

Response to Referee #1

We thank Referee #1 for helpful comments. We have made several changes to our manuscript based on these suggestions. In the following text, the referee's comments are in bold italics, followed by our response. The manuscript with changes tracked follows this response.

1 General comments

The paper describes the retrieval of NO₂ and CH₂O columns and their uncertainties from GCAS instrument during DISCOVER-AQ campaign and compares them with in-situ aircraft and ground-based profile and column observations. The topic of the paper is well within the scope of AMT.

The paper is mostly well structure, but discussions of the results are currently spread over various sections. I suggest adding a “discussions” section at the end of the paper to discuss the large biases between GCAS, Pandora and P-3B in context of the expected uncertainties of the three different datasets.

We have added a section at the end of Section 6 discussing these results. Some earlier text has been moved to this section, and some added for clarity. Please see manuscript for changes to the text.

The description of the retrieval uncertainties is very detailed but does not include uncertainties from the reference columns. Furthermore, the total expected uncertainty of GCAS NO₂ and CH₂O columns due to instrument noise, AMF uncertainties and reference column is not calculated but is important to understand if the results of the comparison are within the expected uncertainties.

We have added a section (Section 4.5.3) on uncertainties from modeled columns used to correct for the reference and model the stratosphere, and have added a section on the total uncertainty (Section 4.5.4).

Furthermore, a calculation of the expected uncertainties from the preparation of the Pandora and P-3B data for comparison with the GCAS columns is also missing. In particular, the effects of cutting and extending the columns using the (uncertain) model data should be calculated.

We have rearranged the P-3B section to discuss the preparation of the columns in its own subsection. We have added the following text to describe uncertainties from the column calculations of the P-3B: “A large source of error from these extrapolations is the inhomogeneity of the trace gas field, which is particularly strong for NO₂ (see Fig. 5 for example), as the lowest mixing ratio could be measured in or out of an area of high NO₂, and is then extended to the ground. Lamsal et al. (2014) estimated errors in the DISCOVER-AQ Maryland P-3B NO₂ columns of generally less than 20 % from extrapolation of the NO₂ profile below ~300 m, assuming a factor of two error in the extrapolation.”

“As CH₂O gradients near the surface tend to be smaller than those of NO₂, the extrapolation error is also likely less significant. P-3B CH₂O columns calculated with an extrapolated model gradient and a direct extrapolation vary by about 5 %.”

“Comparisons of CMAQ and P-3B NO₂ profiles in the free troposphere (3–5 km) suggest a mean absolute error of 70 % in the free troposphere (CMAQ is 10 % higher than the P-3B on average). If we assume similar discrepancies above the highest P-3B altitude, this may lead to an uncertainty of $\sim 2 \times 10^{14}$ molecules cm⁻² in the GCAS column from the removal of the column above the P-3B.”

“The mean absolute error from CMAQ versus P-3B between 2–5 km is 40 %, with much larger biases of ~ 100 % on certain days. We find its removal introduces daily background biases that reduce the overall correlation between P-3B and GCAS observations; as a result, we do not remove the modeled CH₂O above the spiral from the GCAS results in these comparisons. This results in an uncertainty on the order of $1\text{--}3 \times 10^{15}$ molecules cm⁻², depending on the flight.”

We have added the following to the Pandora section: “The uncertainty in the stratospheric NO₂ column in our model is estimated at 30 % (see Section 4.5.3).”.

Finally, the description of the vertical column results (Section 5) is difficult to understand, because the locations of the discussed landmarks are not marked in figures 3 to 6. It would be beneficial to update the figures or provide larger version in the supplement. In summary, I recommend publication of this paper in AMT after minor revision.

We have added landmarks and roads to the summary Figure 1. We have also added the caption “Major roads are shown in yellow. ExxonMobil Baytown and Texas City are large petrochemical and petroleum refinery complexes. The Baytown complex lies near the entrance to the main part of the Houston Ship Channel industrial area, which ends 6.5 km to the east of the downtown.”

2 Specific comments

P8, L4: rename section from “Calibration” to “Spectral calibration”.

Changed in text.

P8, L12-14: The sentence on radiometric calibration can be removed, because it seems not to be relevant to the paper.

We have removed this sentence.

P8, L29: Please add a paragraph about the results of the spectral calibration (wavelength shifts, slit function and their uncertainties) and the impact on the SCD uncertainty.

We have added a paragraph discussing the results. The impact on SCD is discussed in a later section.

P8-9: Sections 4.3 and 4.4 could be subsections of 4.2; similar to the subsections of section 4.5

P9, L28ff: Section 4.4 would fit better at the end of section 4.2

We have moved Sections 4.3 and 4.4 to subsections of 4.2 as suggested, and have changed the first paragraph of Section 4.2 to make it a subsection (“Spectral fitting”) for clarity.

P10, L9: The term “differential slant column” should be already introduced in Section 4.2, because it makes the usage of the reference spectrum clearer.

We have modified the sentence slightly and now introduce the definition of the differential slant column: “The retrieved differential slant columns are represented by x_i . These differential slant columns are the differences between the slant columns in the nadir observation of interest and the slant columns in the reference spectrum.”

P11, L8ff: Please state temporal and spatial resolution of the BRDF product.

We have added the following to the text: “This BRDF product is provided at a spatial resolution of 30 arcsec (~0.80 km in longitude by 0.92 km in latitude over Houston) every 8 days, based on 16 days of MODIS measurements.”

P11, L14: Please give a number for “a few percent”.

We have modified this sentence to read:

“These results are typically within 2–3 % of the results derived ...”

P12, L4ff: How large is the SCD uncertainty due to uncertainties in the spectral calibration?

We have added the following sentence to the text: “Uncertainties in the differential slant columns due to uncertainties in the spectral calibration are $\sim 5 \times 10^{13}$ molecules cm^{-2} for NO₂ and $\sim 2 \times 10^{15}$ molecules cm^{-2} for CH₂O.”

P18, L10: Replace “more diffuse” with “nosier”.

Here we mean to describe the spatial features of CH₂O as being more spread out (diffuse) than those of NO₂, but realize this is not clear from the figures. We have removed this part of the sentence and now start the sentence with “Model profile shapes during the spirals...”, and have added the reference to Fried et al. (2016b) which compared the P-3B with CMAQ.

P19, L9: Please give a number for “a few percent”.

To address this comment and a related one by the other reviewer, we have added text and modified this sentence to read:

“When the spiral profiles are applied to the GCAS observations within their vicinity, the use of the observed profiles lowers the overall slope of GCAS tropospheric NO₂ columns by 4 % (P-3B) and 2 % (Pandora) and the CH₂O columns by 2 % (P-3B) as compared with coincident observations. The NO₂ correlations with the P-3B and Pandora remain the same

but the correlation increases to $r^2 = 0.62$ for P-3B CH₂O. Individual coincident observations can change by as much as -50 to +35 % for NO₂ (mean change of +1 +/- 10 %) and -15 to +25 % for CH₂O (mean change of +3 +/- 8 %). The largest mean changes for a single day occur at the Deer Park site in the Pandora comparisons, where the GCAS NO₂ column on 25 September is reduced by 15 % on average on average.”

P20, Figure 7: The figure is very crowded and error bars are not explained for GCAS and missing for P-3B (extrapolation errors?).

These are precision uncertainties, which we forgot to mention. The extrapolation errors are difficult to quantify here (however, for NO₂ they are the subject of another study by colleagues using the in situ ground-based network). We have added the following to the figure caption: “Error bars represent the uncertainty in the GCAS mean column due to retrieval noise from the observations used to calculate a mean column (typically several hundred at 250mx500m resolution); in the case of NO₂, this uncertainty is generally negligible due to low relative error. Column precisions for P-3B observations are approximately 2×10^{13} molecules cm⁻² (NO₂) and 6×10^{13} molecules cm⁻² (CH₂O). Uncertainties from spatial variability and measurement accuracy are discussed in the text.”

P21, L 8-10: The sentence is very vague. Could you provide numbers?

We have changed this sentence to: “More surprisingly, GCAS NO₂ is 50 % (DS) and 33 % (MAX-DOAS) larger at high NO₂ values.” and also added “or from an underestimation of Pandora columns” to the next sentence as this was missing in the original text.

3 Technical corrections

P10, L5: maybe replace “absorber” with “trace gas”

P10, L7: add a “,” after “atmosphere”

These have been changed in the text.

Response to Referee #2

We thank Referee #2 for helpful comments. We have made a number of changes to the paper based on these comments. In the following text, the referee's comments are in bold italics, followed by our response. The manuscript with changes tracked follows this response.

The paper reports results of the first intensive field campaign (Discover AQ, Texas 2013) of GCAS, a compact 2-channel airborne spectrometer. GCAS NO₂ and HCHO retrievals are compared with trace gas columns derived from coincident in situ profile measurements made by instruments on a P-3B aircraft, and with NO₂ observations from ground-based Pandora spectrometers, operating in direct sun and scattered light modes. In a previous paper, Nowlan et al. (2016), preliminary GCAS retrievals were compared with GEOTASO retrievals.

The paper provides a detailed overview of all retrieval steps and comparison with coincident measurements, including uncertainties, reasons for observed differences, etc. The paper contains useful content for the preparation of validation campaigns for the new generation of air quality sensors, such as TEMPO. These campaigns will likely involve GEOTASO, GCAS and profile flights for the airborne segment and Pandora spectrometers for the ground-based segment. The paper fits well within the scope of AMT, is well-written and well-structured. However, some revisions need to be conducted in the paper before publication.

General comments:

-What is a bit missing in the paper is a geophysical interpretation of the acquired data. Typically there were four similar flights per day over the area which provides a good view on the spatial distribution of NO₂ and HCHO. Even if it is beyond the scope of this paper, a section discussing the changes in the trace gas field and possible explanations would be an added-value to the paper. There are a few sentences in Section 5 on this, but it could be more extended.

We have rearranged and expanded Section 5 to provide a better geophysical interpretation of the data. This section now includes a discussion of the meteorology during the campaign, which drove many of the differences in day-to-day and flight-to-flight observed trace gas fields. Please see the revised manuscript for the complete text.

-Secondly, it is not clear to me why profile shapes from CMAQ model output at 4 by 4 km are used for the AMF calculations, while you have NO₂ and HCHO in-situ measurements from P-3B spiral flights available. I can understand this approach for the comparison with P-3B (Sect. 6.1) as you need independent data, but it is not clear why you don't use the P-3B profile shapes instead of CMAQ when comparing to PANDORA spectrometers (Sect. 6.2). I would expect that the CMAQ model does not represent the strong spatial variability of the 3D NO₂ field, which you can expect in

an urban area, something you mention as well in the manuscript (p.14, L.20). On the other hand, the dependency on the profile uncertainty was assessed in 6.1.3, and seems to be small.

This paper describes the GCAS product on the NASA DISCOVER-AQ data archive, and this is the product we wish to validate in the comparisons with the P-3B and Pandora. We use the model to calculate all air mass factors in this product, although scattering weights are also included in case people want to use independent profiles (like the P-3B). We do this for consistency, as there are several stretches of the GCAS flight that do not coincide with P-3B profiles, days that do not have P-3B flights, Pandora sites with no P-3B profiles, and as the P-3B overpasses Houston 3x/day and GCAS typically 4x/day, there are many GCAS observations that do not satisfy our coincidence criteria with the P-3B of 1 hour. To address this and the other reviewer's comment about the P-3B comparisons themselves, we have expanded our section on using the P-3B for GCAS AMFs to include comparisons with Pandora, and made it into Section 6.3 for improved organization.

The text now reads: "In order to assess the dependence of the GCAS observations on the profile uncertainty, we also apply the P-3B profiles in place of model profiles in the GCAS AMF calculations and compare the new GCAS columns with the P-3B and Pandora columns. When the spiral profiles are applied to the GCAS observations within their vicinity, the use of the observed profiles lowers the overall slope of GCAS tropospheric NO₂ columns by 4 % (P-3B) and 2 % (Pandora) and the CH₂O columns by 2 % (P-3B) as compared with coincident observations. The NO₂ correlations with the P-3B and Pandora remain the same but the correlation increases to $r^2 = 0.62$ for P-3B CH₂O. Individual coincident observations can change by as much as -50 to +35 % for NO₂ (mean change of +1 +/- 10 %) and -15 to +25 % for CH₂O (mean change of +3 +/- 8 %). The largest mean changes for a single day occur at the Deer Park site in the Pandora comparisons, where the GCAS NO₂ column on 25 September is reduced by 15 % on average on average."

Specific comments:

P3, L10: Please add: Tack, F., Merlaud, A., Meier, A. C., Vlemmix, T., Ruhtz, T., Iordache, M.-D., Ge, X., van der Wal, L., Schuettmeyer, D., Ardelean, M., Calcan, A., Schönhardt, A., Meuleman, K., Richter, A., and Van Roozendaal, M.: Intercomparison of four airborne imaging DOAS systems for tropospheric NO₂ mapping – The AROMAPEX campaign, Atmos. Meas. Tech. Discuss., <https://doi.org/10.5194/amt-2017-478>, in review, 2018.

We have updated the references to include this paper.

P4, L1: Please mention also explicitly the swath width at this altitude.

