6 **Abstract**

7

8 The concentrations of cloud condensation nuclei (CCN) modulate cloud properties, rainfall
9 location and intensity, and climate forcings. This work assesses uncertainties in CCN
10 measurements and the apparent hygroscopicity parameter (κ_{app}) which is widely used to represent
11 CCN populations in climate models. CCN measurements require accurate operation of three
12 instruments: the CCN instrument, the differential mobility analyzer (DMA), and the condensation
13 particle counter (CPC). Assessment of DMA operation showed that varying the ratio of aerosol to
14 sheath flow from 0.05 to 0.30 resulted in discrepancies between the κ_{app} values calculated from
15 CCN measurements and the literature value. Discrepancies were found to increase from < 1% to
16 13% for both sodium chloride and ammonium sulfate. The ratio of excess to sheath flow was also
17 varied, which shifted the downstream aerosol distribution towards smaller particle diameters (for
18 excess flow < sheath flow) or larger particle diameters (for excess flow > sheath flow) than
19 predicted. For the CPC instrument, undercounting occurred at high concentrations, resulting in
20 calculated κ_{app} lower than the literature values. Lastly, undercounting by CCN instruments at
21 high concentration was also assessed, taking the effect of supersaturation on counting efficiency
22 into account. Under recommended operating conditions, the combined DMA, CPC, and CCN
23 uncertainties in κ_{app} are 1.2 % or less for 25 to 200 nm diameter aerosols.

26 **1. Introduction**

27

28 Aerosol-cloud interactions represent a major uncertainty in current predictions of the Earth's climate
29 (IPCC, 2013). According to well-known Köhler theory, an aerosol's potential to catalyze cloud droplet
30 formation by activating as a cloud condensation nucleus (CCN) depends on its physical and chemical
31 properties. For any given composition, the CCN activation potential of an aerosol increases as its
32 diameter decreases. While the relationship between aerosol diameter and CCN activation is
33 straightforward, the effect of composition on an aerosol's ability to participate in cloud formation is
34 more complex (Petters and Kreidenweis, 2013; Ovadnevaite et al., 2011). Predicting the cloud forming
35 capacity of various air masses based on the properties of the aerosol they contain is essential for
36 evaluating relative contributions from pollution, continental background and marine aerosol sources
37 (Brooks and Thornton, 2018; Carslaw et al., 2013). Long-term CCN measurements are available from
38 numerous locations globally (Schmale et al., 2018). However, understanding regional and temporal
39 variability in CCN populations requires the ability to assess whether observed differences reflect true
40 physical differences or simply variations in CCN sampling strategies.

41

42 Parameterizations of CCN activity which accurately prescribe CCN measurements are needed for
43 climate models, cloud resolving models, and air quality predictions (Betancourt and Nenes, 2014;
44 Betancourt et al., 2013; Chang et al., 2017; Crosbie et al., 2015; Karydis et al., 2012; Kawecki and
45 Steiner, 2018). One parameterization was designed to represent the cloud droplet activation potential
46 ambient aerosol masses of unknown composition with a single variable, kappa (κ) based on the dry
47 aerosol's hygroscopicity, or ability to uptake water and form a solution droplet (Petters and
48 Kreidenweis, 2007). Various names and abbreviations have been given to κ throughout the literature:
49 "hygroscopicity parameter", "single hygroscopicity parameter", κ (Petters and Kreidenweis, 2007;

50 Carrico et al., 2008; Asa-Awuku et al., 2010; Moore et al., 2012b); “CCN-derived κ ”, κ_{CCN} (Carrico et
51 al., 2008; Petters and Kreidenweis, 2007); and the “apparent hygroscopicity parameter” κ_{app} (Sullivan
52 et al., 2009; Collins et al., 2016; Petters and Kreidenweis, 2013). The term *apparent* hygroscopicity is
53 favored by many because it emphasizes that fact that while CCN activation can often be predicted
54 accurately by hygroscopic water uptake, they are different physical processes. It is possible for a
55 compound to have high intrinsic hygroscopicity and low apparent hygroscopicity if it is poorly soluble
56 in water (Sullivan et al., 2009).

57

58 Parameterizations of hygroscopicity that pre-date Petters and Kreidenweiss 2007 exist as well. Winkler
59 1973 developed an equation for approximating the growth of an aerosol particle with relative humidity,
60 based on the quantity and physical characteristics of the soluble species in the particle. Another
61 approximation for the relationship between the equilibrium size of a particle and relative humidity was
62 derived by Fitzgerald in 1975, in which the soluble fraction and composition of the soluble
63 component(s) are taken into account. Fitzgerald et al., 1982 derived a particle composition parameter
64 using the mass fraction and physical properties of soluble material in a particle. Kreidenweis et al., 2005
65 determined that the critical activation diameter of dry aerosol particles can be calculated from simplified
66 Köhler theory using the physical properties of water and the solute in a solution droplet. This
67 parameterization has been used in CCN closure studies (Bougiatioti et al., 2009; Moore et al., 2011;
68 Moore et al., 2012a). The earliest prediction of CCN concentrations for specific particle diameters and
69 hygroscopicity used this parameterization as well (Mochida et al., 2006).

70

71 Once calculated, hygroscopicity parameters are useful tools for comparing CCN field measurements
72 conducted in various regions and seasons and for making predictions about cloud formation, aerosol-
73 cloud interactions in weather, and climate models. Values of κ_{app} can be used to compare the CCN

74 results in field and laboratory studies, including sea spray aerosol. For example, aggregation of results
75 from several mesocosm experiments and marine field studies found submicron (30-100 nm) κ_{app} for sea
76 spray aerosol as low as 0.4 and as high 1.3 (Collins et al., 2016). Another study, which included a
77 survey of observational CCN data, reported that marine and continental aerosols could be described by
78 κ_{app} values of 0.7 ± 0.2 and 0.3 ± 0.1 respectively (Andreae and Rosenfeld, 2008).

79
80 Several studies have examined the sensitivity of models to κ values derived from HTDMA
81 measurements. An analysis of the NASA Global Modeling Initiative Chemical Transport Model and the
82 GEOS-Chem CTM (Karydis et al., 2012) found that cloud droplet number concentration is sensitive to κ
83 in Arctic and remote regions, where background aerosol loadings are low. Another study (Betancourt
84 and Nenes, 2014) found that a $\pm 50\%$ uncertainty range in the κ of secondary organic aerosols and
85 particulate organic matter resulted in a cloud droplet number concentration uncertainty of up to 15 %
86 and 16 %, respectively. Updating precipitation models with lab-derived κ values for specific inorganic
87 and organic species may increase the accuracy of storm forecasts by providing better predictions of
88 intense precipitation (Kawecki and Steiner, 2018). In terms of climate, (Liu and Wang, 2010) found that
89 increasing the κ of primary organic aerosols from 0 to 0.1, and decreasing the κ of secondary organics
90 aerosols from 0.14 to 0.07, resulted in an uncertainty in global secondary aerosol indirect forcing of 0.4
91 Wm^{-2} from pre-industrial times to present day.

92
93 The sensitivity of weather and climate models to hygroscopicity parameters demonstrates the need for
94 accurate measurements. In this study, we examine experimental uncertainties in CCN measurements and
95 the resulting uncertainties in determination of κ_{app} . Differences in reported κ_{app} values may result
96 from experimental artifacts rather than actual differences in an aerosol's ability to facilitate cloud
97 formation. By systematically quantifying sources of experimental error, this study provides a

- 98 framework for determining the significance of variations in CCN properties reported in multiple studies
- 99 and defining the operating conditions which minimize instrumental artifacts.

100 2. Background

101

102 The Köhler equation relates water vapor saturation ratio at the surface of a wet droplet, s , to its radius at
103 equilibrium (Rogers and Yau, 1989):

104

$$105 \quad s = \left(1 - \frac{b}{r^3}\right) \exp\left(\frac{a}{r}\right) \quad (1a)$$

106

$$107 \quad a = \frac{2\sigma_w M_w}{\rho_w R T} \quad (1b)$$

108

$$109 \quad b = \frac{3im_s M_w}{4\pi\rho_w M_s} \quad (1c)$$

110

111 where s is the equilibrium saturation ratio of a solution droplet with radius r , σ_w is the surface tension of
112 water, M_w is the molecular weight of water, R is the ideal gas constant, T is temperature in Kelvin, ρ_w is
113 the density of water, and M_s is the molecular weight of the solute. The minimum saturation ratio that is
114 required for spontaneous droplet growth, s_{act} , is therefore:

115

$$116 \quad s_{crit} = 1 + \sqrt{\frac{4a^3}{27b}} \quad (2)$$

117

118 Petters and Kreidenweis [2007] reformulated the Köhler equation as κ -Köhler theory:

119

$$120 \quad s_{crit} = \exp\left(\sqrt{\frac{4A^3}{27D_{act}^3 \kappa_{app}}}\right) \quad (3a)$$

121 and

122

123

$$A = \frac{4\sigma_{lv}M_w}{RT\rho_w} \quad (3b)$$

124

125 Where s_{crit} is the critical water vapor saturation ratio, D_{act} is the dry particle activation diameter and

126 κ_{app} is the apparent hygroscopicity parameter. Solving for κ_{app} yields:

127

128

$$\kappa_{app} = \frac{4A^3\sigma_{lv}^3}{27T^3D_{act}^3\ln^2(s_{crit})} \quad (4)$$

129

130 The apparent hygroscopicity parameter can be calculated from experimental CCN results, where the dry

131 diameter and water vapor saturation ratio are known. For a chosen aerosol diameter, the activated

132 fraction is the ratio of the concentration aerosols that activate as CCN to the total aerosol concentration:

133

134

$$\textit{Activated fraction} = \frac{\textit{CCN Concentration}}{\textit{Aerosol Concentration}} \quad (5)$$

135

136 Activated fraction data is fit with a sigmoid error function to determine the percent supersaturation at

137 which 50 % of the particles have activated as CCN (activated fraction = 0.50), which is considered the

138 operationally defined critical percent supersaturation SS_{crit} (Rose et al., 2008). The critical saturation

139 ratio s_{crit} can then be determined and entered into Eq. (4) in order to calculate κ_{app} for the near-

140 monodisperse aerosol:

141

142

$$s_{crit} = 1 + \frac{SS_{crit}}{100} \quad (6)$$

143

144 Reporting κ_{app} as a function of diameter allows for the comparison of the cloud condensation nucleation
145 abilities of multimodal aerosol populations, without overlooking differences which arise due to aerosol
146 composition.

