction coefficient and S
14 ratio for 31 August.

15 Figure 17. One-hour average between 800 UTC and 900 UTC on 31 August for (a) backscatter
16 coefficient (b) extinction coefficient (c) S ratio (d) effective resolution.

17 Figure 18. False color LIDAR plots for 4 – 9 September for (a) ozone (b) backscatter ratio, (c)
18 depolarization ratio and (d) water vapor (night time only).

19 Figure 19. (a) DIAL ozone traces at different altitudes compared to surface ozone for the same
20 period as Figure 18. CAM1 surface measurements for same time period of (b) ozone and NO_x
21 (c) sulfur compounds (d) PM_{2.5} and (e) CH₄, CO, CO₂ and NO.

22 Figure 20. WindRASS data overlaid on 4-9 September AMOLITE aerosol backscatter ratio
23 plot.

24 Figure 21. False color plots of 4-9 September for (a) backscatter coefficient, (b) extinction
25 coefficient and (c) S ratio.

26 Figure 22. One-hour average between 1000 UTC and 1100 UTC on 8 September for (a)
27 backscatter coefficient (b) extinction coefficient and (c) S ratio. The effective resolution is the
28 same as Figure 17.

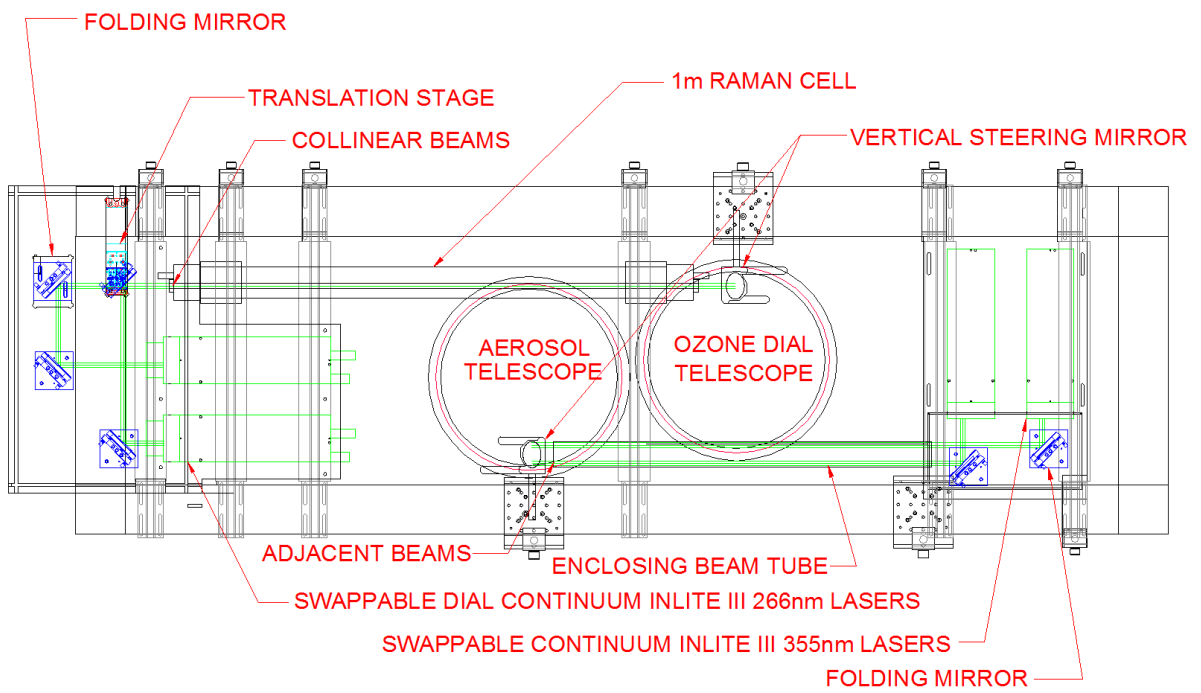

1 Figure 23. (a) S ratio plot of 355 nm and 532 nm for 31 August (b) S ratio plot of 355 nm and
2 532 nm for 8 September (c) Angstrom exponent for 31 August and (d) Angstrom exponent for
3 8 September. Same one-hour averages as Figures 17 and 22.