We have added: "At a typical flight altitude of 9 km, this results in a swath width on the ground of about 6.7 km." When addressing this comment, we also changed the listed effective full FOV to 41 degrees, instead of the 45 degrees previously listed (which was the design FOV).

P4, L12: Explain shortly the impact of not having a zenith sky reference measurement capability when compared to GEOTASO or ACAM.

We have added the following sentence to the text: “As a result, the reference spectra required by the GCAS trace gas retrievals must be derived from nadir observations over clean areas with relatively low pollution.”

P4, L23: Maybe mention here already that GeoTASO and GCAS were intercompared in the previous paper.

We have added the following sentence: “Preliminary GCAS and GeoTASO NO₂ observations were compared in a previous paper (Nowlan et al., 2016).”

P.5, L1: It would be interesting to mention the main drivers for the chosen flight path in section 3.1. Driven by Sources? Pandora sites?

The flight paths were mainly driven by the location of existing surface air quality sites. We have added the following sentence to the beginning of Section 3: “Flight paths were chosen so that the aircraft passed over eight existing ground sites with surface air quality monitors several times per day, in support of the mission goal of investigating the relationship between trace gas columns and surface air quality.”

P.7, L.8: Please specify the vertical resolution (for the part below the aircraft).

We have added the following sentence to this section: “The model’s vertical resolution ranges from 22 m at the surface to ~200 m at an altitude of 2 km, further increasing to ~650 m by the aircraft flight altitude.”

P.8, L.10: Note that the spectral performance can be affected by in-flight pressure changes as well: See Kuhlmann, G., Hueni, A., Damm, A., and Brunner, D.: An Algorithm for In-Flight Spectral Calibration of Imaging Spectrometers, Remote Sensing, 8, 1017, doi:10.3390/rs8121017, 2016.

GCAS is backfilled with gaseous nitrogen and sealed prior to aircraft integration to mitigate moisture in the instrument. There may be small changes in internal pressure due to temperature differences during flight, but we expect the effects of wavelength changes due these pressure differences are likely fairly minimal compared with the thermal shifts in the instrument. To account for both pressure and thermal shifts, the wavelength shift for each observation is retrieved simultaneously with trace gas columns as described in Section 4. We have added the following to the section on spectral calibration: “Pressure changes within the instrument may also shift the wavelength calibration through changes in the index of refraction (Kuhlmann et al., 2016). These changes are minimized in GCAS and are primarily due to changes in ambient temperature as the instrument is backfilled with gaseous nitrogen and sealed prior to aircraft integration to mitigate moisture. The impact of wavelength shifts on retrievals is further minimized through simultaneous fitting of a wavelength shift for each observation as described in Section 4.2.3.”

P.9, L13: Maybe I missed it but I could not find back the estimated reference spectrum amount. The estimation also affects the VCD uncertainty and should be mentioned in Section 4.7. You mention it as an uncertainty on P. 21, L6.

We have added a discussion of the uncertainty from the reference in Section 4.7, and have added the following text to Section 4.3: “NO₂ above the aircraft is dominated by stratospheric NO₂ and varies primarily by time of day, and ranges between $V \uparrow = 2.3\text{--}3.8 \times 10^{15}$ molecules cm⁻². CH₂O in the model is more variable, with the early part of the campaign (4 to 18 September) seeing levels of $V \uparrow = 2\text{--}25 \times 10^{14}$ molecules cm⁻² and the latter part seeing levels of $V = 1\text{--}3 \times 10^{14}$ molecules cm⁻². For our chosen reference location, the modeled vertical columns below the aircraft are $V_{R\downarrow} = 2.0 \times 10^{15}$ molecules cm⁻² for NO₂ and $V_{R\downarrow} = 7.5 \times 10^{15}$ molecules cm⁻² for CH₂O. The modeled vertical columns above the aircraft at the reference location are $V_{R\uparrow} = 3.6 \times 10^{15}$ molecules cm⁻² for NO₂ and $V_{R\uparrow} = 7.9 \times 10^{14}$ molecules cm⁻² for CH₂O.” and have also added the following to Section 4.3.2 for completeness: “The AMF is calculated scene-by-scene for each nadir observation. The reference spectrum AMFs at the swath center are $A_{R\downarrow} = 1.65$ and $A_{R\downarrow} = 1.92$ for NO₂ and $A_{R\uparrow} = 2.03$ and $A_{R\uparrow} = 2.49$ for CH₂O.”

P.9, L30: Why is the fitting window 420-465 nm for NO₂ and for example not 425-490 nm as proposed by NDACC (for MAX-DOAS instruments)? Please clarify. On p. 3, L27 the wavelength range of the UV/Visible channel is 300-490 nm.

The 420-465 nm fitting window is the same used by GeoTASO (Nowlan et al., AMT, 2016), which we have carried forward for GCAS for consistency. The lower limit is determined by the GeoTASO instrument, whose visible channel starts at 415 nm. The SNR on the first few wavelengths near the edge of the GeoTASO detector is typically low, so we chose 420 nm as a starting point for the retrieval. The 465 nm end point is that used by recent OMI retrievals (van Geffen et al., AMT, 2015). While it is possible to extend the fitting window to 490 nm with GCAS (or something slightly short of that to avoid using the edge of the detector where calibration and SNR can be somewhat poor), nadir viewing NO₂ retrievals typically use a shorter wavelength cut-off to avoid complications from the surface, other absorbers or calibration effects. Richter et al. (AMT, 2011) did successfully extend the GOME-2 fit to 497 nm by including liquid H₂O and sand in the retrieval. We attempted to use their fitting window of 425-497 nm with similar inputs, but the resulting GeoTASO NO₂ retrievals were affected by large background biases (likely due to imperfect instrument calibration in combination with surface effects). As a result, we settled on 420-465 nm, which minimized unphysical biases while providing enough wavelengths for acceptable retrieval precision.

P.11, L8: Please mention the spatial resolution of the MODIS BRDF product.

We have added the following to the text: “This BRDF product is provided at a spatial resolution of 30 arcsec (~0.80 km in longitude by 0.92 km in latitude over Houston) every 8 days, based on 16 days of MODIS measurements.”

P.13, L.5: Please specify the impact of the spatial binning on the uncertainty for HCHO.

We have added the text: “As a result, later in this paper we present CH₂O maps at 1 km² resolution, with an effective precision on the order of 7×10^{15} molecules cm⁻².”. We also changed the caption in Figure 6 to be more specific and consistent with this number.

P. 13, L.32: The aerosol effect is also well explained in Meier, A. C., Schönhardt, A., Bösch, T., Richter, A., Seyler, A., Ruhtz, T., Constantin, D.-E., Shaiganfar, R., Wagner, T., Merlaud, A., Van Roozendaal, M., Belegante, L., Nicolae, D., Georgescu, L., and Burrows, J. P.: High-resolution airborne imaging DOAS measurements of NO₂ above Bucharest during AROMAT, Atmos. Meas. Tech., 10, 1831-1857, <https://doi.org/10.5194/amt-10-1831-2017>, 2017.

We have added this reference to others previously listed.

P.14, L.12: Were there no aerosol instruments on the P-3B aircraft? In case not, it would be a real added-value for future campaigns, as you are already doing the efforts to perform spiral flights for NO₂ and HCHO profiles. A good knowledge of the AOD profiles can indeed drastically decrease the uncertainties on the AMF.

A suite of aerosol instruments was deployed on the P-3B aircraft, measuring aerosol dry size distribution, scattering/absorption coefficient and hygroscopicity. Probably even more useful for GCAS was the inclusion of the HSRL-2 lidar on the B-200 aircraft, along with GCAS. This was mentioned in Section 3.1 but we have now added to the sentence for clarity: “as well as the NASA High Spectral Resolution Lidar-2 (HSRL-2) instrument (Hair et al., 2008) for measuring aerosol profiles below the aircraft.”

While much of the analysis of the Texas campaign is ongoing, the P3B and HSRL measurements have been used together in the following publication: Sawamura, P., Moore, R. H., Burton, S. P., Chemyakin, E., Müller, D., Kolgotin, A., Ferrare, R. A., Hostetler, C. A., Ziemba, L. D., Beyersdorf, A. J., and Anderson, B. E.: HSRL-2 aerosol optical measurements and microphysical retrievals vs. airborne in situ measurements during DISCOVER-AQ 2013: an intercomparison study, Atmos. Chem. Phys., 17, 7229-7243, <https://doi.org/10.5194/acp-17-7229-2017>, 2017.

We have performed a brief analysis using the HSRL AOD profiles to assess the uncertainties in the AMF from aerosols (discussed in Section 4.7.2) using some assumptions about optical properties. We are working on implementing more complete lidar measurements, including optical properties, in our radiative transfer code, and on a study to assess the effects of aerosols on the AMF in more detail using data from this and other campaigns.

P.15,L.27: Specify “near-surface” in order to avoid confusion with surface concentrations.

We have changed the sentence to: “These figures illustrate the typical coverage of P-3B spirals relative to GCAS swaths, as well as the air mass measured in the bottom 2 km of the atmosphere by Pandora DS ground-based instruments.”

P.16, Figure3: Indication of the average wind direction (and speed) could help interpretation or describe in text if too variable (same for the other maps).

We have added two paragraphs in Section 5 describing the wind patterns in the Houston area on the different days of the campaign, and further references that go into details of the meteorology.

P.18, Figure 5: Please explain the reason for missing data. Sometimes a full across-track scanline is missing which is not related to cloud filtering. Are there other filters applied?

These stripes occur when the flight software writes to disk. We have added the following line to the figure caption: “Periodic cross-track gaps in the data are due to write-to-disk intervals of the instrument. During these periods, the instrument does not acquire data thus producing small gaps in coverage.”

P.20, Figure 7b: Error bars not explained in text?

We have added the following to the figure caption: “Error bars represent the uncertainty in the GCAS mean column due to retrieval noise from the observations used to calculate a mean column (typically several hundred at 250 m x 500 m resolution); in the case of NO₂, this uncertainty is generally negligible due to low relative error. Column precisions for P-3B observations are approximately 2×10^{13} molecules cm⁻² (NO₂) and 6×10^{13} molecules cm⁻² (CH₂O). Uncertainties from spatial variability and measurement accuracy are discussed in the text.”

P.21, L.6: What about the use of the simple geometric AMF for PANDORA (P.6, L3). Could this also contribute (significantly) to the differences observed?

The uncertainty from the use of the Pandora geometric AMF should be small (<1% , see Herman et al., JGR, 2009) at solar zenith angles less than 80°, so we don’t expect its influence to be significant. There may be some influence from aerosols and clouds (see a similar discussion in <https://www.atmos-meas-tech-discuss.net/amt-2018-57/amt-2018-57-AC3.pdf>), but as both the Pandora data and GCAS data are cloud screened, this is likely minimal as compared to uncertainties introduced by other sources in the Pandora spectral fitting.

Technical corrections:

P3, L1-L7: This paragraph is a bit too technical and would be better fitting in section 2.

We have moved this paragraph to Section 2.

P.15, L13: Change “individual industrial sites” to “single industrial sites” or “single Stacks”.

This has been changed to “single industrial sites and stacks”.

P.20, L13: Change line-of-site to line-of-sight

This has been changed in text.

P.21, L27: Please reformulate as sentence is not clear. Maybe: “...with retrievals from a spectrometer from the Network for the Detection of Atmospheric Composition Change (NDACC) using...” + Please specify also the type of (DOAS) instrument.

We have rearranged and shortened and these sentences to: “Previous comparisons of Pandora DS total column NO₂ observations with other ground-based observations have shown good agreement (Herman et al., 2009; Wang et al., 2010a). In contrast, Knepp et al. (2017) compared a year of Pandora zenith-sky stratospheric NO₂ slant columns with those from a zenith-looking UV-Vis spectrometer (DOAS M07) from the Network for the Detection of Atmospheric Composition Change (NDACC) using different retrieval settings, and found Pandora underestimated the NDACC instrument by 7–40 %.”

P.22, L1: Please put comma after “inputs” and after “columns”.

These commas have been added.

P.24, Figure10: acronym DS is used here for the first time. Should also be used in text and written in full at first appearance.

The acronym DS now replaces most uses of “direct sun” in text, and has been defined at first use.

The following is a tracked changes version of the manuscript. Note that latexdiff is unable to properly handle some section re-numbering -- these should appear correct in the manuscript without tracked changes.

Nitrogen dioxide and formaldehyde measurements from the GEOstationary Coastal and Air Pollution Events (GEO-CAPE) Airborne Simulator over Houston, Texas

Abstract. The GEOstationary Coastal and Air Pollution Events (GEO-CAPE) Airborne Simulator (GCAS) was developed in support of NASA's decadal survey GEO-CAPE geostationary satellite mission. GCAS is an airborne pushbroom remote sensing instrument, consisting of two channels which make hyperspectral measurements in the ultraviolet/visible (optimized for air quality observations) and the visible/near-infrared (optimized for ocean color observations). The GCAS instrument participated in its first intensive field campaign during the Deriving Information on Surface Conditions from Column and Vertically Resolved Observations Relevant to Air Quality (DISCOVER-AQ) in Texas in September 2013. During this campaign, the instrument flew on a King Air B-200 aircraft during 21 flights on 11 days to make air quality observations over Houston, Texas. We present GCAS trace gas retrievals of nitrogen dioxide (NO₂) and formaldehyde (CH₂O), and compare these results with trace gas columns derived from coincident in situ profile measurements of NO₂ and CH₂O made by instruments on a P-3B aircraft, and with NO₂ observations from ground-based Pandora spectrometers operating in direct sun and scattered light modes. GCAS tropospheric column measurements correlate well spatially and temporally with columns estimated from the P-3B measurements for both NO₂ ($r^2 = 0.89$) and CH₂O ($r^2 = 0.54$) and with Pandora direct sun ($r^2 = 0.85$) and scattered light ($r^2 = 0.94$) observed NO₂ columns. Coincident GCAS columns agree in magnitude with NO₂ and CH₂O P-3B-observed columns to within 10 %, but are larger than scattered light Pandora tropospheric NO₂ columns by 33 % and direct sun Pandora NO₂ columns by 50 %.