147

148 The apparent hygroscopicity parameter is related to chemical composition; therefore, the calculated κ_{app}
149 of a pure substance should be constant across CCN experiments. However, discrepancies between κ_{app}
150 for a single chemical species have been observed. Experimental results for ammonium nitrate are
151 inconsistent with reported values ranging from $0.577 \leq \kappa_{app} \leq 0.753$ (Svenningsson et al., 2006).

152 Also, large ranges are often observed for organic compounds, such as glutaric acid ($0.054 \leq \kappa_{app} \leq$
153 0.16) and malonic acid ($0.199 \leq \kappa_{app} \leq 0.255$) (Koehler et al., 2006; Kumar et al., 2003; Hartz et al.,
154 2006). Below we evaluate potential sources of uncertainties in CCN measurements and the resulting
155 uncertainties in κ_{app} .

156

157 **3. Artifacts derived from sized CCN measurements**

158

159 CCN measurements used for calculating apparent hygroscopicity from monodisperse aerosol require
160 accurate operation of three instruments: the CCN, the differential mobility analyzer (DMA), and the
161 condensational particle counter (CPC). The setup for laboratory CCN experiments is shown in Fig. 1.
162 First, a polydisperse population of aerosols is generated by an atomizer and dried using a desiccant tube
163 packed with silica gel. A near-monodisperse flow is obtained through size-selection in the DMA. The
164 flow is then split between a CPC (which measures aerosol concentration) and a CCN counter (which
165 measures the concentration of particles that activate as cloud condensation nuclei at a given percent
166 supersaturation). Instrument artifacts will first be assessed separately for the DMA, CPC, and CCN
167 counter. In the concluding section of the paper (and Fig. 10), the overall uncertainty due to the
168 combination of these is presented and discussed.

169

170 We note that this study considers sized CCN measurements which may be used for the determination of
171 κ_{app} . In contrast, a number of earlier CCN studies conducted on the full ambient aerosol population
172 without sizing the aerosol (Jennings et al., 1996; Hudson and Xie, 1998; Modini et al., 2015; Duan et al.,
173 2017; Schmale et al., 2018; Leng et al., 2013). While useful, such studies do not produce the data
174 required for accurate determination of κ_{app} from the CCN measurements.

175

176 **3.1 Artifacts derived from differential mobility analyzers**

177

178 **3.1.1 DMA operation and electrical mobility**

179

180 Differential mobility analyzers used in atmospheric science include commercially available instruments
 181 from Grimm Aerosol Technik, TSI Incorporated, and MSP Corporation. They have also been custom
 182 built by a number of research groups (Mei et al., 2011; Barmounis et al., 2016; Jokinen and Makela,
 183 1997; Seol et al., 2000). All models allow for the selection of particles through electrical mobility, the
 184 ability of a particle to move through a medium (such as air) while acted upon by an electrical field. The
 185 DMA size-selects near-monodisperse aerosol from a polydisperse aerosol source, as shown in Fig. 2
 186 (modeled after the Vienna-type long Differential Mobility Analyzer from Grimm Technologies). The
 187 electrical mobility Z_p of a particle with mobility diameter d_m can be calculated according to:

188

$$189 \quad Z_p = \frac{neC_C(d_m)}{3\pi\eta d_m} \quad (7)$$

190

191 where n is the number of charges on the particle (assumed to be one in this study), e is the elementary
 192 unit of charge, η is the gas dynamic viscosity, and $C_C(d_m)$ is the Cunningham slip correction factor:

193

$$194 \quad C_C(d_m) = 1 + \frac{2\lambda}{d_m} \left(\alpha_{CC} + \beta_{CC} \exp \left[-\frac{\gamma_{CC}}{2\lambda/d_m} \right] \right) \quad (8)$$

195

196 where λ is the mean free path (DeCarlo et al., 2004). For the Vienna-type long Differential Mobility
 197 Analyzer from Grimm Technologies, Inc. considered here, $\alpha_{CC} = 1.246$, $\beta_{CC} = 0.42$, and $\gamma_{CC} = 0.86$
 198 (Grimm Aerosol Technik, 2009).

199

200 Particle-laden flow enters the differential mobility analyzer through the aerosol inlet (flow Q_a), and travels
 201 down the DMA column (inner radius r_1 , outer radius r_2) with the clean air sheath flow Q_{sh} . Positively-
 202 charged particles are attracted by the negatively-charged inner electrode, to which voltage V_0 has been

203 applied. Ideally, selection of a voltage allows only particles of a specific mobility diameter to exit the
 204 DMA through the sample flow Q_s . All particles with larger diameter (lower Z_p) or smaller diameter
 205 (higher Z_p) will exit the DMA through the excess flow Q_e . In other words, Q_s would ideally consist only
 206 of aerosols with diameters equal to, or very nearly equal to, the selected diameter.

207

208 In reality, the aerosol flow that leaves the DMA through Q_s is polydisperse with a mobility distribution
 209 determined by instrumental parameters. A triangular approximation has been chosen as a model for this
 210 distribution, as particle inertia is negligible for the diameters considered in this study (Stratmann et al.,
 211 1997; Mamakos et al., 2007). The probability that a particle at the aerosol inlet will exit with the sampling
 212 flow is defined by transfer function $f(Z_p, Z_{p,mid})$:

213

$$214 \quad f(Z_p, Z_{p,mid}) = \frac{\alpha_{TF}}{2\beta_{TF}} \left(\left| \frac{Z_p}{Z_{p,mid}} - (1 + \beta_{TF}) \right| + \left| \frac{Z_p}{Z_{p,mid}} - (1 - \beta_{TF}) \right| - 2 \left| \frac{Z_p}{Z_{p,mid}} - 1 \right| \right) \quad (9)$$

215 where $Z_{p,mid}$ is the midpoint mobility of the transfer function, and α_{TF} and β_{TF} are flow-derived
 216 constants, defined as:

217

$$218 \quad \alpha_{TF} = \frac{Q_s + Q_a}{2Q_a} \quad (10a)$$

219 and

$$220 \quad \beta_{TF} = \frac{Q_s}{Q_{sh}} \quad (10b)$$

221

222 The midpoint and half-width of the transfer function are respectively calculated according to: (Knutson
 223 and Whitby, 1975)

$$224 \quad Z_{p,mid} = \frac{Q_e + Q_{sh}}{4\pi LV_0} \ln \left(\frac{r_2}{r_1} \right) \quad (11a)$$

225 and

226

$$227 \quad \Delta Z_p = \frac{Q_a}{2\pi LV_0} \ln\left(\frac{r_2}{r_1}\right) \quad (11b)$$

228

229 where L is the distance between the DMA inlet and outlet.

230

231 **3.1.2 κ_{app} artifacts arising from DMA flow ratios**

232

233 Next we assess the ramifications of the DMA transfer function for the derived κ_{app} . A lognormal
234 theoretical aerosol number distribution was used to represent a polydisperse ambient aerosol population
235 (Fig. 3a). This distribution was converted to an electrical mobility distribution using Eq. (7) and Eq. (8),
236 assuming that the aerosols in the distribution were spherical and singly charged. From the distribution, a
237 series of single aerosol sizes were selected (25, 50, 100, and 200 nm diameter). For each aerosol size,
238 the resulting DMA transfer functions were calculated for seven cases using Eq. (9) and the various
239 parameters for DMA sheath, excess, aerosol, and sample flow listed in Table 1. These seven cases were
240 chosen to represent possible measurements scenarios that may be encountered in a CCN experiment.
241 The aerosol/sheath ratio is varied in Cases 1-4 in order to study the effects of chosen experimental
242 parameters. Sheath flow is predetermined in some DMAs (for example, the Grimm Vienna DMA
243 considered in this study), but can be varied in other instruments. The aerosol flow rate may also be
244 selected in an experiment. Cases 5-7 vary the excess/sheath ratio in order to take proper instrument
245 operation into account. The excess and sheath flow should be identical, but small discrepancies may
246 occur.

247

248 For example, the resulting DMA transfer functions for a 100 nm aerosol conditions constrained by Cases
249 1-4 are shown in Fig. 3b, where an increase in Q_a/Q_{sh} from 0.1 (black line) to 0.3 (green line) tripled
250 the width of the number distribution, and decreasing Q_a/Q_{sh} to 0.05 (blue line) from 0.10 halved the
251 width of the number distribution. The result of applying the transfer functions shown in Fig. 3b to the
252 distribution in Fig. 3a is shown in Fig. 3c.

253

254 All downstream distributions for all seven DMA cases and all aerosol sizes are shown in Fig. S1 in the
255 Supplement. DMA Cases 1-4 represent experimental conditions in which the sheath and excess air
256 flows are equal and the aerosol/sheath flow ratio is varied. As Q_a/Q_{sh} increases, the width of the
257 number distribution measured downstream of the DMA increases, while the midpoint diameter remains
258 constant. It was found that doubling the aerosol to sheath ratio doubled the width of the downstream
259 number distribution for 25, 50, 100, and 200 nm particles. For example, when selecting 200 nm
260 particles, increasing Q_a/Q_{sh} from 0.10 to 0.20 increased the downstream diameter range from 181-222
261 nm (a spread of 41 nm) to 167-250 nm (a spread of 87 nm). The particle diameter ranges that would be
262 observed downstream of the DMA are summarized in Table 2.

263

264 To assess the variations in CCN properties resulting from DMA uncertainties the critical percent
265 supersaturation were calculated for representative atmospheric aerosols. The value of SS_{crit} was
266 calculated for each particle diameter using Eq. (3a), using literature values for apparent hygroscopicity
267 of 0.61 for ammonium sulfate and 1.28 for sodium chloride (Clegg et al., 1998). It should be noted that
268 this analysis considers two homogeneous aerosol distributions of hygroscopic salts. Real aerosol
269 distributions tend to be mixtures of many species, and the shape of the number distribution can vary
270 between species.