1 Introduction

The GEOstationary Coastal and Air Pollution Events (GEO-CAPE) Airborne Simulator (GCAS) is an airborne hyperspectral remote sensing instrument developed in support of future Earth-observing geostationary satellite missions. GCAS was originally developed by NASA Goddard Space Flight Center's (GSFC) Radiometric Calibration and Flight Development Laboratory as a simulator for GEO-CAPE, a NASA decadal survey mission for observing pollution and ocean color from geostationary orbit (Fishman et al., 2012). GCAS is now also a test-bed instrument for the Tropospheric Emissions: Monitoring of POLLution (TEMPO) instrument (Chance et al., 2013; Zoogman et al., 2017), which will monitor air quality over North America from a geostationary orbit. TEMPO is the ultraviolet/visible/near-infrared air quality component of GEO-CAPE and is scheduled for launch in the 2019–2021 timeframe. As a satellite airborne simulator, GCAS provides an algorithm development test-bed for GEO-CAPE and TEMPO, serves as a satellite analogue during field campaigns, and will eventually act as a validation instrument when geostationary satellite instruments are on orbit.

GCAS is a pushbroom remote sensing instrument consisting of two spectrometers. The first spectrometer operates in the UV/visible region of the spectrum, where observations can be made of several atmospheric constituents of interest to air quality. The second spectrometer operates in the visible/near-infrared (NIR) for measurements focused on ocean color. In this paper, we focus on air quality observations of nitrogen dioxide (NO_2) and formaldehyde (CH_2O) using data from the UV/visible channel collected during the Deriving Information on Surface Conditions from Column and Vertically Resolved Observations Relevant to Air Quality (DISCOVER-AQ) campaign in Texas during September 2013. NO_2 and CH_2O have spectral absorption signatures in the UV/visible channel and are two core operational data products of future geostationary air quality instruments.

Nitrogen oxides ($\text{NO}_x = \text{NO} + \text{NO}_2$) are of central importance to air quality and atmospheric chemistry. NO_x is involved in the formation of photochemical ozone and fine aerosol particles, with implications for both surface air quality and climate. Both short- and long-term enhanced NO_2 concentrations are associated with increased mortality (Hoek et al., 2013; Mills et al., 2015). NO_x emissions can also lead to excess nitrogen deposition (Fowler et al., 2013; Nowlan et al., 2014). Globally, the major sources of NO_x are combustion, lightning and soils. In populated regions, sources are typically dominated by combustion of fuel for transportation and industry. The relatively strong NO_2 spectral absorption features at ultraviolet (Yang et al., 2014) and visible (Martin et al., 2002; Boersma et al., 2008; Richter et al., 2011; Bucsela et al., 2013) wavelengths have been used for over two decades to derive global maps of NO_2 from several sun-synchronous satellite sensors in low Earth orbit.

Formaldehyde (CH_2O) is found in the Earth's atmosphere due to the oxidation of both methane and the non-methane volatile organic compounds (NMVOCs) that result from biogenic and anthropogenic activity and fires (Fried et al., 2008, 2011, 2016a, and references therein). Industrial activity and fires can also be direct sources of CH_2O (Fried et al., 2016b). The absorption signature of CH_2O in the ultraviolet has permitted its detection from the same nadir-viewing satellite instruments that measure NO_2 (Chance et al., 2000; De Smedt et al., 2008, 2012; González Abad et al., 2015, 2016). Its short lifetime of $\sim 1.5 - 3$ h (around local noon) means that satellite-observed CH_2O can be used as a proxy of NMVOC emissions (Barkley et al., 2008; Zhu et al., 2014; Stavrakou et al., 2015).

Both the air quality and ocean color spectrometers in the GCAS instrument use CCD array detectors to measure solar radiation backscattered from the surface and atmosphere. The pushbroom technique used by GCAS provides data for constructing two-dimensional maps beneath the aircraft, and is also employed by satellite instruments such as the Ozone Monitoring Instrument (OMI) (Levelt et al., 2006) and Ozone Mapping Profiler Suite (OMPS) nadir mapper (Flynn et al., 2014). In these instruments, one axis of the CCD array detector provides spectral information while the other CCD axis provides spatial cross-track information below the aircraft or satellite. The second spatial dimension is provided by the movement of the aircraft or satellite in its flight track.

NO₂ amounts over industrial regions and urban areas have been mapped at high spatial resolution by several recently-developed airborne pushbroom sensors (Heue et al., 2008; Popp et al., 2012; Schönhardt et al., 2015; Lawrence et al., 2015; Nowlan et al., 2015). Airborne remote sensing CH₂O measurements have previously been made from aircraft using limb viewing geometry by Airborne Multi-Axis Differential Optical Absorption Spectroscopy (AMAX-DOAS) (Baidar et al., 2013) and by the whiskbroom scanning technique (where the cross-track spatial dimension is provided by mechanical scanning) using the Airborne Compact Atmospheric Mapper (ACAM) (Liu et al., 2015b). Operated by the NASA GSFC Radiometric Calibration and Flight Development Laboratory, ACAM is a precursor instrument to GCAS, and has also been used to measure NO₂ and ozone (Liu et al., 2015b; Lamsal et al., 2017). To the best of our knowledge, the GCAS measurements presented here are the first CH₂O published observations from an airborne pushbroom nadir mapper.

GCAS flew in its first field campaign during the DISCOVER-AQ campaign in Texas in 2013. In the following sections, we present and validate trace gas retrievals of NO₂ and CH₂O from the GCAS instrument during DISCOVER-AQ Texas. Section 2 describes the GCAS instrument and measurement approach. Section 3 describes the DISCOVER-AQ Texas campaign deployment, measurements from GCAS and relevant ground-based spectrometers and in situ aircraft instruments, and the atmospheric models used in data analysis. Section 4 presents the trace gas retrievals, including the spectral fitting used to derive NO₂ and CH₂O slant columns, and air mass factor calculations. Section 5 describes the vertical column results from the campaign. Section 6 presents comparisons of GCAS observations with other coincident observations of NO₂ and CH₂O.

2 The GCAS instrument

The GCAS instrument is a nadir-looking hyperspectral instrument consisting of two Offner spectrometers operating at wavelengths 300–490 nm (UV/visible, air quality channel) and 480–900 nm (visible/NIR, ocean color channel). The instrument has dimensions of 48 cm × 48 cm × 46 cm and a mass of 36 kg. We briefly describe the GCAS instrument below; a more detailed description of the instrument and laboratory characterization can be found in Kowalewski and Janz (2014).

Both the air quality and ocean color spectrometers in the GCAS instrument use CCD array detectors to measure solar radiation backscattered from the surface and atmosphere. The pushbroom technique used by GCAS provides data for constructing two-dimensional maps beneath the aircraft, and is also employed by satellite instruments such as the Ozone Monitoring Instrument (OMI) (Levelt et al., 2006) and Ozone Mapping Profiler Suite (OMPS) nadir mapper (Flynn et al., 2014). In these instruments, one axis of the CCD array detector provides spectral information while the other CCD axis provides spatial

cross-track information below the aircraft or satellite. The second spatial dimension is provided by the movement of the aircraft or satellite in its flight track.

The UV/visible air quality channel consists of a thermo-electrically cooled 1072×1024 CCD detector array, measuring an image with 1072 wavelengths in the spectral dimension and 1024 positions in the spatial dimension across the flight track, with a spectral sampling of 0.2 nm and spectral resolution of 0.57 nm. Polarization sensitivity is reduced by the use of a dual wedge crystal quartz and fused silica depolarizer fitted between the slit and instrument fore-optics. The visible/NIR ocean color channel uses a 1004×1002 CCD array to collect spectra with a spectral sampling of 0.8 nm and resolution of 2.8 nm, and has an order sorting filter to reduce grating second order effects. The spectrometer units are operated at a temperature of 20°C and are stable to 0.25°C 40 minutes after a nominal take-off to a typical cruise altitude (Kowalewski and Janz, 2014). In addition to the two spectrometers, a video camera is also included in the housing for collecting relevant scene information.

The GCAS instrument fore-optics collect backscattered light below the aircraft through a common fused silica window. The full field of view (FOV) of the air quality channel covers 45.41° in the cross-track dimension and the instantaneous FOV (IFOV) along the flight track is 0.8 mrad. At a typical flight altitude of 9 km, this results in a swath width on the ground of about 6.7 km. The ocean color channel full FOV is 70° , with an IFOV of 1.2 mrad. All observations in this study use the UV/visible air quality channel.

Spectra are spatially averaged in post-processing to increase the signal-to-noise ratio for air quality trace gas observations. NASA GSFC typically produces averaged Level 1B calibrated spectra at 21 cross-track positions, at a spatial resolution of 250 m cross-track and 500 m along track from a ~9 km flight altitude, with a resulting signal-to-noise ratio of ~360 at 340 nm and ~540 at 440 nm. GCAS does not have a zenith sky reference measurement capability, unlike the Geostationary Trace gas and Aerosol Sensor Optimization (GeoTASO) (Nowlan et al., 2016) or ACAM (Liu et al., 2015b) airborne instruments also operated by the NASA GSFC. As a result, the reference spectra required by the GCAS trace gas retrievals must be derived from nadir observations over clean areas with relatively low pollution.

3 DISCOVER-AQ Texas 2013

DISCOVER-AQ (<http://discover-aq.larc.nasa.gov/>) was a suborbital-class NASA Earth Venture mission consisting of four major field campaigns (Maryland 2011, California 2013, Texas 2013 and Colorado 2014) whose goal was to improve air quality monitoring by satellites. During the campaigns, NASA's King Air B-200 (remote sensing) and P-3B (in situ) aircraft made measurements of trace gases, aerosols and meteorological variables, while balloon-borne, ship-based, mobile, and stationary instruments collected large amounts of in situ and remote sensing data.

As part of the remote sensing component of DISCOVER-AQ, NASA GSFC deployed the airborne ACAM scanning instrument during the Maryland 2011 (Liu et al., 2015a, b; Lamsal et al., 2017) and California 2013 campaigns, and the GCAS instrument during the Texas 2013 and Colorado 2014 campaigns. Additionally, the first test flights of the GeoTASO airborne instrument, another geostationary airborne simulator, were performed during the Texas (Nowlan et al., 2016) and Col-

Figure 1. Map of Houston area showing sample flight tracks for the King Air B-200 (GCAS) and the P-3B aircraft on 6 September 2013, and ground sites where Pandora spectrometers were located. Major roads are shown in yellow. ExonMobil Baytown and Texas City are large petrochemical and petroleum refinery complexes. The Baytown complex lies near the entrance to the main part of the Houston Ship Channel industrial area, which ends 6.5 km to the east of the downtown. The red triangle shows the location of the observations used to calculate the GCAS reference spectra.

orado (Crawford et al., 2016) campaigns from the NASA HU-25C Falcon aircraft. Preliminary GCAS and GeoTASO NO₂ observations were compared in a previous paper (Nowlan et al., 2016).

The DISCOVER-AQ Texas campaign took place in September 2013. The campaign aircraft, sondes, and ground-based instruments were based in and around Houston, Texas, an urban area with large emission contributions from both transportation and the petrochemical industry, and air quality often influenced by land-sea breezes. Figure 1 shows the location of the 10 DISCOVER-AQ ground sites with Pandora spectrometers which GCAS overflow, and a day of flight tracks from the King Air B-200 and P-3B aircraft. Flight paths were chosen so that the aircraft passed over eight existing ground sites with surface air quality monitors several times per day, in support of the mission goal of investigating the relationship between trace gas columns and surface air quality.

3.1 GCAS observations

During the DISCOVER-AQ Texas campaign in September 2013, the NASA King Air B-200 carried the GCAS instrument for remote sensing of trace gases and aerosols, as well as the NASA High Spectral Resolution ~~Lidar~~ (HSRL) Lidar-2 (HSRL-2) instrument (Hair et al., 2008) for measuring aerosol profiles below the aircraft. The B-200 typically flew at a cruise altitude of ~9 km, with occasional descents to avoid cirrus clouds. Table 1 summarizes the 26 GCAS flights (21 for air quality and 5 for

ocean color), which took place on 13 days. Most flights were designed to coincide with P-3B flight paths. The B-200 aircraft was based at Ellington Field in south-east Houston, and typically flew a morning flight, refueled, and then flew an afternoon flight. Each B-200 flight over Houston consisted of two overpasses of nearly the same flight path, so that there are typically four GCAS overpasses of Houston each day. The ocean color flights involved collecting data over the Gulf of Mexico in support of the ocean color component of GEO-CAPE. In this study, we focus only on the air quality flights over the Houston area.

3.2 Pandora observations

Total column observations of NO₂ were made from 15 ground-based Pandora spectrometers viewing in direct sun (DS) mode (Herman et al., 2009) at 11 sites during the DISCOVER-AQ Texas campaign. GCAS overflow 14 of these spectrometers at 10 sites, which are summarized in Table 2. Pandora NO₂ is determined at a temporal resolution of 90 s using the ratio of direct-sun spectra to a reference spectrum derived by a top-of-the-atmosphere Langley extrapolation using spectra collected on a clear day with low NO₂ (Herman et al., 2009). Spectra are fit from 400–440 nm with NO₂ cross sections interpolated to 264 K (Vandaele et al., 1998) and O₃ at 225 K (Brion et al., 1993). At solar zenith angles (SZA) less than 80°, the observed direct-sun DS slant column is converted to vertical total column using a simple geometric air mass factor (Herman et al., 2009). Pandora DS NO₂ measurements have a nominal precision of 2.7×10^{14} molecules cm⁻² and accuracy of 2.7×10^{15} molecules cm⁻². Pandora observations with fitting RMS < 0.005 and relative error < 10 % are included in this study, to exclude possible cloud-contaminated measurements.

Pandoras also operated in multi-axis sky scanning mode (MAX-DOAS) measuring lower tropospheric NO₂ distribution and tropospheric columns at the La Porte, Moody Tower and Smith Point sites. Pandora head sensors sequentially pointed at 1, 2, 3, 4, 6, 8, 10, 15, 20, 30, 40, and 90° elevation angles from the horizon with a field of view of 1.6°. Azimuth angles were chosen to ensure an unobstructed view down to the horizon and were 320° from north at La Porte, 45° at Moody Tower and 270° at Smith Point. Differential slant column densities of NO₂ and O₂–O₂ within a single scan were calculated using a zenith sky reference spectrum. A temperature dependent NO₂ absorption cross section (linear and constant terms) and Ring, H₂O and O₂–O₂ cross sections (see Table 3 for references) were used in MAX-DOAS fitting window 425–490 nm. The profile inversion was performed using the maximum a posteriori optimal estimation method (Rodgers, 2000) with aerosol and gas weighting functions calculated using VLIDORT 2.7 (Spurr, 2008). Tropospheric columns were also estimated using a geometrical approach using NO₂ and O₂–O₂ columns derived from 15° elevation angle measurements when inversions failed.

The Pandora dataset contains observations from two Pandora instruments placed at the Moody Tower site at the University of Houston, 70 m above the surface. We correct for the column in the bottom 70 m of the atmosphere using in situ observations at the base and top of the towers collected every 5 min by the University of Houston following Nowlan et al. (2016). The in situ measurements indicated that NO₂ within these altitudes was usually well-mixed at the overpasses. This correction varies in magnitude from 0.3×10^{15} molecules cm⁻² to 3.7×10^{15} molecules cm⁻² for different GCAS overpasses.

3.3 P-3B aircraft observations

The P-3B aircraft carried a suite of in situ instruments for profiling the atmosphere during the campaign. Profiles were collected during aircraft spirals near eight DISCOVER-AQ ground sites, with each site typically overflowed two or three times each day. Depending on the site and flight, the aircraft typically flew between a lowermost altitude of 0–300 m and an uppermost altitude of 3.5–5 km. The typical radius of a spiral was 4–5 km.

The National Center for Atmospheric Research’s (NCAR) chemiluminescence instrument (P-CL) (Ridley and Grahek, 1990) measured in situ NO_2 concentrations from the P-3B. P-CL observations of NO_2 have uncertainties of 0.02 ppbv in precision and 10 % in accuracy.

The NCAR Differential Frequency Generation Absorption Spectrometer (DFGAS) (Weibring et al., 2006, 2007) measured in situ CH_2O concentrations from the P-3B. The DFGAS instrument collects data with a temporal resolution of 1 second, with a 15-second background zero air addition period every 60 to 120 seconds. This addition captures and removes both inlet/sample cell CH_2O outgassing as well as optical noise. For a typical spiral, the temporal resolution translates to a vertical resolution of approximately 5 m. The 1-second measurements have a precision of ~ 0.08 ppbv (upper limit) and an estimated accuracy of 4 % at the 1σ level.

3.4 Model simulations

This study uses model simulated trace gas profiles for radiative transfer calculations in order to determine vertical column densities from observed slant column densities. Tropospheric simulations are performed with the Environmental Protection Agency’s (EPA) Community Multiscale Air Quality (CMAQ) version 5.0.2 modeling system (Byun and Schere, 2006) over the campaign domain at a spatial resolution of $4 \times 4 \text{ km}^2$ and a temporal resolution of 20 minutes. The model has 45 vertical levels from the surface to 50 hPa. The model’s vertical resolution ranges from 22 m at the surface to ~ 200 m at an altitude of 2 km, further increasing to ~ 650 m by the aircraft flight altitude. CMAQ simulations are driven by offline meteorology from the Advanced Research Weather and Forecasting (WRF-ARW) model (Skamarock et al., 2008) via the Meteorology-Chemistry Interface Processor (MCIP) (Otte and Pleim, 2010). Loughner and Follette-Cook (2015) describe the CMAQ and WRF modeling approach used for the DISCOVER-AQ Texas campaign in detail.

Stratospheric NO_2 profiles used in the study are estimated using the PRATMO chemical box model (Prather, 1992; McLinden et al., 2000) from simulated profiles provided as a function of month, solar zenith angle and latitude. Stratospheric ozone profiles are from the September 2013 monthly climatology derived at $1^\circ \times 1^\circ$ from the OMI ozone profile product (Liu et al., 2010) up to 0.3 hPa.

4 GCAS trace gas retrievals

The GCAS vertical column density retrieval uses a two-step approach. First, we derive the slant column density (SCD) by directly fitting a modeled spectrum to the observed spectrum, starting from a reference spectrum derived from observations

over an unpolluted area. Second, we convert SCD to a vertical column density (VCD) using an air mass factor (AMF) that represents the path of light through the atmosphere based on the viewing geometry and radiative transfer calculations.

The GCAS trace gas retrieval algorithms used in this paper are derived from the Smithsonian Astrophysical Observatory (SAO) trace gas algorithms originally developed for GOME, and since applied to GOME-2, SCIAMACHY, OMI, OMPS and GeoTASO for a range of trace gases (Chance, 1998; Chance et al., 2000; Sioris et al., 2004; Nowlan et al., 2011; Chan Miller et al., 2014; Wang et al., 2014; González Abad et al., 2015, 2016; Nowlan et al., 2016). These algorithms are also the basis for the TEMPO trace gas retrieval algorithms. A separate slant column trace gas product at $350\text{ m} \times 1000\text{ m}$ was provided by the GCAS instrument team at NASA GSFC to the DISCOVER-AQ data archive shortly after the campaign using the publicly-available QDOAS spectral fitting package (<http://uv-vis.aeronomie.be/software/QDOAS/>) and preliminary calibrated spectra. This product is not examined in the current study.

Nowlan et al. (2016) compared preliminary SAO GCAS NO_2 slant columns with GeoTASO slant columns within 10 minutes and 500 m from four coincident flights during the DISCOVER-AQ Texas campaign (13, 14, 18 and 24 September) at a resolution of $250\text{ m} \times 500\text{ m}$. Overall, slant columns agreed well ($r = 0.81$, $N = 77320$), with GCAS lower than GeoTASO by $\sim 6\%$. The current GCAS retrieval algorithm used in this study is similar to the previous algorithm, but the slant column retrieval uses a separate reference spectrum for each cross-track position and a cross-track dependent instrument line shape, so that the results no longer require a cross-track bias correction. The new NO_2 and CH_2O products also include improved georegistration.

4.1 Calibration Spectral calibration

We perform spectral fitting to derive slant columns using radiometrically-calibrated spectra (Level 1B), which are geolocated and derived from raw (Level 0) data using characterization data collected in the laboratory before the campaign, as described in detail by Kowalewski and Janz (2014). The first-guess wavelength calibration was determined from spectra collected in the laboratory using mercury-argon, cadmium, neon and krypton discharge lamps as sources. The pre-flight slit function shape and width as functions of cross-track position, wavelength and temperature were also determined using a tunable-laser with an integrating sphere. These laboratory tests indicated the instrument's spectral shift is $\sim 0.004\text{ nm}$ and the change in the slit function's full width at half maximum (FWHM) is less than 0.0013 nm within the instrument's thermal stability range of $\pm 0.25^\circ\text{C}$ and nominal operating temperature of 20°C . ~~The absolute radiometric calibration was determined using a NIST-calibrated integrating sphere with an uncertainty of 3 % and stable to 1 %. Polarization sensitivity was determined using an integrating sphere and polarizer, and is on the order of 1–3 %, depending on field angle (Kowalewski and Janz, 2014).~~ Pressure changes within the instrument may also shift the wavelength calibration through changes in the index of refraction (Kuhlmann et al., 2016). These changes are minimized in GCAS and are primarily due to changes in ambient temperature as the instrument is backfilled with gaseous nitrogen and sealed prior to aircraft integration to mitigate moisture. The impact of wavelength shifts on retrievals is further minimized through simultaneous fitting of a wavelength shift for each observation as described in Section 4.2.1.

We further refine the instrument spectral registration and slit function calibration using spectra collected during the Texas flights, following our calibration approach previously applied to GOME, GOME-2, OCO-2, ACAM and GeoTASO (Liu et al.,

2005; Cai et al., 2012; Liu et al., 2015b; Nowlan et al., 2016; Sun et al., 2017a, b). As a first step in the spectral fitting, we simultaneously derive a wavelength dispersion and slit function shape by fitting a reference spectrum to a high spectral resolution solar atlas (Chance and Kurucz, 2010). This is similar to the approach employed in our satellite retrievals, but as the airborne nadir reference spectrum contains atmospheric features (which are not present in a satellite-observed exo-atmospheric reference), we also simultaneously fit preliminary amounts of the atmospheric molecular absorbers listed in Table 3 and the Ring effect (rotational Raman scattering) to account for these spectral features (Liu et al., 2015b; Nowlan et al., 2016).

We determine a separate wavelength dispersion and slit function shape for each of the 21 cross-track positions. The wavelength dispersion is determined by fitting the coefficients in a 5th-order (NO_2) or 7th-order (CH_2O) polynomial that represents the wavelength as a function of detector pixel. For NO_2 , we model the slit function using an asymmetric super Gaussian (Beirle et al., 2017). For CH_2O , we fit parameters describing the shape and width of an asymmetric Gaussian (Cai et al., 2012; Nowlan et al., 2016). While the super Gaussian works well for NO_2 , it results in a very small increase ($\sim 5\%$) in fitting residuals for CH_2O over an asymmetric Gaussian, possibly due to the presence of a double shoulder to one side of the slit function shape, as measured in the laboratory at wavelengths less than 380 nm (Kowalewski and Janz, 2014).

The retrieved slit function in the NO_2 fitting window is nearly symmetric and very similar in width to the FWHM=0.58 nm (Kowalewski and Janz, 2014) measured in the laboratory. Using in-flight data, the retrieved FWHM is 0.57 nm at the nadir center position, expanding to 0.58 nm at the edges of the swath. The retrieved slit width in the CH_2O fitting window changes in a similar way, but is larger at the edges (0.57 nm at swath center, growing to 0.60 nm at the leftmost cross-track position 1 and to 0.63 nm at the rightmost cross-track position 21). We estimate the uncertainty in the slit width is ~ 0.01 nm, primarily due to temperature fluctuations during flight. In-flight data shows the center detector pixel-to-wavelength registration for both the NO_2 and CH_2O fitting windows varies nearly linearly as a function of swath cross-track position across the left-hand of the swath, varying by ~ 0.1 nm between cross-track positions 1 and 11, but remains approximately constant from positions 11 to 21. The retrieved wavelength calibration is stable to ~ 0.002 nm after the instrument has thermally stabilized during flight.

4.2 Slant column retrieval

4.2.1 Spectral fitting

We determine NO_2 and CH_2O slant columns using least-squares minimization to directly fit a modeled radiance spectrum $\mathbf{F}(\mathbf{x}, \mathbf{b})$ to our observed radiance spectrum. The modeled spectrum is a function of pre-determined model parameters $\mathbf{b}$ and the retrieved state vector $\mathbf{x}$. The modeled spectrum is represented by

$$F(\lambda) = ([x_a I_0(\lambda) + b_u(\lambda)x_u + b_r(\lambda)x_r]e^{-\sum_i b_i(\lambda)x_i}) \sum_j (\lambda - \bar{\lambda})^j x_j^{SC} + \sum_k (\lambda - \bar{\lambda})^k x_k^{BL}. \quad (1)$$

In this equation, I_0 is a reference spectrum determined from clean nadir observations, scaled by a retrieved intensity parameter x_a (which represents reflectivity factors such as surface albedo or clouds). The derivation of the reference is discussed in Section 4.2.1. The term $b_u(\lambda)$ describes a correction for spectral undersampling (Chance et al., 2005), while $b_r(\lambda)$ represents the effects of rotational Raman scattering (Chance and Spurr, 1997). The retrieved differential slant columns are represented

by x_i and include the gases listed in Table 3. These differential slant columns are the differences between the slant columns in the nadir observation of interest and the slant columns in the reference spectrum. Their absorption cross sections, as listed in Table 3, convolved with the instrument line shape and corrected for the " I_0 effect" (Aliwell et al., 2002), are included as $b_i(\lambda)$. In addition, the retrieval also determines scaling (of order j) and baseline (of order k) wavelength-dependent polynomial coefficients (x^{SC} and x^{BL}) that represent low frequency wavelength-dependent effects from surface reflectivity, molecular scattering, aerosols and instrument artifacts.