271

272 To test how uncertainties in DMA diameter translate to uncertainties in κ_{app} , the activation of particles
 273 downstream of the DMA was assessed. First, for each case and diameter (25, 50, 100, and 200 nm) the
 274 critical saturation ratio s_{crit} was calculated for each particle diameter range downstream from the DMA
 275 using Eq. 3a. These critical saturation ratios were converted to critical percent supersaturation SS_{crit}
 276 and used to calculate the activated fraction AF for the aerosol particles downstream from the DMA for
 277 percent supersaturations $0.01 < SS < 1.5$, using the equation:

278

$$279 \quad AF = \frac{1}{2} \left(1 + \operatorname{erf} \left(\frac{SS - SS_{crit}}{\sigma \sqrt{2}} \right) \right) \quad (12)$$

280

281 where the standard deviation σ was equal to one-hundredth of SS_{crit} . The small σ/SS_{crit} ratio was
 282 chosen in order to generate accurate activated fraction curves for each particle diameter.

283

284 The activated fraction curve for each selected diameter (25, 50, 100, and 200 nm) was then calculated as
 285 the sum of the number-weighted activated fractions of each particle diameter downstream from the
 286 DMA. For example, for a selected diameter of 25 nm, the downstream diameters ranged from 23 nm to
 287 27 nm for DMA Case 1 and from 20 nm to 36 nm in DMA Case 4. The equation used for this
 288 calculation is:

289

$$290 \quad AF_{weighted} = \sum_i \frac{n_i}{n_{total}} AF_i \quad (13)$$

291

292 where AF_i is the activated fraction calculated using Eq. 12 and $\frac{n_i}{n_{total}}$ is the fraction of particle
 293 downstream from the DMA of diameter i .

294

295 This calculation was repeated for each selected diameter (25, 50, 100, and 200 nm), each DMA Case (1-
296 7), and percent supersaturation (0.01-1.5) in order to construct activation curves for each selected
297 diameter and DMA Case. As an example, in Fig. S2, the shape and position of each activated fraction
298 curve vary with the DMA flow ratios. As the aerosol/sheath ratio increases, the activated fraction curve
299 flattens out (DMA Case 4). The critical percent supersaturation SS_{crit} was then determined for each
300 activation curve as the percent supersaturation where $AF = 0.50$. These results are shown in Fig. 4a
301 for ammonium sulfate and sodium chloride. Eq. 4 was then used to calculate $\kappa_{app,theory}$ for each DMA
302 Case and selected diameter, as shown in Fig. 4b. Discrepancies between $\kappa_{app,theory}$ calculated in this
303 study and literature values (hereon referred to as “ κ_{app} artifacts”) are shown for both compounds in Fig.
304 4c-d.

305

306 The largest κ_{app} artifact was found in DMA case 4 (where the aerosol/sheath ratio was the highest) for
307 both ammonium sulfate and sodium chloride aerosols. The artifacts for 25 nm ammonium sulfate
308 aerosol in DMA case 4 was 0.08 , or ~13% of the literature value used for $\kappa_{app}^{(NH_4)_2SO_4}$, while the artifacts
309 for 25 nm sodium chloride in DMA case 4 was 0.16, or ~13% of the literature value used for κ_{app}^{NaCl} .

310 Artifacts were also high for DMA case 6 ($-0.041 \leq \kappa_{app,artifact}^{(NH_4)_2SO_4} \leq -0.048$) and DMA case 7
311 ($0.014 \leq \kappa_{app,artifact}^{(NH_4)_2SO_4} \leq 0.024$), where sheath and excess flow were unequal. This result demonstrates
312 that artifacts may still occur when low aerosol/sheath flow ratios are chosen (0.15 and 0.08 for DMA
313 cases 6 and 7, respectively) due to small differences between sheath and excess flow rates (5% and 2%
314 for DMA cases 6 and 7, respectively).

315

316 κ_{app} artifacts were larger for sodium chloride ($-0.10 \leq \kappa_{app,artifact}^{NaCl} \leq 0.16$) than for ammonium
317 sulfate ($-0.05 \leq \kappa_{app,artifact}^{(NH_4)_2SO_4} \leq 0.08$) across the DMA cases. As our results show, when two or more
318 compounds are compared, the more hygroscopic compound will have larger κ_{app} artifacts.
319
320 This analysis was also applied to the range of apparent hygroscopicity values Svenningsson et al., 2006
321 reported for ammonium nitrate $0.577 \leq \kappa_{app} \leq 0.753$, with a mean value of 0.670. If 0.670 is
322 assumed to be the true κ_{app} for ammonium nitrate, then the sample/sheath ratio used to determine κ_{app}
323 ($1.2\text{-}2.0 \text{ L min}^{-1}$) could lead an experimental kappa as low as 0.665 or as high as 0.674, which would not
324 fully explain the actual experimental range. This assessment ignores possibility of under/over counting
325 which could introduce additional errors.
326
327 In addition to the errors discussed above, accuracy in CCN measurements depend on the accuracy of the
328 instrument calibration. Specifically, accurate determination of the percent supersaturation set points
329 within the CCN instrument are dependent on accurate sizing of aerosols entering the CCN, and therefore
330 are dependent on the DMA sizing during CCN calibration. CCN calibrations during two standard
331 compounds, ammonium sulfate and sodium chloride, as described in detail in Rose (2008). Fortunately,
332 if the calibration procedure described by Rose is followed and an optimal DMA aerosol to sheath ratios
333 employed, the uncertainties will be minimal. Specifically, this analysis shows that an aerosol/sheath
334 ratio of 1:10 or 1:20 (Case 1 or 2, respectively) is recommended for all CCN calibrations. This will
335 result in κ_{app} uncertainties of less than 1% for all dry sizes (25 to 200 nm). However, if CCN
336 calibrations are performed using a DMA operated with less than ideal aerosol to sheath ratios,
337 substantial errors will be introduced. Analysis of the impact of DMA uncertainties on CCN calibrations

338 are discussed in detail in the Supplemental Materials. In the worst case scenario amongst the cases
339 evaluated here (Case 4), the resulting uncertainty in κ_{app} is 15%.

340

341 **3.1.3 Effect of double and triple charges on particles**

342

343 During normal operation, the Grimm DMA employs a bipolar charger (also known as a neutralizer) to
344 charge aerosol particles through the capture of gaseous ions. The analysis in Section 3.1.2 assumes that
345 each particle carries a single (+1) charge. In reality, the methods used to charge particles prior to
346 entering a DMA may impart two, three, or more charges to individual particles (Fuchs, 1963). The
347 charge distribution resulting from a bipolar charger is roughly approximated using the Boltzmann law
348 (Keefe et al., 1959). However, the Boltzmann law assumes symmetric aerosol particle charging (equal
349 concentrations of negatively and positively charged particles). Deviation from symmetric charging is
350 observed in regions of high ionizations, and this deviation becomes more pronounced as particle size
351 increases (Hoppel and Frick, 1990). A more accurate estimation of stationary charge distribution has
352 been calculated using an approximation formula for the charge distribution produced by a bipolar
353 charger:

354

$$355 \quad f(k) = 10^{\left[\sum_{i=0}^{i=5} a_i(k) (\log_{10} D_{nm})^i\right]} \quad (14)$$

356

357 where $f(k)$ is the fraction of particles carrying k charges, $a_i(k)$ are approximation coefficients
358 determined using a least-squares regression analysis, and D_{nm} is the particle diameter in nanometers
359 (Wiedensohler, 1988). The approximation coefficients only apply to particles with 0, ± 1 , and ± 2
360 charges. In a separate study, Maricq et al., 2008 determined approximation coefficients for poly (α -
361 olefin) oligomer oil droplets with ± 1 , ± 2 , and ± 3 charges. The approximation coefficients reported by

362 these two studies were in excellent agreement for particles with ± 1 and in weak agreement for ± 2
 363 charges (+2 and -2 charging efficiencies were overestimated by 50% and 100%, respectively).
 364 Therefore, this analysis will use the approximation coefficients from Wiedensohler, 1988 for particles
 365 with +1 and +2 charges, and the approximation coefficient for particles with +3 charge from Maricq et
 366 al., 2008.

367
 368 In order to assess the impact of multiple charges on κ_{app} , Eq. (14) and the approximation coefficients
 369 from Wiedensohler, 1988 and Maricq et al., 2008 were used to calculate the charge distribution of the
 370 representative aerosol population shown in Fig. 3a. The resulting charge distribution is shown in Fig.
 371 S6a. An increase in multiple charging is observed as particle diameter increases, though this is offset
 372 somewhat by the decrease in concentration with particle size above 50 nm.

373
 374 It follows that aerosols incorrectly sized due to double and triple charging will be passed from the DMA
 375 to the CCN and result in an additional uncertainty in the CCN measurements. To illustrate this, activated
 376 fraction curves, were generated for 25, 50, 100, and 200 nm sodium chloride particle selection by the
 377 DMA (Fig. 5). The activation of sodium chloride is represented by sigmoid curves, where the midpoint
 378 of each activation curve is the κ -Köhler-derived critical supersaturation of sodium chloride, and the
 379 standard deviation of each curve is one-tenth of this value (consistent with the standard
 380 deviation/midpoint ratio observed from our instrument's ammonium sulfate CCN calibration data). For
 381 each particle diameter, D , the observed activated fraction, $AF_{D,weighted}^{SS}$, for each percent supersaturation
 382 SS was determined by weighting the activated fraction $AF_{D,i}^{SS}$ of each particle diameter/charge at that
 383 percent supersaturation, by the fraction of particles of that diameter:

384
 385
$$AF_{D,weighted}^{SS} = \sum_{i=1}^{i=3} \frac{\text{concentration of particles with charge } i \text{ and diameter } D}{\text{concentration of particles with charge } +1, +2, +3, \text{ and diameter } D} AF_{D,i}^{SS} \quad (15)$$

386

387 The raw data shown in Fig. 5 (green curves) can be corrected for multiple charging by determining the
388 fraction of particles with $> +1$ charge from the lower plateau in each plot (dashed lines). The adjusted
389 activated fraction for each percent supersaturation, $AF_{adjusted}$, is calculated using the equation:

390

$$391 \quad AF_{adjusted} = \frac{AF_{raw} - AF_{plateau}}{1 - AF_{plateau}} \quad (16)$$

392

393 where AF_{raw} is the raw activated fraction at that percent supersaturation, and $AF_{plateau}$ is the activated
394 fraction corresponding to the lower plateau (Rose, 2008). The adjusted activated fraction curves are
395 shown in Fig. 5 (blue curves). These are in good agreement with the theoretical κ -Köhler-derived
396 activation curves for sodium chloride (not shown).