4.3 Reference spectrum

4.2.1 Reference spectrum

Each trace gas retrieval uses reference spectra determined from nadir observations over a clean area. We determine a mean reference spectrum for each of the 21 cross-track positions by averaging 40 spectra at $250\text{ m} \times 500\text{ m}$ resolution for each cross-position from a cloud-free and clean area over the Gulf of Mexico during the 6 September afternoon flight. This location and date were chosen after CMAQ simulations and preliminary retrievals of NO_2 and CH_2O predicted relatively low columns of those trace gases. In addition, we found that the use of a reference collected before the instrument was thermally stable (within the first ~ 40 minutes of a flight) resulted in cross-track biases in the CH_2O retrieval. As observations over the relatively clean Gulf are often collected in the period soon after take-off, this constraint limited the availability of a suitable reference to a reference spectrum taken late in the flight, close to landing, and with a relatively high solar zenith angle (58°).

We use a single reference spectrum at each cross-track position for the entire campaign, instead of a daily or higher frequency reference, to ensure that all days during the campaign have the same background correction applied for the reference spectrum. Due to the use of a nadir reference, the retrieved differential slant columns must be corrected by the reference background column derived from the model to produce an effective tropospheric column (discussed in further detail in Section 4.3). We find that the use of a single reference for the campaign removes day-to-day relative background biases in the GCAS column that can result from uncertainties in daily modeled columns, and improves the daily consistency of background CH_2O in the in situ P-3B CH_2O comparison discussed later in Section 6.1. The use of a single versus daily reference spectrum has little effect on the NO_2 validation.

4.3 and-fitting

4.2.1 NO_2 and CH_2O fitting

The NO_2 and CH_2O slant column density retrievals use the fitting parameters summarized in Table 3. NO_2 is fit at wavelengths 420–465 nm with an NO_2 absorption cross section at 294 K. The NO_2 retrieval also simultaneously fits O_3 at two temperatures, as well as H_2O vapor and $\text{O}_2\text{--O}_2$, which all have spectral absorption features in the NO_2 wavelength fitting window. The CH_2O retrieval is performed at 328.5–356.5 nm, and simultaneously fits NO_2 , O_3 , BrO and $\text{O}_2\text{--O}_2$. Both retrievals also fit the undersampling correction, Ring spectrum, a 5th-order scaling polynomial, and a 4th-order baseline polynomial. Each

retrieval also determines a wavelength shift that represents the relative difference in the detector pixel to wavelength registration between the radiance and reference spectra.

4.3 Conversion to vertical column

For air quality applications, we are interested in the vertical column density, V , of the ~~absorber~~trace gas (NO_2 or CH_2O) in the troposphere. The vertical column density can be derived from the slant column density, S , using an air mass factor, A , which describes the mean light path through the atmosphere, by

$$V = \frac{S}{A}. \quad (2)$$

In practice, the retrieval algorithm determines a differential slant column ΔS , which is the difference between the slant column S of the absorber in the spectrum of interest, and the slant column S_R in the reference spectrum. Each of these slant columns is the sum of the slant column of absorber in the light path above ($\uparrow$) and below ($\downarrow$) the aircraft, so that

$$\Delta S = (S^\downarrow + S^\uparrow) - (S_R^\downarrow + S_R^\uparrow). \quad (3)$$

In terms of the air mass factor and vertical column, the vertical column below the aircraft can then be expressed as

$$V^\downarrow = \frac{\Delta S - V^\uparrow A^\uparrow + V_R^\downarrow A_R^\downarrow + V_R^\uparrow A_R^\uparrow}{A^\downarrow}, \quad (4)$$

where the vertical columns $V^\uparrow$, $V_R^\downarrow$ and $V_R^\uparrow$ are typically determined from a model. Because the flight altitude of 9 km is well above the majority of tropospheric NO_2 and CH_2O , we refer to $V^\downarrow$ and $V^\uparrow$ as the tropospheric and stratospheric trace gas columns. NO_2 above the aircraft is dominated by stratospheric NO_2 and varies primarily by time of day, and ranges between $V^\uparrow = 2.3 - 3.8 \times 10^{15}$ molecules cm^{-2} . CH_2O in the model is more variable, with the early part of the campaign (4 to 18 September) seeing levels of $V^\uparrow = 2 - 25 \times 10^{14}$ molecules cm^{-2} and the latter part seeing levels of $V^\uparrow = 1 - 3 \times 10^{14}$ molecules cm^{-2} . For our chosen reference location, the modeled vertical columns below the aircraft are $V_R^\downarrow = 2.0 \times 10^{15}$ molecules cm^{-2} for NO_2 and $V_R^\downarrow = 7.5 \times 10^{15}$ molecules cm^{-2} for CH_2O . The modeled vertical columns above the aircraft at the reference location are $V_R^\uparrow = 3.6 \times 10^{15}$ molecules cm^{-2} for NO_2 and $V_R^\uparrow = 7.9 \times 10^{14}$ molecules cm^{-2} for CH_2O .

4.3.1 Air mass factor calculation

We calculate the air mass factors on a scene-by-scene basis using the formulation of Palmer et al. (2001) and Martin et al. (2002) with the VLIDORT radiative transfer model (Spurr, 2006, 2008). In this approach, the radiative transfer model provides scattering weights w as a function of altitude z . The scattering weights describe the sensitivity of the measurement to the different altitude layers and are a function of the viewing geometry, ozone profile, aerosol and molecular scattering, and surface reflectance. These can be used with shape factor s , which is the normalized partial column n of the trace gas at each altitude layer:

$$s(z) = \frac{n(z)}{\int_z n(z) dz}. \quad (5)$$

The AMF is defined as

$$A = \int_z w(z)s(z)dz. \quad (6)$$

The air mass factor below the aircraft $A^\downarrow$ is calculated from the surface z_0 to the aircraft altitude z_{ac} as

$$A^\downarrow = \int_{z_0}^{z_{ac}} w(z)s(z)dz, \quad (7)$$

- 5 while the air mass factor above the aircraft $A^\uparrow$ is determined from the aircraft altitude to the top of the atmosphere at z_{TOA} , with

$$A^\uparrow = \int_{z_{ac}}^{z_{TOA}} w(z)s(z)dz. \quad (8)$$

4.3.2 Radiative transfer calculations

We use the radiative transfer algorithm to determine scattering weights in 56 vertical layers. These include the 45 CMAQ
 10 layers up to ~19 km and 11 additional layers to 0.3 hPa. We use the MODIS BRDF (bidirectional reflectance distribution functions) gap-filled MCD43GF V005 Band 3 product (Schaaf et al., 2002; Sun et al., 2017) to represent surface reflectance in the VLIDORT model. This BRDF product is provided at a spatial resolution of 30 arcsec (~0.80 km in longitude by 0.92 km in latitude over Houston) every 8 days, based on 16 days of MODIS measurements. The MODIS Band 3 product is derived at 470 nm. While this is close to the NO₂ fitting window, there currently exists no BRDF climatology at shorter wavelengths. We
 15 determine effective BRDFs at 442 nm (NO₂) and 342 nm (CH₂O) by scaling the BRDF functions by the ratio of the 0.5° × 0.5° monthly OMI Earth Surface Reflectance Climatology product (OMLER) (Kleipool et al., 2008) at either 442 nm or 342 nm to its value at 470 nm. These results are typically within ~~a few percent~~ 2–3 % of the results derived using a black-sky/white-sky approach to estimate surface reflectance (McLinden et al., 2014).

Figure 2 shows profiles for 1) a sample polluted observation at the Moody Tower site in downtown Houston and 2) the
 20 reference spectrum. For the AMF calculation, the shape factors are derived from the model profiles shown in Figures 2a and 2c and then applied to the corresponding scattering weights. Differences in the scattering weights of the reference and Moody Tower observations at higher altitudes are mainly driven by differences in the solar zenith angles. The smaller CH₂O scattering weights near the surface relative to those of NO₂ indicate the relatively lower sensitivity of the observations to near-surface CH₂O. This is due primarily to the wavelength dependency of the AMF, as stronger Rayleigh scattering and ozone absorption
 25 at shorter wavelengths decreases the measurement sensitivity to lower altitudes. The AMF is calculated scene-by-scene for each nadir observation. The reference spectrum AMFs at the swath center are $A_R^\downarrow = 1.65$ and $A_R^\uparrow = 1.92$ for NO₂ and $A_R^\downarrow = 2.03$ and $A_R^\uparrow = 2.49$ for CH₂O.

Figure 2. Sample mixing ratio (mxr) and scattering weight ($w(z)$) profiles used in the GCAS AMF calculations. The reference spectrum profiles are taken from the 6 September afternoon flight over the Gulf of Mexico at average location 29.126°N, 94.818°W, 17:04 LT (local time = UTC time - 5 hours) with SZA=58.0°, VZA=10.5°. The profiles at the Moody Tower site in downtown Houston are from the 25 September morning flight at 10:56 LT with SZA=45.0°, VZA=10.7°. The estimated surface reflectivities at 442 nm (NO₂) and 342 nm (CH₂O) are 0.04 and 0.05 at the reference location and are both 0.07 at Moody Tower. The dashed black line indicates the aircraft flight altitude.

4.4 Cloud flagging

Only cloud-free measurements are used in this study, and the radiative transfer calculations assume cloud-free conditions. Unlike the case of satellite observations with footprints on the order of tens of square kilometers, GCAS observations are of sufficiently high spatial resolution that cloudy pixels can be discarded without loss of a significant amount of data. We flag as

5 cloudy any pixel that has a mean radiance in the NO₂ fitting window over a threshold of 2×10^{13} photons cm⁻² nm⁻¹ s⁻¹ sr⁻¹, which is typically only exceeded in the case of a bright cloud. The Ring scattering parameter retrieved simultaneously with NO₂ and a color index (the radiance ratio at wavelengths 320 to 440 nm) are also used to flag less bright pixels where clouds likely occur (Wagner et al., 2014).

4.5 Trace gas uncertainties

Uncertainties in the vertical column density result from uncertainties in 1) the slant column fitting ~~and~~; 2) the air mass factor calculation ~~;~~ and 3) the modeled reference and stratospheric columns needed for determining the vertical column below the aircraft using Eq. 4.

5 4.5.1 Slant column uncertainties

The slant column fitting uncertainty on a single observation is dominated by the random noise in the spectrum. Over a typical day, the mean fitting uncertainty in ~~a~~ an NO_2 differential slant column at $250 \text{ m} \times 500 \text{ m}$ resolution is $1.3 \times 10^{15} \text{ molecules cm}^{-2}$, including all solar zenith angles in the morning and afternoon flights. The typical fitting uncertainty in a CH_2O differential slant column is $2.5 \times 10^{16} \text{ molecules cm}^{-2}$. After AMFs are applied, typical mean vertical column precisions are $1 \times 10^{15} \text{ molecules cm}^{-2}$ for NO_2 and $1.9 \times 10^{16} \text{ molecules cm}^{-2}$ for CH_2O . The precision requirements of the TEMPO instrument are $1 \times 10^{15} \text{ molecules cm}^{-2}$ for NO_2 and $1 \times 10^{16} \text{ molecules cm}^{-2}$ for CH_2O (Zoogman et al., 2017). (Note that the signal-to-noise is higher at CH_2O wavelengths relative to that at NO_2 wavelengths for TEMPO, which is the opposite of GCAS.) CH_2O in particular is noisy at the provided GCAS spatial resolution of $250 \text{ m} \times 500 \text{ m}$, with enhanced CH_2O columns often on the order of the retrieval precision. GCAS CH_2O must be spatially averaged to meet the TEMPO precision requirement and to improve the detection limit in order to observe polluted columns over Houston. As a result, later in this paper we present CH_2O maps at 1 km^2 resolution, with an effective precision on the order of $7 \times 10^{15} \text{ molecules cm}^{-2}$. It should be noted that even at precisions of $1 \times 10^{16} \text{ molecules cm}^{-2}$, CH_2O columns from satellite instruments like OMI typically must be temporally averaged to resolve local CH_2O features (e.g., Marais et al., 2014; Zhu et al., 2014).

Additional errors in NO_2 slant column retrievals can also result from the use of an NO_2 cross section at a single temperature (Boersma et al., 2004). The profile-weighted effective temperature of NO_2 during the Houston campaign in polluted observations was typically within a few degrees of the 294 K cross section temperature, resulting in an expected bias within 1–2 % in the tropospheric slant column. The stratospheric slant column may be biased by ~15 % due to its colder temperature, but the influence of this uncertainty is minimized by the use of a nadir reference spectrum, resulting in a possible systematic bias on the order of $4 \times 10^{14} \text{ molecules cm}^{-2}$ (an uncertainty of 1–2 % for polluted pixels). Uncertainties in the laboratory cross sections introduce additional uncertainties in the slant columns of 2 % for NO_2 (Boersma et al., 2004) and 5 % for CH_2O (Chance and Orphal, 2011). Uncertainties in the differential slant columns due to uncertainties in the spectral calibration are $\sim 5 \times 10^{13} \text{ molecules cm}^{-2}$ for NO_2 and $\sim 2 \times 10^{15} \text{ molecules cm}^{-2}$ for CH_2O .

4.5.2 Air mass factor uncertainties

The air mass factor uncertainties in cloud-free satellite observations are typically dominated by uncertainties in the surface albedo, trace gas profile shape and aerosols (Boersma et al., 2004). A recent study by Lorente et al. (2017) found an average AMF structural uncertainty of 42 % in polluted observations and 31 % in unpolluted regions when different retrieval groups

used different inputs to NO₂ AMF calculations; the most significant impacts overall were from differences in surface albedo, cloud parameters and trace gas profile inputs.

MODIS BRDF comparisons with aircraft observations of the surface indicate an uncertainty in the MODIS BRDF product of 20 % for both accuracy and precision (Román et al., 2011) at GCAS spatial resolutions. We estimate the impact of those uncertainties from the MODIS surface BRDF on our individual AMFs to be 10 % for polluted observations and 5 % for clean observations. Wang et al. (2010b) showed that the use of the Lambertian approximation in the derivation of the MODIS products may result in surface reflectance underestimation of 0.008 by MODIS in the green bands. This surface bias on average could cause the GCAS AMF to be underestimated (and the resulting trace gas column to be overestimated) by ~10 %.

The radiative effects of aerosols are not typically included in operational satellite retrieval trace gas AMFs, except as an implicit component of the cloud fraction, and we have not included aerosols in the current study. In reality, the presence of aerosols can increase or decrease the AMF, with effects depending on aerosol type and altitude (Leitão et al., 2010; Lin et al., 2014; Chimot et al., 2016). When scattering aerosols are in the boundary layer, for example, the backscattered light path increases the radiative sensitivity (an enhancement effect), resulting in an increase in the AMF. Ignoring these aerosols in the radiative transfer calculation will cause the retrieved column to be overestimated. When scattering aerosols are aloft, the radiative sensitivity decreases near the surface (a shielding effect), resulting in a decrease in the AMF. Absorbing aerosols aloft or at the altitude of the trace gas can decrease the measurement sensitivity by reducing the number of photons backscattered to the instrument, thereby reducing the AMF. Even when aerosols are considered, assumptions about aerosol optical properties and profiles can cause large uncertainties; Lorente et al. (2017) found different aerosol corrections used by different research groups introduced an average uncertainty of 50 % for polluted satellite observations with high aerosol loading.

Aerosol optical depth (AOD) measured by the HSRL lidar on the B-200 (Sawamura et al., 2017) showed aerosols varying day-to-day, along the flight track and with altitude during the DISCOVER-AQ Texas campaign. The beginning of the campaign saw moderate AOD on the order of 0.2–0.3 (532 nm), often with a smoke plume at altitudes 2–4 km which sometimes merged with aerosols from lower layers later in the day. Observed AODs rose sharply on 14 September, with AODs in excess of 0.7 in some areas. Aerosol loading from 18 September onwards was relatively low (<0.15) and primarily located near the surface with occasional AOD reaching 0.25 at some points along the flight track. A full assessment of the effects of aerosols on the AMF is beyond the scope of this paper and the subject of ongoing work, but our simulations with typical AOD profiles from the HSRL lidar show a potential overestimation of the column of 10–30 % for individual polluted pixels when scattering aerosols in the PBL are ignored, and a potential 15 % underestimation of the column when the smoke layer aloft is ignored. These results are consistent with Lin et al. (2014), whose satellite biases are typically within ± 25 % due to the neglect of aerosols at these AODs.

Nowlan et al. (2016) previously compared mean profile shapes from the P-CL observations and the CMAQ simulations for the eight core ground sites during DISCOVER-AQ Texas; mean differences were typically within 20 % for individual sites. Individual total column observations can vary by >100 % (Nowlan et al., 2016), with differences mostly resulting from the small scale features of NO₂ plumes, which are difficult to resolve with model resolution. ~~We also estimate an uncertainty of 30 % in the stratospheric column, based on PRATMO comparisons with the Optical Spectrograph and InfraRed Imaging~~

~~System (OSIRIS) limb sounder (Bourassa et al., 2011).~~ Previous comparisons of DISCOVER-AQ Texas CMAQ CH₂O 1-km simulations with P-3B DFGAS observations showed agreement between the model and observations for most days of the campaign (Fried et al., 2016b). The average of daily mean biases indicated a low bias of CMAQ relative to DFGAS of -0.44 ± 0.39 ppbv in the PBL and -0.32 ± 0.40 ppbv overall ($-11.8 \pm 15.7\%$) over all days, excluding 25 September. 5 September 25 was a unique day characterized by very large CH₂O levels of up to 25 ppbv as measured by the DFGAS instrument on the P-3B in the boundary layer over petrochemical facilities in Houston, and up to 33 ppbv downwind over Galveston Bay and Smith Point later in the day due to photochemical processing (Fried et al., 2016b). From P-3B comparisons discussed later in this paper (Section 6.3), we estimate these profile shape uncertainties typically result in uncertainties in the AMF of 10 % for NO₂ and 8 % for CH₂O.

Souri et al. (2018) calculated GCAS NO₂ vertical columns independently for our derived slant columns and found a mean tropospheric AMF over all days of 1.26 ± 0.32 . This compares closely with our mean AMF of 1.29 ± 0.27 . Their inputs included MODIS BRDF for surface reflectance, GEOS-Chem modeled stratospheric profiles, and an independently-run CMAQ simulation whose aerosol fields were used to determine aerosol optical depths for input to the VLIDORT model. The similar AMF from a separate study suggests a low structural uncertainty in AMF calculations using currently available ancillary information.

5 Vertical column results

4.0.1 Modeled column uncertainties

~~Figures 3 and 4 show examples of retrieved~~ Equation 4 requires the modeled vertical column below the aircraft at the reference spectrum location ($V_R^\downarrow$) and the modeled vertical columns above the aircraft at the observation location ($V^\uparrow$) and the reference location ($V_R^\uparrow$). Systematic uncertainties in the effective slant columns above the aircraft at the observation and the reference may cancel out to some degree, but small uncertainties may still propagate to the final vertical column through the use of different observation and reference times and locations. We estimate an uncertainty of 30 % in the NO₂ and stratospheric column, based on PRATMO comparisons with the Optical Spectrograph and InfraRed Imaging System (OSIRIS) limb sounder (Bourassa et al., 2011). We estimate reference location tropospheric vertical column uncertainties of 40 % for NO₂ and 31 % for CH₂O. ~~tropospheric vertical columns for two consecutive days during the campaign, and illustrate both the day-to-day and hourly variabilities observed in and columns. The 24 September day is more typical of columns measured during the campaign in terms of magnitude. The 25 September flights show the largest pollution episode of the campaign; this case study has been previously examined in model and in situ measurement studies of ozone, and (Loughner and Follette-Cook, 2015; Souri et al., 2016; Fried et al., 2016b; Mazzuca et al., 2017; Pan et al., 2017).~~, based on comparisons of the CMAQ model columns with the P-3B inferred columns of the four cleanest spirals during the campaign at the coastal sites Galveston and Smith Point. An additional uncertainty is added by uncertainty in the reference AMFs, as discussed in the previous section.

~~In general, the largest~~

4.0.2 Total uncertainties

We estimate total uncertainties by error propagation through Eq. 4. Total uncertainties in cloud-free tropospheric NO_2 columns are seen in morning flights during all days of the campaign. On a given day, the location of the peak columns varies with overpass time and meteorology, and the largest at $250 \text{ m} \times 500 \text{ m}$ resolution range from 30 to $>100 \%$ for clean pixels ($< 0.5 \times 10^{16} \text{ molecules cm}^{-2}$), 20 to 50 % for moderately polluted pixels ($0.5 - 1 \times 10^{16} \text{ molecules cm}^{-2}$) and 18 to 30 % for more heavily polluted pixels ($> 2 \times 10^{16} \text{ molecules cm}^{-2}$). Total uncertainties in CH_2O columns at this spatial resolution vary from 30 to $>100 \%$ for clean pixels ($< 1 \times 10^{16} \text{ molecules cm}^{-2}$), 20 to 50 % for moderately polluted pixels ($1 - 2 \times 10^{16} \text{ molecules cm}^{-2}$) and 18 to 40 % for very polluted pixels ($> 2 \times 10^{16} \text{ molecules cm}^{-2}$).

5 Vertical column results

Retrieved GCAS columns in the Houston area during the campaign show enhanced NO_2 amounts over central Houston (close to Moody Tower), in the vicinity of the Houston Ship Channel industrial area (Pandora sites Channelview, Deer Park and La Porte) ~~or~~ and sometimes along the more suburban flight track to the west of and over Manvel Croix, which is the case for morning overpasses on 6 and 13 September (Nowlan et al., 2016). Individual NO_2 plumes can also often be observed from ~~individual industrial facilities~~ single industrial sites and stacks. Emissions estimates using GCAS and CMAQ indicate the highest source regions for NO_x are the Houston metropolitan area (145 t/day), where mobile sources dominate, the Houston Ship Channel region (54 t/day), where many petrochemical plants are concentrated, and to a lesser extent, the Texas City area (17 t/day), which is home to petroleum refining and petrochemical processing facilities (Souri et al., 2018).

Figures 3 and 4 show examples of retrieved NO_2 and CH_2O tropospheric vertical columns for two consecutive days during the campaign, and illustrate both the day-to-day and hourly variabilities observed in NO_2 and CH_2O columns. In general, the largest NO_2 columns are seen in morning flights during all days of the campaign, with the peak columns varying with overpass time and meteorological conditions. The 24 September day is typical of columns measured during the campaign in terms of magnitude. The 25 September flights show the largest pollution episode of the campaign.

Formaldehyde observations are noisier, but enhanced CH_2O columns are clearly observable on some days when data are spatially averaged. In particular, the 4 and 25 September show the largest CH_2O enhancements, with peak values on the order of $5 \times 10^{16} \text{ molecules cm}^{-2}$ at 1 km^2 resolution. Figure 4 shows the significant enhancement in CH_2O near the Houston Ship Channel industrial area on 25 September. ~~High levels of measured in situ on this day have been previously attributed to increased emissions from the ExxonMobil Baytown Complex (located 9 to the northeast of La Porte) and the industrial Channelview/Deer Park region (Fried et al., 2016b).~~ Several other days exhibit enhanced ~~backgrounds~~ background over land, with the largest values of CH_2O columns on these days to the north of Houston over the Conroe region, potentially from biogenic sources as well as transport of CH_2O and its precursors. These days with large background CH_2O highlight the importance of using the clean reference over the water, where background CH_2O is typically lower than over land.

The month of September 2013 was relatively dry over Houston, and B-200 flights typically occurred on dry days with little cloud. Li et al. (2016) and Loughner and Follette-Cook (2015) describe the overall meteorological conditions present during the campaign as well as detailed meteorological conditions on certain days. In the early part of September, the area saw little influence from strong synoptic weather systems, with winds mostly light and northeasterly in the early morning, shifting clockwise to southeasterly in the afternoons and resulting in the transport of clean marine air over Houston. The 11–14 September were characterized by winds from the northeast, parallel to the coastline. A cold front passed over Houston with northerly transport on 24 September, while 26 September saw stagnant conditions overnight, followed by a sea breeze.

The 25 September pollution episode has been previously examined in several model and in situ measurement studies (Loughner and Follette-Cook, 2015; Li et al., 2016; Souri et al., 2016; Fried et al., 2016b; Mazzuca et al., 2017; Pan et al., 2017). This day saw a light morning land breeze which removed pollutants from the Ship Channel to Galveston Bay. A later bay breeze then brought pollutants from the bay back to land. In the mid-morning, the prevailing winds were northwesterly over most of the city, with northeasterly winds observed at the Houston Ship Channel. When combined with the bay breeze, these winds set up a convergence zone, trapping pollutants from the Ship Channel region. In combination with a suspected emissions event (Fried et al., 2016b; Souri et al., 2018), these meteorological conditions produced very high levels of ozone, NO_2 , CH_2O and related species. NO_2 columns on this day are largest in the morning flight, while CH_2O columns are largest in the afternoon. GCAS is likely measuring both directly emitted CH_2O and secondary CH_2O produced from other precursors.

6 Comparisons with coincident measurements

In this section, we compare GCAS observations from all days with coincident observations from Pandoras and the P-3B aircraft. Figures 5 and 6 show enlarged views of NO_2 and CH_2O observations over the downtown and Ship Channel regions of Houston on 25 September, along with coincident Pandora ground site observations and the P-3B flight track nearest in time. These figures illustrate the typical coverage of P-3B spirals relative to GCAS swaths, as well as the ~~near-surface~~ air mass measured ~~by Pandora in the bottom 2 km of the atmosphere by Pandora DS~~ ground-based instruments.