397

398 Critical supersaturation was determined for each diameter by calculating the percent supersaturation at
399 which the raw $AF_{D,weighted}^{SS} = 0.5$. These critical supersaturations are shown in Fig. 6a, and the
400 theoretical critical supersaturations calculated from κ -Köhler theory are shown for comparison. Eq. 4
401 was used to calculate apparent hygroscopicity for each particle diameter, shown in Fig. 6b. A dashed
402 line in Fig. 6b indicates the literature value for κ_{app}^{NaCl} . It is apparent that failing to account for multiply-
403 charged particle in the activated fraction curves shown in Fig. 5 leads to an overestimation of κ_{app} .
404 Artifacts in κ_{app} are shown in Fig. 6c.

405

406 For the theoretical aerosol distribution used in this analysis (Fig. 3a), small, positive deviations from κ -
407 Köhler theory and the literature value for κ_{app}^{NaCl} were observed ($0.01 \leq \kappa_{app,artifact}^{NaCl} \leq 0.04, 1 -$
408 3% of κ_{app}^{NaCl}). As shown in the figure, κ_{app} artifacts resulting from unaccounted-for multiple charges

409 decrease with particle diameter for this theoretical aerosol population. Greater κ_{app} artifacts would be
410 expected for aerosol populations with more prevalent accumulation modes.

411

412 The aerosol/sheath ratio within the DMA also modulates the effect of multiple charges on κ_{app} . As the
413 aerosol/sheath ratio increases, the transfer function broadens, allowing particles that are both larger and
414 smaller than the selected diameter to exit the DMA. This in turn broadens the CCN activated fraction
415 curve (Rose et al., 2008). The larger particles will activate as CCN at lower supersaturations than
416 particles with the selected diameter, resulting in an increase in the activated fraction plateau due to
417 multiple-charged particles and a further decrease in the determined SS_{crit} . Petters et al. 2007b showed
418 that CCN activated fraction curves are significantly skewed by multiply-charged particles when the
419 mode diameter of the aerosol population upstream of the DMA exceeds the critical diameter of the size-
420 selected particles. In an example CCN activated fraction curve, Rose et al. 2008 demonstrated that a 1:6
421 ratio of doubly-to-singly charged particles resulted in an underestimation of the critical activation
422 diameter by 2%. Zhao-Ze and Liang, 2014 also showed that multiply-charged particles can introduce
423 significant uncertainty into hygroscopicity calculations.

424

425 **3.1.4 Additional artifacts resulting from DMA measurements**

426

427 Several additional factors that may impact experimental κ_{app} are beyond the scope of this study, but are
428 worth mentioning as they represent additional potential sources of error in some cases. First, volatile
429 aerosols may partially evaporate inside the DMA, resulting in a decrease in particle size exiting the
430 DMA. DMA sizing error due to aerosol volatility (defined as the ratio of sampled diameter to the
431 selected diameter) increases with volatility, though sizing error can be decreased by increasing the
432 sheath flow rate in the DMA. Conversely, hygroscopic aerosols may grow inside the DMA, resulting in

433 larger particles existing the DMA. Operationally, errors in DMA sizing due to hygroscopic growth can
434 be mitigated if aerosols entering the DMA inlet are in wet metastable states (higher aerosol RH at DMA
435 inlet), and if DMA sheath flow rates are kept low (Khlystov, 2014).

436

437 Voltage shifts within the DMA (differences between the selected voltage and the actual voltage inside
438 the DMA) can lead to discrepancies between selected and sampled particle diameters. Voltage shifts
439 may result from a space-charge field generated by the motion of charges within the DMA. Particles
440 charged by the bi-polar neutralizer will either be attracted towards or repelled away from the inner
441 column of the DMA, depending on whether they are positively or negatively charged. This charge
442 separation creates a space-charge field which shifts the actual voltage within the DMA from the selected
443 voltage. The impact of the space-charge field on the midpoint and spread of the DMA transfer function
444 increases as particle mobility increases (as particle size decreases), and as particle concentration
445 increases (Alonso and Kousaka, 1996; Alonso et al., 2000; Alonso et al., 2001).

446 4. Artifacts derived from condensation particle counters

447

448 4.1 CPC operation at low concentration

449

450 The second instrument which must function accurately during CCN experiments is the condensation
451 particle counter. CPC performance is characterized by the maximum counting efficiency (which may be
452 influenced by the working fluid in the instrument) and the 50 %-cut-off diameter (d_{50}), the particle
453 diameter at which 50 % counting efficiency is observed, both of which can vary between commercially
454 available models and even between individual CPCs (Heim et al., 2004). One study found that n-
455 butanol CPCs (TSI, Inc. Models 3772, 3775, and 3776) exhibited smaller d_{50} for silver particles than
456 sodium chloride ($3.3 \text{ nm} \leq d_{50}^{Ag} \leq 7.8 \text{ nm}$ and $4.1 \text{ nm} \leq d_{50}^{NaCl} \leq 14.7 \text{ nm}$), due to the more effective
457 condensation of n-butanol on silver particles (Hermann et al., 2007).

458

459 Maximum counting efficiencies in that study varied from 88.9 % to 100.3 %. Another comparison of n-
460 butanol CPCs (TSI Inc. Models 3010 and 3022, Grimm Tech. Inc. Model 5.403) found $3.1 \text{ nm} \leq d_{50} \leq$
461 11.9 nm for sodium chloride aerosols (Heim et al., 2004). In another study, the counting efficiencies
462 observed in measurements of tungsten oxide particles by different instruments of the same model (TSI
463 3025) varied from 88.9 % to 138.9 %, while $d_{50}^{WO_x}$ varied from 3.2 nm to 11.0 nm (Hameri et al., 2002).

464

465 While some issues can cause undercounting at all concentrations, the additional issue of uncounted
466 particles due to the arrival of more than one particle in the detector's field of view at any time arises
467 only at higher concentrations. The cut-off between "low" and "high" concentration is not exact and
468 varies between instruments. CPC undercounting issues which arise even at relatively low concentrations
469 (which one would expect to encounter under standard experimental conditions) will be discussed in this

470 section. Concentration-dependent effects encountered at higher concentrations will be explored in Sect.
471 4.2.

472

473 Six counting efficiency curves were generated using sigmoidal distributions and the 50 % cut-off
474 diameters and maximum counting efficiencies listed in Table 3. Chosen values represent d_{50} values and
475 maximum counting efficiencies reported in the literature under relatively low concentrations of 1000-
476 4000 cm^{-3} (Hermann et al., 2007). The resulting sigmoidal distributions (Fig. 7a) were used to
477 determine the counting efficiency of 25, 50, 100, and 200 nm particles.

478

479 Next, κ_{app} was calculated from theoretical critical percent supersaturations for each chosen diameter. To
480 do so, four sigmoid curves representing sodium chloride CCN activation (hereon referred to as
481 “activation curves”) for 25, 50, 100, and 200 nm were generated. The κ -Köhler- SS_{crit} of sodium
482 chloride was used as the midpoint of each activation curve, and one-tenth of this value was used as the
483 standard deviation (100 % CE, Fig. 7b-e). These values are consistent with the standard
484 deviation/midpoint ratio observed from our instrument’s ammonium sulfate CCN calibration data.

485

486 Activation curves were then generated for CPC Cases 1-6 by dividing the activated fraction for each dry
487 particle diameter by the counting efficiency for that diameter. SS_{crit} was determined for each CPC case
488 by finding the percent supersaturation at which activated fraction = 0.50. Results are summarized in
489 Fig. 7f. Next, critical supersaturation was converted to saturation, and $\kappa_{app,theory}$ was calculated for
490 each diameter in each CPC Case using Eq. (4) (see Fig. 7g). As above, κ_{app} artifacts were calculated by
491 finding the difference between these results and the literature value of κ_{app} for sodium chloride (see Fig.
492 7h).

493

494 For the diameters studied, the effect of maximum counting efficiency on CPC concentration (and
495 activated fraction) is greater than the effect of 50 %-cutoff diameter. However, neither characteristic
496 resulted in large κ_{app} artifacts. The largest κ_{app} artifact observed at “low” concentrations was 0.035 for
497 CPC Case 4, 2.4 % of the literature value for the apparent hygroscopicity factor for sodium chloride.

498 **4.2 CPC operation at high concentration**

499

500 Operation at high concentrations introduces an additional source of undercounting through particle
501 coincidence at the CPC optical counter. For the TSI 3010 CPC, undercounting is observed is for particle
502 concentrations above $1 \times 10^4 \text{ cm}^{-3}$. At $5 \times 10^4 \text{ cm}^{-3}$, the detector saturates and cannot detect higher
503 concentrations. By comparison, the TSI 3025 is effective at counting higher particle concentrations, of
504 up to $2.5 \times 10^4 \text{ cm}^{-3}$ (Hameri et al., 2002; Sem, 2002).

505

506 To model undercounting due to particle coincidence, four CPC counting curves (Fig. 8a) were generated
507 using the equations in Table 4. Case 7 represents a CPC where counting efficiency decreases with
508 particle concentration, without reaching saturation. Cases 8-10 represent CPCs where saturation is
509 reached at $4 \times 10^4 \text{ cm}^{-3}$, $2 \times 10^4 \text{ cm}^{-3}$, and $1 \times 10^4 \text{ cm}^{-3}$, respectively. These saturation
510 concentrations are of similar magnitude to those observed from TSI 3010 concentration data. It should
511 be noted that the CPC concentration in Cases 7-10 levels off at the saturation concentration for each
512 case.

513

514 In order to assess the importance of undercounting in CPC Cases 7-10, four theoretical aerosol
515 distributions with a peak concentration at 50 nm were employed (Table 5, Fig. 8b). CPC Distribution 1
516 represents a worst-case scenario of similar magnitude to the highest particle concentrations measured
517 during a coastal nucleation event (Hameri et al., 2002; Sem, 2002), while CPC Distributions 2, 3, and 4
518 are lower in concentration (due to the lack of undercounting in CPC Distributions 2, 3, and 4 as
519 demonstrated in Figure 6b, the remaining analysis for CPC operation at high concentration considers
520 only CPC Distribution 1.) CPC Cases 8-10 were applied to CPC Distribution 1 in order to determine the

521 concentration measured by the CPC for 25, 50, 100 and 200 nm aerosols. The counting efficiency was
522 then calculated for each case and aerosol diameter in CPC Distribution 1.
523
524 Sigmoidal activated fraction curves were generated for 25, 50, 100 and 200 nm sodium chloride
525 aerosols. As in the low concentration cases, the midpoint of each 100 % CE curve was chosen to be
526 equal to the κ -Köhler-derived SS_{crit} of sodium chloride at each dry diameter, and the standard deviation
527 of each curve is equal to one-tenth of the SS_{crit} . These activated fraction curves were adjusted using the
528 counting efficiencies calculated in the previous step. In cases where the activated fraction has increased
529 due to undercounting by the CPC, the theoretical sigmoidal curve shifts to the left relative to the 100 %
530 CE case (Fig. 8c-f). Thus, undercounting by the CPC effectively increases the reported activated
531 fraction. As before, SS_{crit} was determined from each of these curves, and $\kappa_{app,theory}$ was subsequently
532 calculated using Eq. (4) (Fig. 8g-h).
533
534 $\kappa_{app,theory}$ fell over a much wider range for 25, 50, and 100 nm particles (1.30-1.56, 1.32-1.70, and
535 1.30-1.55, respectively) than for 200 nm particles (1.28-1.29) due to the lower concentration of 200 nm
536 particles in the chosen aerosol distribution, which resulted in a higher counting efficiency for these
537 aerosols. In comparison, the largest range in $\kappa_{app,theory}$ was observed for 50 nm aerosols, the peak
538 diameter in this aerosol distribution.
539
540 A wider range in $\kappa_{app,theory}$ was observed for the high-concentration CPC Cases (7-10) compared to the
541 low-concentration CPC Cases (1-6). The lowest counting efficiency observed across the low-
542 concentration cases was 89.9 % for 25 nm aerosol in Case 4, while the lowest counting efficiency
543 observed in the high-concentration cases was 18.0 % for 50 nm aerosol in Case 10.
544

545 Artifacts in the apparent hygroscopicity parameter are shown in Fig. 8i. κ_{app} artifacts were the greatest
546 for a CPC that becomes saturated at 20,000 particles/cm³ ($0.0131 \leq \kappa_{app} \leq 0.4206$). The lower the
547 concentration at which a CPC becomes saturated, the more quickly its counting efficiency will drop as
548 concentration increases, resulting in increased activated fraction and increased apparent hygroscopicity.
549 The magnitude of artifacts due to CPC undercounting depends on the saturation concentration of the
550 CPC and the distribution of the aerosol population being studied.

551 **5. Artifacts derived from cloud condensation nuclei instruments**

552

553 Finally, the third instrument whose performance accuracy contributes to the overall certainty in CCN
554 assessment in the CCN instrument itself. Several instruments have been implemented for measuring
555 CCN concentrations over the last few decades. Older models include the Continuous Flow Parallel Plate
556 Diffusion Chamber (Sinnarwalla, 1973) and the Hudson CCN spectrometer (Hudson, 1989) which both
557 employ an applied temperature gradient perpendicular to the aerosol flow. Newer models, such as the
558 widely-used Droplet Measurement Technology Cloud Condensation Nuclei Counter (DMT CCN-100),
559 operate with a streamwise temperature gradient and continuous, laminar flow (Lance et al., 2006). The
560 total flow through the DMT CCN-100 is 0.20-0.90 L min⁻¹, though the instrument is typically operated
561 with a total flow of 0.50 L min⁻¹. The aerosol/sheath ratio in the DMT CCN-100 is set by the user, and a
562 ratio of 1:10 is commonly chosen. The following analysis considers the DMT CCN-100. According to
563 the CCN-100 manual, the counting efficiency for this CCN instrument depends on concentration and
564 supersaturation (Fig. 9a). The counting efficiency decreases rapidly with concentration at < 0.2 % SS
565 due to rapid water vapor depletion at these low supersaturations, and falls off more slowly for > 0.2 %
566 SS (DMT CCN-100 manual).

567

568 The counting efficiency of the DMT CCN-100 was tested for four lognormal aerosol distributions with
569 peak concentrations at 50 nm and varying total concentrations (Table 5, Fig. 9b). Note that CCN Cases
570 1-4 are identical to the aerosol distributions CPC Distributions 1-4 used for the high-concentration CPC
571 cases.

572

573 The counting efficiencies for each case were applied to theoretical sodium chloride sigmoidal activated
574 fraction curves to produce normalized activated fraction curves (Fig. 9c-f). As above, the midpoint is

575 set to the SS_{crit} of sodium chloride at each dry diameter, and the standard deviation is assumed to be
576 one-tenth of SS_{crit} . CCN undercounting effectively decreases activated fraction, therefore shifting the
577 activated fraction curve downwards and towards higher percent supersaturations. The opposite effect is
578 observed when CPC undercounting occurs. Critical supersaturation was determined for each CCN case,
579 as above (Fig. 9g). Values of SS_{crit} were then converted to saturation, and $\kappa_{app,theory}$ was calculated
580 using Eq. (4) (Fig. 9h).

581
582 Significant deviations from κ -Köhler theory were only observed in CCN Case 1, with total aerosol
583 concentration 5×10^6 particles/cm³ (Fig. 9g-i). The largest deviation for CCN Case 1 was observed in
584 100 nm particles ($\kappa_{app,artifact} = -0.57$), due to the higher concentration of 100 nm particles compared
585 to 25 and 200 nm particles, and the lower percent supersaturation necessary for activation. The largest
586 artifacts across CCN Cases 2 and 3 were also observed for 100 nm particles, though no artifacts were
587 observed for any particle diameter in CCN Case 4 due to the much lower concentrations.

588
589 Sodium chloride is very hygroscopic. It should be noted that aerosols consisting of less hygroscopic
590 compounds will activate at higher percent supersaturations (> 0.2 % SS regime) which will lead to
591 smaller κ_{app} artifacts when the same aerosol distribution and total aerosol concentration is considered.
592 If a mixture was considered (for example, sodium chloride with a non-hygroscopic species such as soot)
593 the results may also be different. The shape of the aerosol distribution must also be taken into account.
594 A distribution with a narrower peak than the one generated for this analysis would be at risk for larger
595 κ_{app} artifacts for any total aerosol concentration, and these artifacts would be greater at the peak
596 diameter, while a broader distribution would result in less variation in κ_{app} artifacts for each particle
597 diameter.

598 6. Counting statistics in CCN and CPC measurements

599

600 Though it is beyond the scope of this analysis, it should be mentioned that sampling at very low particle
601 concentrations ($< 200 \text{ cm}^{-3}$ total particle concentration) can introduce additional error into CCN and
602 CPC measurements. This error can be mitigated by increasing scan times (Moore et al., 2010). For
603 example, Moore et al., 2010 averaged CCN and particle concentrations over 5-second intervals for
604 monodisperse particle concentrations $< 10 \text{ cm}^{-3}$, and increased averaging time to 20-second intervals
605 when the monodisperse particle concentration reached $< 6 \text{ cm}^{-3}$.

606

607 7. Discussion

608

609 A comparison of the major instrument sources of error in CCN-derived κ_{app} is shown in Fig. 10. In
610 addition, the best and worst case combination of errors, determined by additive error propagation, are
611 also shown. DMA Case 4, CPC Case 4, CPC Case 10, and CCN Case 1 represent the operating
612 conditions that resulted in the largest κ_{app} artifacts in this study. In DMA Case 4, the aerosol/sheath
613 ratio of 0.30 resulted in a broadened aerosol distribution downstream of the DMA. Compared to DMA
614 Case 1, where $Q_a/Q_{sh} = 0.10$, the downstream diameter range in DMA Case 4 was 300 % higher for 25
615 nm particles, resulting in a spread of 20-36 nm. Similarly, the diameter ranges for 50, 100, and 200 nm
616 diameter were 220 %, 230 %, and 220 % wider than in Case 1, respectively. Compared to the most ideal
617 DMA case presented in this study (DMA Case 2), where $Q_a/Q_{sh} = 0.05$, the downstream diameter
618 range in DMA Case 4 was 700 % higher for 25 nm particles; the diameter ranges for 50, 100, and 200
619 nm diameter were 540 %, 560 %, and 520 % wider than in Case 2, respectively. The results
620 demonstrate that limiting Q_a/Q_{sh} to ≤ 0.10 will result in a narrow particle size distribution downstream
621 of the DMA. Other studies have recommended employing DMA sample/sheath ratios of 0.2 (Petters et

622 al., 2007; Carrico et al., 2008; Moore et al., 2010) or 0.1 (Moore et al., 2010; Zhao-Ze and Liang, 2014)
623 in order to minimize measurement aerosols due to transfer function broadening.

624

625 The effects of multiply-charged particles on κ_{app} calculations were also quantified, as shown in Fig. 10.
626 Small, positive κ_{app} artifacts (1 – 3 % of κ_{app}^{NaCl}) were observed when particles with +2 and +3 charges
627 were not accounted for. This analysis considered a theoretical aerosol distribution in which most of the
628 particles measure less than 100 nm in diameter. Actual aerosol distributions vary temporally and
629 spatially, and often include accumulation and coarse modes that would result in larger κ_{app} artifacts.