6.1 P-3B airborne in situ measurements

~~Columns derived from in situ measurements of (a) from the chemiluminescence instrument and (b) from the DFGAS instrument on the P-3B aircraft compared with vertical columns measured by the GCAS instrument, over nine days during the DISCOVER-AQ Texas campaign. Each GCAS vertical column is the mean of all retrieved cloud-free GCAS columns below the aircraft within 5 and 1 of its coincident P-3B spiral center. GCAS air mass factors are determined using modeled CMAQ profiles. The solid line represents the 1:1 ratio. The dotted line represents the reduced major axis linear regression.~~

~~Figure 7 shows regression plots for the We compare the retrieved GCAS NO_2 and CH_2O columns as a function of those derived from the respective in situ instruments with columns derived from in situ observations on the P-3B aircraft, with statistics computed using a bivariate regression where the residuals in both measurements are minimized. The P-3B profiles are~~

Figure 3. Tropospheric NO_2 and CH_2O vertical columns measured by GCAS over Houston on 24 September 2013. NO_2 observations are at $\sim 250 \text{ m} \times 500 \text{ m}$ resolution and CH_2O columns are at $0.01^\circ \times 0.01^\circ$ ($\sim 1 \text{ km}^2$) resolution. Times are local time. Black crosses indicate ground sites.

converted into column amounts below the top flight altitude (usually 3.5–5 km) using mixing ratios and pressure/temperature profiles measured from on board the P-3B aircraft. Comparisons between GCAS and P-3B columns are shown in Fig. 7.

6.1.1 P-3B and GCAS column preparation

Each P-3B column is calculated by integrating the NO_2 or CH_2O partial columns derived from observed mixing ratios over the
5 altitude of the spiral. The lowest altitude of each P-3B spiral varies by location. At Deer Park, Galveston and West Houston, the mean minimum spiral altitude is $\sim 20\text{--}40 \text{ m}$, while Conroe and Smith Point spirals typically go as low as $\sim 130 \text{ m}$. At Channelview, Manvel Croix, and Moody Tower, the lowest spiral altitude is typically $\sim 300 \text{ m}$. To determine the NO_2 profile below the lowest P-3B altitude, we estimate the P-3B mixing ratio below the aircraft following Lamsal et al. (2014), by extrapolating the mixing ratio at the lowest aircraft altitude to the surface using the vertical gradient from the CMAQ model at

Figure 4. Same as Fig. 3 but for 25 September 2013.

altitudes below the spiral. A large source of error from these extrapolations is the inhomogeneity of the trace gas field, which is particularly strong for NO_2 (see Fig. 5 for example), as the lowest mixing ratio could be measured in or out of an area of high NO_2 , and is then extended to the ground. Lamsal et al. (2014) estimated errors in the DISCOVER-AQ Maryland P-3B NO_2 columns of generally less than 20 % from extrapolation of the NO_2 profile below ~300 m, assuming a factor of two error in the extrapolation. CH_2O DFGAS mixing ratios below the spiral are extrapolated to the ground from the lowest mixing ratio in the bottom 100 m of the spiral, as described by Fried et al. (in preparation). As CH_2O gradients near the surface tend to be smaller than those of NO_2 , the extrapolation error is also likely less significant. P-3B CH_2O columns calculated with an extrapolated model gradient and a direct extrapolation vary by about 5 %.

The GCAS column for the P-3B comparison is calculated by averaging all GCAS columns within 1 h and 5 km of a spiral center. We exclude spirals where there are less than 30 GCAS observations within the coincident area; most spirals typically include hundreds of GCAS pixels. The modeled NO_2 column above the top P-3B spiral altitude is subtracted from the retrieved GCAS tropospheric NO_2 column ($\sim 3 \times 10^{14}$ molecules cm^{-2} on average). According to the CMAQ simulations, the column

Figure 5. GCAS tropospheric NO₂ columns measured near DISCOVER-AQ ground sites in the area of downtown Houston on 25 September 2013. P-3B flight tracks are shown in white. Pandora direct sun NO₂ tropospheric columns (total column NO₂ minus modeled NO₂ above the aircraft) are shown in filled circles. Black lines represent the line of sight of each Pandora in intersecting the bottom 2 km of the atmosphere. The largest NO₂ column observed by GCAS on this day was 16×10^{16} molecules cm⁻². The NO₂ precision at this resolution is $\sim 1 \times 10^{15}$ molecules cm⁻². Periodic cross-track gaps in the data are due to write-to-disk intervals of the instrument. During these periods, the instrument does not acquire data, thus producing small gaps in coverage.

above the P-3B is on the order of 2×10^{15} . Comparisons of CMAQ and P-3B NO₂ profiles in the free troposphere (3–5 km) suggest a mean absolute error of 70 % in the free troposphere (CMAQ is 10 % higher than the P-3B on average). If we assume similar discrepancies above the highest P-3B altitude, this may lead to an uncertainty of $\sim 2 \times 10^{14}$ molecules cm⁻² from 4 to 14 September, and 1×10^{15} from 24 to 26 September flights, in the GCAS column from the removal of the column above the P-3B.

Free tropospheric CH₂O in the model is much larger than that observed by the in situ instrument during several early flights during the 4 to 14 September period, possibly due to the transport of too much boundary layer air in the model (Fried et al., 2016b). The mean absolute error from CMAQ versus P-3B between 2–5 km is 40 %, with much larger biases of ~100 % on certain days. We find its removal introduces daily background biases that reduce the overall correlation between P-3B

Figure 6. GCAS tropospheric CH_2O columns measured near DISCOVER-AQ ground sites in the area of downtown Houston on 25 September 2013. P-3B flight tracks are shown in white. CH_2O columns are spatially averaged on a $0.01^\circ \times 0.01^\circ$ grid ($\sim 1 \text{ km}^2$). The CH_2O precision at this resolution is $\sim 1 \times 10^{16} - 7 \times 10^{15} \text{ molecules cm}^{-2}$.

and GCAS observations; as a result, we do not remove the modeled CH_2O above the spiral from the GCAS results in these comparisons. This results in an uncertainty on the order of $1 - 3 \times 10^{15} \text{ molecules cm}^{-2}$, depending on the flight.

6.1.2 NO_2

The overall correlation between the P-3B P-CL and GCAS NO_2 measurements is very good ($r^2 = 0.89$). The two instruments also agree well in magnitude, with GCAS slightly lower than the P-3B at larger NO_2 columns by $\sim 10 \%$. At background levels, GCAS overestimates the P-3B columns by $\sim 1.6 \times 10^{15} \text{ molecules cm}^{-2}$. This background offset is most likely due to a combination of uncertainties introduced by the GCAS stratospheric correction and the modeled tropospheric background column in the reference spectrum in Equation 4, with a possible contribution from the uncertainty in the column below the minimum P-3B spiral altitude. ~~Most of the variability observed in the column comparisons is due to the large radius of the P-3B spiral, which can mean the P-3B flies in and out of plumes in some spirals, as is shown in Fig. 5, as well as the inability of the P-3B to capture profiles of near-surface below 300 near the Channelview, Manvel Croix and Moody Tower sites.~~

Figure 7. Columns derived from in situ measurements of (a) NO_2 from the chemiluminescence instrument and (b) CH_2O from the DFGAS instrument on the P-3B aircraft compared with vertical columns measured by the GCAS instrument, over nine days during the DISCOVER-AQ Texas campaign. Each GCAS vertical column is the mean of all retrieved cloud-free GCAS columns below the aircraft within 5 km and 1 h of its coincident P-3B spiral center. GCAS air mass factors are determined using modeled CMAQ profiles. The solid line represents the 1:1 ratio. The dotted line represents the reduced major axis linear regression. Error bars represent the uncertainty in the GCAS mean column due to retrieval noise from the observations used to calculate a mean column (typically several hundred at $250\text{ m} \times 500\text{ m}$ resolution); in the case of NO_2 , this uncertainty is generally negligible due to low relative error. Column precisions for P-3B observations are approximately 2×10^{13} molecules cm^{-2} (NO_2) and 6×10^{13} molecules cm^{-2} (CH_2O). Uncertainties from spatial variability and measurement accuracy are discussed in the text.

6.1.3 CH_2O

The agreement between the P-3B DFGAS and GCAS CH_2O columns is also reasonably good ($r^2 = 0.54$), with GCAS on average 8 % larger than DFGAS. There appears to be little background offset bias influence from the reference spectrum, although the GCAS columns are likely overestimated by some small amount as the CH_2O above the P-3B has not been removed, as discussed previously. ~~The spatial features in our GCAS observations are often more diffuse than those of, and modeled profile shapes during the spirals are often in close agreement with the P-3B observations in the boundary layer, indicating that the profile shapes used in the GCAS AMF calculations are likely reliable in the boundary layer overall.~~ Large columns are often seen at Deer Park and Channelview near industrial facilities, and at Conroe and West Houston (likely from biogenic sources as well as transport from the industrial regions).

6.1.4 AMF from P-3B profiles

In order to assess the dependence of the GCAS observations on the profile uncertainty, we also apply the P-3B profiles in place of model profiles in the GCAS AMF calculations. In this case, when the spiral profile is applied to the GCAS observations within its vicinity, the correlation remains the same but increases to $r^2 = 0.62$ for . On average, the use of the observed profiles lowers the GCAS tropospheric and column estimates by a few percent. In the case of , the reduced major axis linear regression of GCAS as a function of P-3B column results in a change in the slope from 0.90 to 0.86 and in the intercept from 1.7×10^{15} to 1.6×10^{15} . For , the slope changes from 1.08 to 1.06, and the intercept from -5×10^{14} to 3×10^{14} .

6.2 Pandora NO₂ column measurements

Figures 8 and 9 show comparisons of GCAS tropospheric columns with Pandora NO₂ columns derived from both direct sun (DS) and MAX-DOAS scattered light retrievals, by day and by site. Figure 10 shows the Pandora measurements at four sites as a function of time, and GCAS coincidences with those observations. In the case of the direct-sun Pandora-Pandora DS observations, we have estimated the tropospheric Pandora column by subtracting the modeled NO₂ above the GCAS instrument (typically $\sim 2.5\text{--}4 \times 10^{15}$ molecules cm⁻²) from the closest Pandora observation in time within 3 minutes. The uncertainty in the stratospheric NO₂ column in our model is estimated at 30 % (see Section 4.0.1). In the case of MAX-DOAS comparisons, we compare a single GCAS observation over each site with the closest MAX-DOAS observation within 20 min. For the comparison with direct-sun DS observations, we have determined the GCAS observation from the mean of GCAS ground pixels intersected by the Pandora line-of-sight in the bottom 2 km of the atmosphere (shown in Fig. 5). This helps to minimize the influence of the Pandora viewing geometry on the comparison. For instance, GCAS consistently measures large columns over the Deer Park site, with some of the largest NO₂ often to the north of the site; however, when viewing the sun directly, Pandora always looks south into cleaner air. The use of a GCAS NO₂ amount determined along the Pandora direct sun-line-of-site DS line-of-sight reduces the influence of these biased site locations on the results, with an overall reduction in the GCAS versus Pandora bias of 20 %. There remain, however, several sites with an obvious difference in GCAS versus Pandora direct-sun DS measurements, despite considering the field-of-view.

Overall, GCAS tropospheric NO₂ is larger than Pandora (GCAS/Pandora=1.50 for direct-sun DS and 1.33 for MAX-DOAS), although the spatial correlations are very good at $r^2 = 0.85$ (direct-sun DS) and $r^2 = 0.94$ (MAX-DOAS). A background offset of $\sim 2 \times 10^{15}$ molecules cm⁻² is seen between GCAS and the Pandora direct-sun DS measurements, similar to that seen in the P-3B comparisons. Again, this is most likely from uncertainties in the modeled stratospheric correction and reference spectrum correction, with a possible contribution from the Pandora reference as well. More surprisingly, GCAS NO₂ is consistently larger than Pandora measurements 50 % (DS) and 33 % (MAX-DOAS) larger at high NO₂ values. The larger GCAS values

6.3 AMF from P-3B profiles

In order to assess the dependence of the GCAS observations on the profile uncertainty, we also apply the P-3B profiles in place of model profiles in the GCAS AMF calculations and compare the new GCAS columns with the P-3B and Pandora columns.

Figure 8. Pandora direct sun NO_2 tropospheric columns vs. GCAS NO_2 tropospheric columns by day for cloud-free observations over Houston during DISCOVER-AQ Texas 2013. The Pandora columns are the total NO_2 columns measured by Pandora minus the colocated modeled stratospheric NO_2 columns used in the GCAS analysis. All correlations are statistically significant at the $p < 0.001$ level except for those of 14 ($p = 0.09$) and 27 ($p = 0.01$) September. The solid line represents the 1:1 ratio. The dotted line represents the reduced major axis linear regression.

When the spiral profiles are applied to the GCAS observations within their vicinity, the use of the observed profiles lowers the overall slope of GCAS tropospheric NO_2 columns by 4 % (P-3B) and 2 % (Pandora) and the CH_2O columns by 2 % (P-3B) as compared with coincident observations. The NO_2 correlations with the P-3B and Pandora remain the same but the correlation increases to $r^2 = 0.62$ for P-3B CH_2O . Individual coincident observations can change by as much as -50 to +35 % for NO_2 (mean change of $+1 \pm 10$ %) and -15 to +25 % for CH_2O (mean change of $+3 \pm 8$ %). The largest mean changes for a single day occur at the Deer Park site in the Pandora comparisons, where the GCAS NO_2 column on 25 September is reduced by 15 % on average.