630

631 CPC Case 4 represents κ_{app} artifacts (0.031-0.035) due to undercounting that arises from poor
632 maximum CPC counting efficiency (90 %), which may be observed when using butanol as a working
633 fluid while measuring the concentration of inorganic aerosols. In contrast, κ_{app} artifacts are negligible
634 (< 0.10 % of κ_{app}^{NaCl}) in CPC Case 3, where maximum counting efficiency = 100 %. CPC Cases 8 and 10
635 (applied to the highest-concentration case, CPC Distribution 1) represent undercounting at high
636 concentration with CPCs where saturation is observed at $4 \times 10^4 \text{ cm}^{-3}$ and $1 \times 10^4 \text{ cm}^{-3}$, respectively.
637 Counting efficiency drops off more rapidly with concentration in the latter case, resulting in κ_{app}
638 artifacts that are highest at the peak of the aerosol distribution (0.1190 and 0.4206 for 50 nm aerosols in
639 CPC Cases 8 and 10, respectively). It should be noted that undercounting was only observed for one of
640 the four upstream distributions studied, CPC Distribution 1. No undercounting was observed when CPC
641 Cases 7-10 were applied to CPC Distributions 2-4.

642

643 CCN Case 1 represents CCN undercounting at high concentration (total aerosol concentration = $5 \times$
644 10^6 cm^{-3}). CCN undercounting is greatest for low supersaturation (< 0.2 %) and high concentration,

645 resulting in the lowest counting efficiency and highest κ_{app} artifacts (- 0.57) for 100 nm aerosols in
646 CCN Case 1. The largest CCN-derived κ_{app} artifact observed outside of CCN Case 1 was - 0.01 for
647 100 nm aerosols in CCN Case 2.

648

649 The combined artifacts for the cases where the highest artifacts were observed (DMA Case 4, multiple
650 particle charging, CPC Case 4, CPC Case 10, CCN Case 1) are 0.24, 0.21, 0.23, and 0.15 for 25, 50,
651 100, and 200 nm particles respectively, as shown in Fig. 10. The combined artifacts for the lowest-
652 artifact cases (DMA Case 2, CPC Case 3, and CCN Case 4) are < 0.008 except for all four particle
653 diameters.

654

655

656 **Conclusions**

657

658 The sensitivity of weather and climate models to accuracy in CCN activation predictions has been
659 demonstrated in other works. Possible sources of apparent hygroscopicity artifacts calculated from CCN
660 measurements have been presented in this study. This analysis has focused on sodium chloride and
661 ammonium sulfate aerosols, but it can be extended to other aerosol populations, including mixtures and
662 field samples.

663

664 The greatest combined artifacts ($0.15 < \kappa_{app,artifact} < 0.24$, NaCl) occurred as a result of the
665 combined issues of the highest DMA aerosol/sheath ratio, uncorrected multiple particle charging, and
666 undercounting by both CPC and CCN instrument. The lowest combined artifacts ($0.0021 <$
667 $\kappa_{app,artifact} < 0.0074$, NaCl) occurred as a result of ideal operating conditions: lowest DMA/sheath
668 ratio, corrected multiple particle charging, and little to no undercounting.

669

670 The largest single-instrument artifacts ($-0.57 < \kappa_{app,artifact} < 0.42$ for sodium chloride) in this study
671 arise from undercounting by either the CPC or CCN counter at high concentration. This problem occurs
672 during attempts to measure aerosol concentrations of $\sim 10^4 \text{ cm}^{-3}$ which is much higher than the
673 recommended concentration ranges for either instrument, (CPC Cases 7-10 and CCN Case 4).

674 Corrective action should be taken to dilute aerosol samples in order to avoid undercounting. It should be
675 noted that these artifacts are for individual instruments and do not take combined operation of the CPC
676 and CCN into account; when both instruments undercount, artifacts in $\kappa_{app,artifact}$ are reduced.

677

678 Smaller single-instrument artifacts ($\kappa_{app,artifact} < 0.04$) were observed for the CPC cases where 50 %-
679 cut-off diameter and maximum counting efficiency were varied. Given the chosen particle diameters

680 (25, 50, 100, 200 nm), κ_{app} artifacts due to d_{50} were minimal. The largest κ_{app} artifacts for a CPC
681 counting at low concentration (0.031-0.035) were observed where the maximum counting efficiency was
682 equal 0.90. This may represent a compositional mismatch between n-butanol as the working fluid and
683 sodium chloride as the aerosol, due to the poor solubility of the latter in the former. Individual n-butanol
684 CPCs may exhibit higher maximum counting efficiencies for sodium chloride.

685

686 Uncertainty arising from the DMA depended greatly on the chosen aerosol and sheath settings. One set
687 of DMA cases (Cases 2-4) examined the effect of aerosol/sheath ratio. By decreasing this ratio, a
688 narrower near-monodisperse flow can be produced, which increases the accuracy of calculated κ_{app} .
689 The κ_{app} artifacts for an aerosol/sheath ratio of 0.10 were 0.65 % of $\kappa_{literature}$ for 25 nm sodium
690 chloride aerosols, 0.31 % for 50 nm, -0.17 % for 100 nm, and -1.2 % for 200 nm.

691

692 The second set of DMA cases (5-7) were designed to evaluate the effects of holding the sheath flow
693 constant while varying the excess air flow by -2 %, +2 %, and +5 %. These resulted in shifts of ≤ 2 nm
694 for 25 nm and 50 nm particles, ≤ 4 nm for 100 nm particles, and ≤ 7 nm for 200 nm particles. The
695 downstream aerosol distribution was shifted towards larger particle diameters when sheath flow
696 exceeded excess flow, and towards smaller particle diameter when sheath flow was less than excess
697 flow. When taking field measurements, the composition of the sample may vary with particle diameter,
698 thereby introducing another source of error from a broader DMA distribution.

699 By extension, the issue of uncertain sizing by the DMA leads to added uncertainties in the CCN
700 instrument calibrations which are strongly dependent on the chosen aerosol to sheath ration within the
701 DMA. We recommend conducting all CCN calibrations with DMA aerosol to sheath ratio of 1:10 or
702 1:20 which will reduce kappa uncertainties to less than 1% for all dry sizes (25 to 200 nm).

703

704 Overall, under optimal operating conditions, where the DMA aerosol/sheath ratio is 0.10 and
705 excess/sheath ratio is 1.0, and in the absence of undercounting by the CPC or CCN, uncertainties in κ_{app}
706 are less than $\pm 1.2\%$ for 25 to 200 nm particles. During sampling, when the DMA sample/sheath ratio is
707 reduced to 0.05, κ_{app} uncertainties decrease to $\pm 0.58\%$. Additionally, errors in activated fraction (and
708 therefore κ_{app}) resulting from the bipolar charge distribution can be corrected by determining the
709 fraction of particles with multiple charges.

710

711 In this study, apparent hygroscopicity parameter artifacts were calculated for two pure, inorganic species
712 in this study. This analysis could be used to estimate κ_{app} artifacts for ambient aerosol populations,
713 which may result in a better understanding of the “real” differences between these populations. As
714 discussed in the introduction, Collins et al. 2016 aggregated κ_{app} from several mesocosm and field
715 studies for 30-100 nm sea spray aerosol ($0.4 < \kappa_{app}^{SSA} < 1.3$). The wide range of κ_{app} in these studies
716 may be attributed to differences in composition, experimental artifacts, or a combination of the two.
717 Quantification of experimental artifacts would facilitate interpretation of κ_{app} in aerosol populations and
718 constrain the importance of composition in CCN activation. There has been a recent proliferation of
719 CCN data availability from multiple researchers and multiple experimental setups. To maximize the
720 utility of these studies and to compare cloud-activating properties of various ambient aerosol masses, it
721 is essential that artifacts are considered in both CCN data collection and in reporting of the data.

Notation	
$\alpha_{cc}, \beta_{cc}, \gamma_{cc}$	Empirically-determined constants used to calculate Cunningham slip correction factor
Z_p	Aerosol particle electrical mobility
C_c	Cunningham slip correction factor
d_m	Electrical mobility diameter
n	Number of charges on particle
e	Elementary unit of charge
η	Gas dynamic viscosity
λ	Mean free path
Q_{sh}	Sheath flow
Q_e	Excess air flow
Q_a	Aerosol flow
Q_s	Sample flow
κ_{app}	Apparent hygroscopicity parameter
$\kappa_{app,artifact}$	Apparent hygroscopicity parameter artifact
s	Equilibrium water vapor saturation
s_{crit}	Critical saturation (50 % of aerosols active as cloud condensation nuclei)
A	Constant used in calculating κ_{app}
σ_{lv}	Surface tension of water
T	Temperature
D_{act}	Activation diameter
SS_{crit}	Critical percent supersaturation
α_{TF}	Height of DMA transfer function
β_{TF}	Half-width of DMA transfer function
Z'_p	Mobility of particle at DMA inlet
$Z_{p,mid}$	Midpoint of transfer function
ΔZ_p	Half-width of transfer function
V_0	Voltage selected at DMA
r_1	DMA inner radius
r_2	DMA outer radius
L	DMA length
d_{50}	50 %-cut-off diameter

1003

1004 **Figure 1** Experimental setup used for obtaining sized CCN and particle concentration measurements

1005 from an aerosol sample.

1006

1007 **Figure 2** Simplified flow diagram of a DMA with an inner electrode radius r_1 , outer electrode radius r_2 ,
 1008 distance between aerosol inlet and sample outlet L , clean sheath air flow Q_{sh} , aerosol flow Q_a , excess air
 1009 flow Q_e , and sample air flow Q_s .

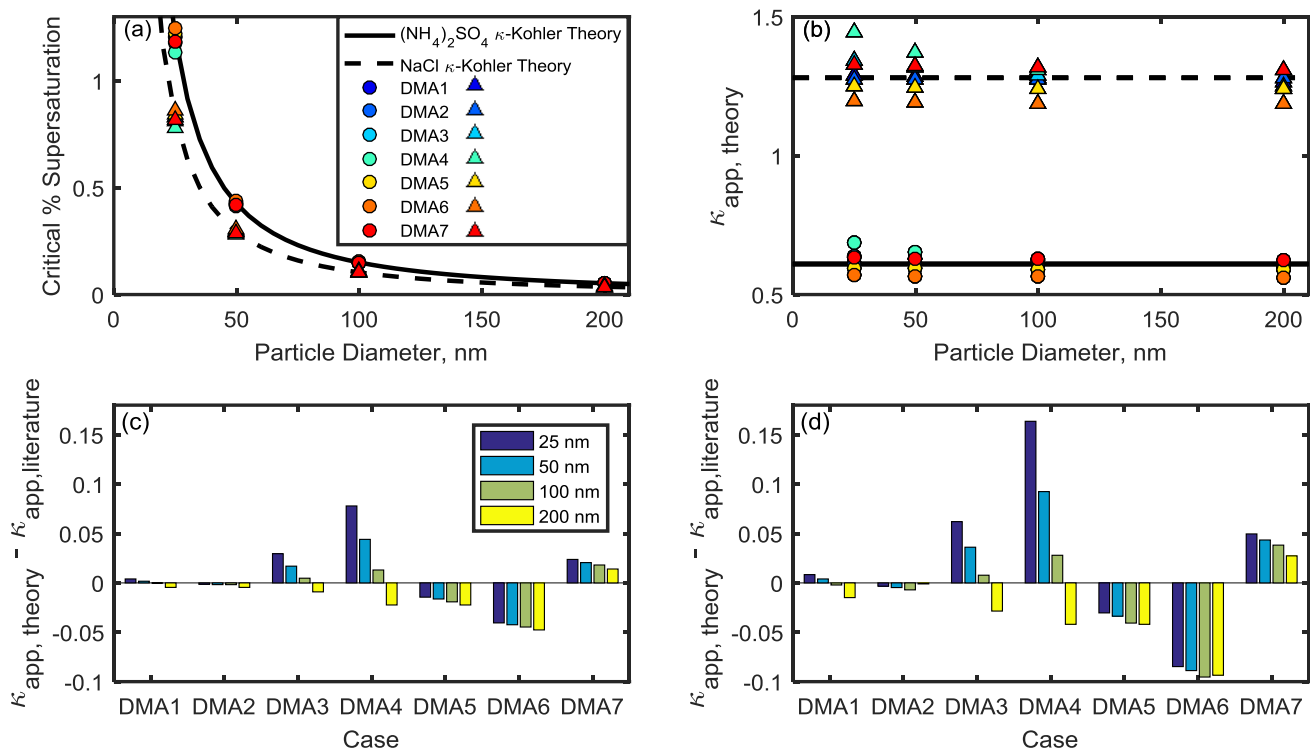

1010

1011

1012 **Figure 3** (a) A theoretical aerosol distribution generated using a lognormal function centered at 50 nm. .

1013 (b) The transfer function calculated using Eq. (7). (c) Multiplying the distribution by the transfer function

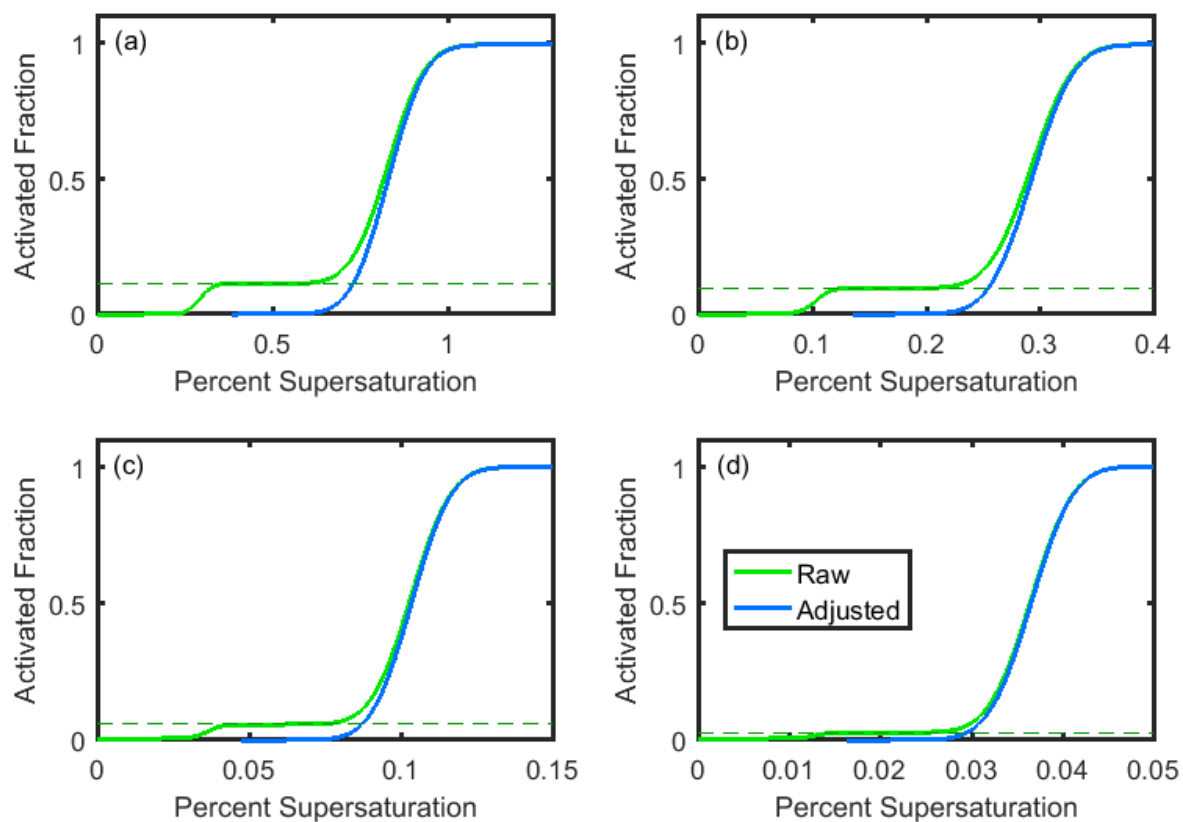

1014 gives the downstream aerosol concentration (cm⁻³).

1015

1016

101 **Figure 4** (a) Critical supersaturation of ammonium sulfate and sodium chloride particles calculated for DMA
 1018 Cases 1-7 for sodium chloride (triangles) and ammonium sulfate (circles). Ammonium sulfate and sodium
 1019 chloride curves from κ -Köhler theory are shown for comparison. (b) Apparent hygroscopicity κ_{app} for
 1020 DMA cases 1-7. (c) DMA-flow-derived artifacts in ammonium sulfate κ_{app} are shown for each DMA case.
 1021 (d) DMA-flow-derived artifacts in sodium chloride κ_{app} are shown for each DMA case.

1022

1023 **Figure 5** Theoretical raw (green) and adjusted (blue) activated fraction curves for (a) 25 nm (+1), 50 nm

1024 (+2), and 75 nm (+3) particles; (b) 50 nm (+1), 100 nm (+2), and 150 nm (+3) particles; (c) 100 nm

1025 (+1), 200 nm (+2), and 300 nm (+3) particles; (d) 200 nm (+1), 400 nm (+2), and 600 nm (+3) particles.

1026 All particles are pure sodium chloride.

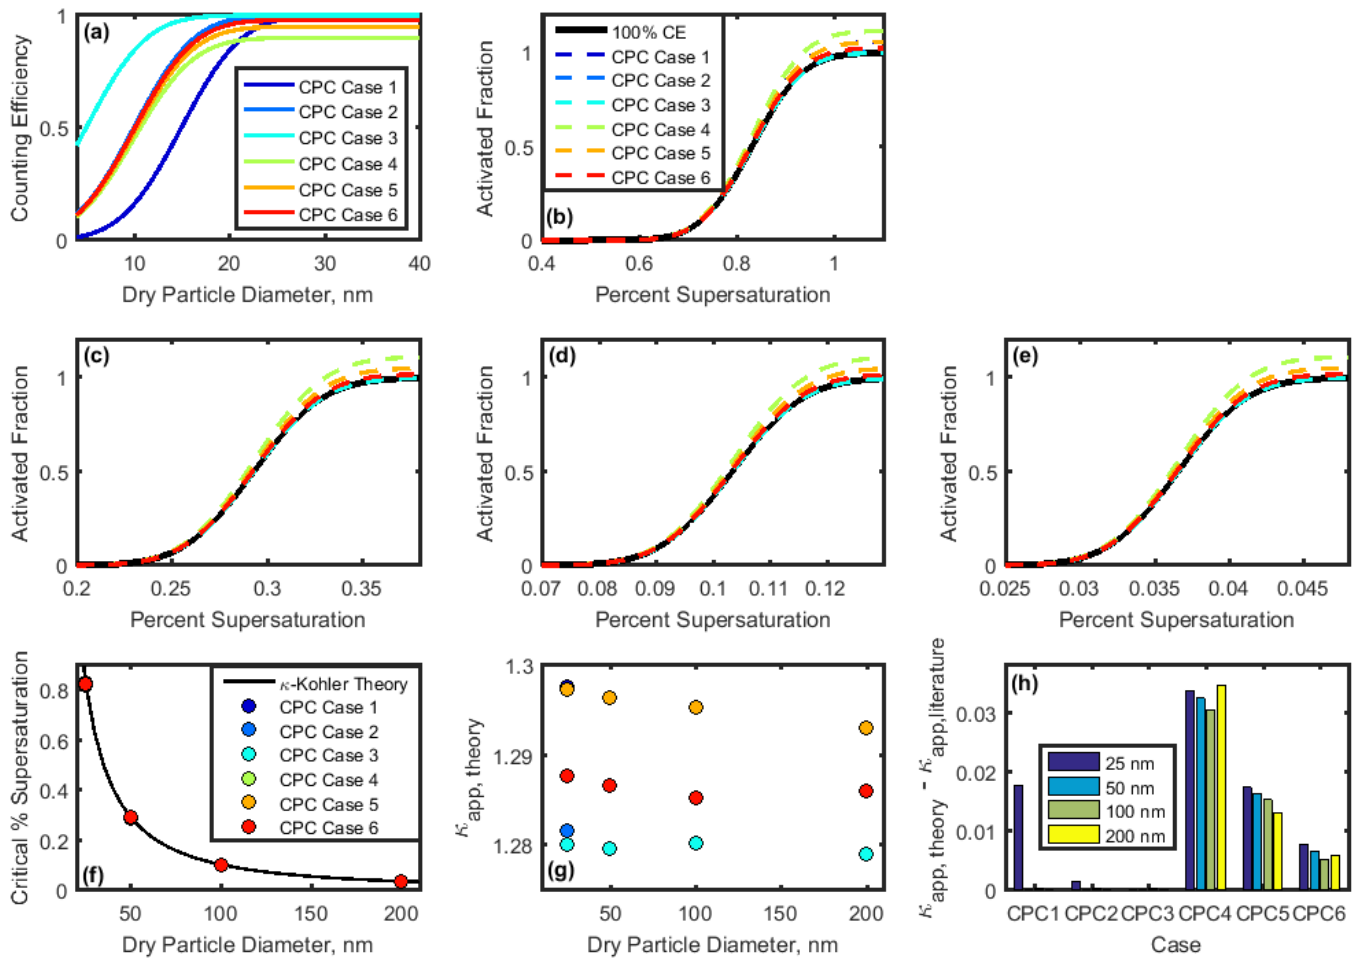

1027

1028 **Figure 6** (a) Critical percent supersaturation of sodium chloride particles determined from activated
 1029 fraction curves shown in Fig. 5. A κ -Köhler curve for sodium chloride is shown for comparison. (b)