Figure 9. Pandora NO₂ tropospheric columns from direct sun and MAX-DOAS observations vs. GCAS NO₂ tropospheric columns by site for cloud-free observations over Houston during DISCOVER-AQ Texas 2013. The Pandora direct sun columns are the total NO₂ columns measured by Pandora minus the co-located modeled stratospheric NO₂ columns used in the GCAS analysis. The solid line represents the 1:1 ratio. The dotted lines represent the reduced major axis linear regressions.

6.4 Discussion of coincident measurement comparisons

Overall, the GCAS observations correlate well spatially and temporally with the P-3B and Pandora observations. The GCAS observations also show agreement in magnitude with the P-3B inferred NO₂ and CH₂O columns well within the measurement uncertainties. The GCAS NO₂ observations are significantly higher than those of the Pandora direct Sun instruments by 50 %.

5 They are also higher than the Pandora MAX-DOAS by 33 %, although there are fewer coincidences with the MAX-DOAS observations and there is good agreement at the La Porte site.

Differences between GCAS and the P-3B primarily result from errors in the GCAS AMF (surface reflectance, aerosols and profile shape), the inability of the P-3B to capture profiles of near-surface gases below 300 m near the Channelview, Manvel

Figure 10. Tropospheric NO_2 columns from Pandora direct sun (DS) and MAX-DOAS observations as a function of time between 4 and 27 September at Deer Park, La Porte, Moody Tower and Smith Point sites, and GCAS coincidences with those observations, as well as stratospheric NO_2 from a model at Pandora DS measurements. Pandora DS tropospheric columns are derived by removing the modeled stratosphere from the retrieved Pandora total columns.

Croix and Moody Tower sites, and spatial variability and P-3B sampling. Much of the variability observed in individual spirals in the NO_2 column comparison in Fig. 7 is due to the large radius of the P-3B spiral, which can mean the P-3B sometimes flies in and out of NO_2 plumes, as seen in Fig. 5.

The differences between GCAS and Pandora NO_2 are much larger. GCAS NO_2 columns could be influenced by several uncertainties that can result in cumulative biases in the AMF calculation ~~caused by potential uncertainties (again, primarily from errors~~ in surface reflectance, ~~profile shape and aerosols.~~

~~Previous airborne comparisons with aerosols and profile shape).~~ Different factors likely dominate the uncertainties at different sites; some sites are located at locations with very inhomogeneous surface reflectance (Smith Point and Moody

5 Tower) and some at locations with large uncertainties in profile shape. The slope is also dominated by the larger polluted measurements on the GeoTASO instrument during DISCOVER-AQ Texas on four relatively unpolluted or cloudy days (13, 14, 18, 24 September) also suggested airborne larger than Pandora (Nowlan et al., 2016). 25 September, which was a day with complicated meteorology, a morning boundary layer of ~200 m (according to HSRL data), and uncertain emissions (Souri et al., 2018).

Souri et al. (2018) also found a large difference between GCAS and Pandora observations during the Texas campaign. By using a Bayesian inversion to constrain the MODIS BRDF, they reduced the overestimation of GCAS relative to Pandora by 23 % through a 0.023 increase in surface albedo, broadly consistent with studies that have found a low bias in MODIS surface reflectance (Wang et al., 2010b; Salomon et al., 2006) at short wavelengths. The exclusion of aerosols in our AMF calculation may cause the AMF to be underestimated (and therefore the vertical column to be overestimated) in some cases, particularly where scattering aerosols are in the lowest part of the boundary layer (see discussion in Section 4.5.2). We find that the GCAS vertical columns at Pandora coincidences are reduced on average by 10 % when the air mass factor is calculated using the nearest HSRL aerosol optical thickness profiles below the aircraft for scattering aerosols. In the previous section, we saw that P-3B observations point to there is likely a small +4-2 % bias in the GCAS column from the use of CMAQ modeled NO₂ profiles, on average profile shapes in measurements coincident with Pandora. Therefore, while profile shape may contribute to large errors on individual observations, it is unlikely to produce a large bias in the GCAS observations overall.

Differences in the GCAS and Pandora slant column retrievals themselves may also play a role, including the wavelength fitting region and atmospheric temperature assumptions. The Pandora slant column product used in our study was produced assuming a fixed effective temperature of 264 K, which could result in a low bias in the retrieved Pandora slant column of 10 % (Spinei et al., 2014). Previous comparisons of Pandora direct sun-DS total column NO₂ observations with other ground based-ground-based observations have shown good agreement (Herman et al., 2009; Wang et al., 2010a), while. In contrast, Knepp et al. (2017) compared a year of retrieved Pandora zenith-sky stratospheric NO₂ slant columns with those from a zenith-looking UV-Vis spectrometer (DOAS M07) from the Network for the Detection of Atmospheric Composition Change (NDACC) spectrometer, using different retrieval settings, and found Pandora underestimated the NDACC instrument by 7-40 %, with the bias dependent on season and solar zenith angle. The Pandora slant column product used in our study was produced assuming a fixed effective temperature of 264 K, which could result in a low bias in the retrieved Pandora slant column of 10 % (Spinei et al., 2014).

Different factors likely dominate the uncertainties at different sites; some sites are located at locations with very inhomogeneous surface reflectance (Smith Point and Moody Tower) and some at locations with large uncertainties in profile shape. The slope is also dominated by the larger polluted measurements on the 25 September, which was a day with complicated meteorology, a morning boundary layer of ~200 (according to HSRL data), and uncertain emissions (Souri et al., 2018). Despite the sources of uncertainty on the GCAS columns, it should be noted that a large reduction in the GCAS vertical columns from the use of different AMF inputs that resulted resulting in better agreement with the Pandora columns could would mean a significant underestimation by GCAS of both the NO₂ and CH₂O P-3B columns. Recent comparisons of Pandora DS NO₂ columns and NO₂ inferred from the P-3B P-CL instrument for the four DISCOVER-AQ campaigns (Maryland, California, Texas and Colorado)

show the P-3B agrees well with Pandora DS measurements for all campaigns except Texas, where Pandora NO₂ is significantly underestimated (Sungyeon Choi, personal communication). Previous airborne comparisons with the GeoTASO instrument during DISCOVER-AQ Texas on four relatively unpolluted or cloudy days (13, 14, 18, 24 September) also suggested airborne NO₂ larger than Pandora (Nowlan et al., 2016).

7 Conclusions

- We have presented trace gas retrievals of NO₂ and CH₂O from the GCAS instrument during the DISCOVER-AQ Texas 2013
- 20 campaign. In these retrievals, we first use a spectral fit to derive slant column densities from nadir spectra, in combination with reference spectra measured over a clean area. We then convert those slant columns to vertical columns using tropospheric trace gas profiles from the CMAQ model and surface reflectance from the MODIS BRDF product. At a spatial resolution of 250 m × 500 m, the NO₂ product has a mean precision of 1×10^{15} molecules cm⁻², and the CH₂O product has a mean precision of 1.9×10^{16} molecules cm⁻². In order to meet TEMPO precision requirements, and to detect enhanced CH₂O
 - 25 during the DISCOVER-AQ Texas campaign, we recommend CH₂O be spatially averaged to 1 km². Uncertainties in NO₂ polluted observations are dominated by air mass factor uncertainties, which result primarily from uncertainties in surface reflectance, aerosol loading and trace gas profile shape. These air mass factor uncertainties also play a role in individual CH₂O uncertainties, but can be similar in magnitude to uncertainties from spectral fitting noise.

- Comparisons between GCAS and P-3B and Pandora observations show GCAS data are very well correlated with these
- 30 coincident measurements, but in some cases show differences in magnitude. GCAS columns agree well with those inferred from P-3B in situ profiles for both NO₂ ($r^2 = 0.89$, GCAS/P-3B slope=0.90 and intercept= 1.6×10^{15} molecules cm⁻²) and CH₂O ($r^2 = 0.54$, GCAS/P-3B slope=1.08 and intercept= -5×10^{14} molecules cm⁻²). The use of P-3B profiles ~~in GCAS air mass factor calculations indicates a mean uncertainty of 2-4~~ instead of modeled profile shapes results in a mean difference of

2–4 % in GCAS columns ~~from the use of a modeled profile shape over Houston~~ in comparisons with coincident observations.

GCAS is higher than Pandora MAX-DOAS tropospheric NO₂ columns but shows excellent spatial agreement ($r^2 = 0.94$, GCAS/Pandora slope=1.33 and intercept= 4×10^{14} molecules cm⁻²); these differences in magnitude, however, remain within the bounds of GCAS systematic error estimates in the AMF. The largest discrepancies in magnitude are seen between GCAS
5 and Pandora direct sun observations, although spatial correlations are very good ($r^2 = 0.85$, GCAS/Pandora slope=1.50 and intercept= 1.9×10^{15} molecules cm⁻²). As both Pandora and GCAS are key instruments in planned TEMPO validation activities, there is clearly a need to resolve these differences in magnitude to ensure reliable validation studies. Further opportunities for comparisons over different geographic areas and pollution regimes exist in other campaigns.

Since DISCOVER-AQ Texas in 2013, the airborne GCAS and GeoTASO instruments have been deployed in the DISCOVER-
10 AQ Colorado field campaign (2014), KORUS-AQ field campaign (2016), GOES-R Validation Campaign (2017) ~~and~~, Lake Michigan Ozone Study (2017) and Long Island Sound Tropospheric Ozone Study (2018). These data are currently under study, and offer further opportunities to examine the effects of surface characterization, profile shape, aerosols, viewing geometries and trace gas heterogeneity on ground, airborne and satellite remotely-sensed trace gas columns.

8 Data availability

15 The GCAS and P-3B NO₂ and C₂H₄ data and Pandora direct sun NO₂ columns are publicly available from the DISCOVER-AQ data archive at <http://www-air.larc.nasa.gov/missions/discover-aq/discover-aq.html> (doi: 10.5067/Aircraft/DISCOVER-AQ/Aerosol-TraceGas). The archived GCAS data also include coincident model profiles for each observation.

Table 1. Summary of GCAS flights during DISCOVER-AQ Texas 2013. Times are Local Time (LT) (UTC - 5 hours). Days with P-3B aircraft flights are denoted by an X in the rightmost column.

Date	Description	Flight Time (AM)	Flight Time (PM)	P-3B ?
4 September	Houston	08:46–12:05	13:37–17:12	X
6 September	Houston	08:47–12:04	13:59–17:13	X
10 September	Ocean color	07:57–10:10 11:41–12:59	15:03–17:19	
11 September	Houston	08:47–12:06	13:39–16:50	X
12 September	Houston	08:47–10:44	13:42–17:00	X
13 September	Houston	08:41–12:14	13:56–17:17	X
14 September	Houston	07:53–11:23	12:26–15:52	X
17 September	Ocean color	07:55–11:11	13:45–17:09	
18 September	Houston	08:43–12:16	14:06–17:31	
24 September	Houston	08:42–12:00	13:12–16:25	X
25 September	Houston	08:45–12:02	13:50–17:10	X
26 September	Houston	08:40–11:50	14:18–17:41	X
27 September	Houston	08:39–12:04		

Table 2. DISCOVER-AQ sites with Pandora spectrometers overflown by GCAS. The Pandora ID is a identification number given to each individual Pandora instrument. Asterisks indicate Pandoras used for MAX-DOAS measurements; all other Pandoras were used solely for direct sun (DS) measurements. The mean GCAS overpass time of Pandora sites is 10:07 LT (earliest/latest 08:18/11:51 LT) for morning flights and 15:25 LT (earliest/latest 12:51/17:12 LT) for afternoon flights.

Site	Latitude (°)	Longitude (°)	Pandora ID
Channelview	29.803	−95.126	P26
Conroe	30.350	−95.425	P31
Deer Park	29.670	−95.128	P32
Galveston	29.254	−94.861	P34
Northwest Harris County	30.039	−95.674	P30
La Porte	29.672	−95.065	P38*, P39
Manvel Croix	29.520	−95.392	P33
Moody Tower	29.718	−95.341	P28, P35*
Smith Point	29.546	−94.787	P8, P29*, P36
West Houston	29.833	−95.657	P18

Table 3. Fitting details and fitted parameters used in GCAS trace gas retrievals.

Parameter	NO ₂ Retrieval	CH ₂ O Retrieval
Fitting window	420.0–465.0 nm	328.5–356.5 nm
NO ₂ cross section	Vandaele et al. (1998), 294 K	Vandaele et al. (1998), 294 K
CH ₂ O cross section	N/A	Chance and Orphal (2011), 300 K
O ₃ cross section	Brion et al. (1993), 218 and 295 K	Brion et al. (1993), 218 and 295 K
H ₂ O vapor cross section	Rothman et al. (2013), 288 K, 1 atm	N/A
BrO cross section	N/A	Wilmouth et al. (1999), 228 K
O ₂ –O ₂ cross section	Thalman and Volkamer (2013), 293 K	Thalman and Volkamer (2013), 293 K
Undersampling	Chance et al. (2005)	Chance et al. (2005)
Ring spectrum	Chance and Spurr (1997)	Chance and Spurr (1997)
Scaling polynomial	5th order	5th order
Baseline polynomial	4th order	4th order
Wavelength shift