1030 Theoretical κ_{app} for each particle diameter (gray dashed line indicates literature value for κ_{app}^{NaCl}). (c)

1031 Artifacts in κ_{app} resulting from multiple particle charges.

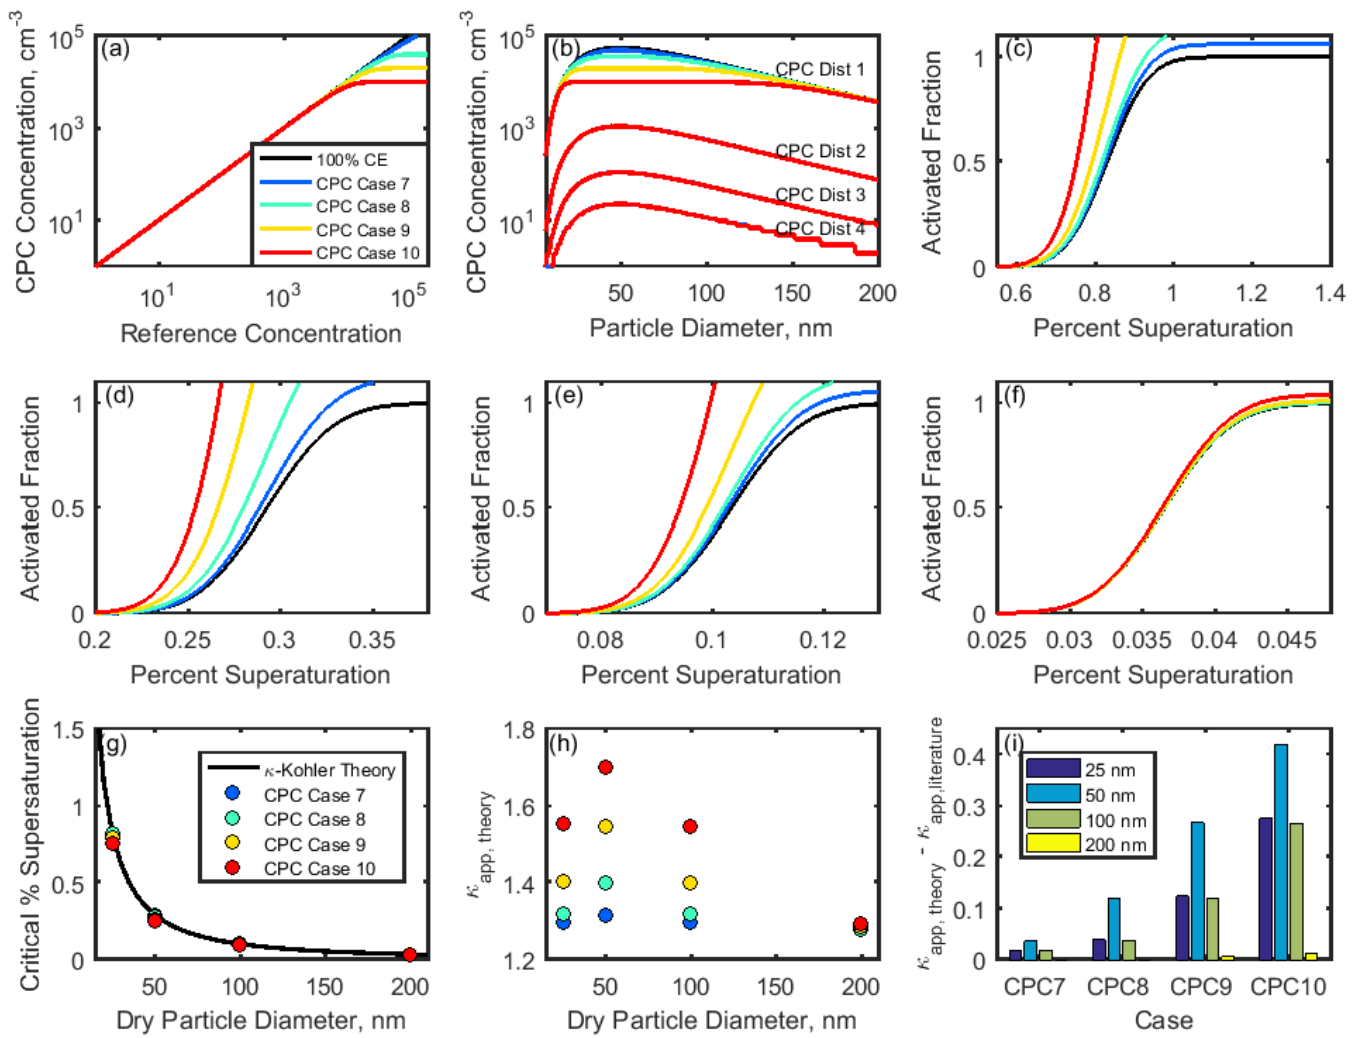

1032

1033 **Figure 7** (a) Counting efficiency curves for CPC Cases 1-6 (shown in Table 3).

1034 (b-e) CCN activated fraction curves for 25, 50, 100, and 200 nm NaCl, respectively. (f) Critical

1035 supersaturation calculated for each particle diameter. (g) Theoretical κ_{app} for each CPC case and

1036 particle diameter. (h) Artifacts in κ_{app} for each CPC case and particle diameter.

1037

1038 **Figure 8** (a) Theoretical relationships between the reference aerosol concentration and CPC
 1039 concentration. (b) Concentration-dependent counting efficiencies from (a) were applied to four
 1040 theoretical aerosol distributions. (c-f) Activated fraction curves for CPC Distribution 1 and particle
 1041 diameters 25, 50, 100, and 200 nm NaCl aerosol, respectively. (g,h) Critical supersaturation and κ_{app} for
 1042 each case. (i) Artifacts in κ_{app} for each case.

1043

1044 **Figure 9** (a) Counting efficiencies of the DMT CCN-100 for specific supersaturations. (b) Lognormal
 1045 aerosol distributions used to study CCN undercounting at high concentrations. (c-f) Activated fraction
 1046 curves for 25, 50, 100, and 200 nm NaCl particles. Supersaturation-specific counting efficiencies from
 1047 (a) applied to theoretical sigmoid curves for NaCl CCN activation. Activated fraction in the case of 100
 1048 % counting efficiency is shown for comparison. (g) Critical supersaturation for each case. (h)
 1049 Theoretical κ_{app} calculated for each case. (i) Artifacts in κ_{app} artifacts for each case.

1050

1051 **Figure 10** Comparison of κ_{app} artifacts derived from best and worst case scenarios for instrumental
 1052 measurements for sodium chloride. Combined artifacts for the lowest-artifact cases (Best: DMA Case
 1053 2, CPC Case 3, and CCN Case 4) and the highest-artifact cases (Worst: DMA Case 4, multiple charging,
 1054 CPC Case 4, CPC Case 8, and CCN Case 1).

1055

Table 1 Theoretical DMA Flow Test Cases

Case	Q_{sh} (L min ⁻¹)	Q_e (L min ⁻¹)	Q_a (L min ⁻¹)	Q_s (L min ⁻¹)	Q_a/Q_{sh}	Q_e/Q_{sh}
DMA 1	3.00	3.00	0.30	0.30	0.10	1.00
DMA 2	3.00	3.00	0.15	0.15	0.05	1.00
DMA 3	3.00	3.00	0.60	0.60	0.20	1.00
DMA 4	3.00	3.00	0.90	0.90	0.30	1.00
DMA 5	3.00	3.06	0.36	0.30	0.12	1.02
DMA 6	3.00	3.15	0.45	0.30	0.15	1.05
DMA 7	3.00	2.94	0.24	0.30	0.08	0.98

1056

Table 2 Predicted downstream particle diameter range for each DMA case.

Case	25 nm	50 nm	100 nm	200 nm
DMA 1	23-27	46-56	91-111	181-222
DMA 2	24-26	48-53	95-105	190-211
DMA 3	21-31	42-62	83-125	167-250
DMA 4	20-36	39-71	77-143	154-285
DMA 5	23-27	45-55	90-110	181-220
DMA 6	22-27	45-54	89-107	178-215
DMA 7	23-28	46-56	92-112	183-225

1057

Table 3 Values of 50%-cutoff diameter and maximum counting efficiency used in investigating κ_{app} artifacts for low particle concentrations measured by a CPC.

Case	d_{50}, nm	Maximum Counting Efficiency
CPC 1	15	100 %
CPC 2	10	100 %
CPC 3	5	100 %
CPC 4	10	90 %
CPC 5	10	95 %
CPC 6	10	98 %

1058

Table 4 Equations used to model the relationship between a reference or “true” aerosol concentration x (particles cm^{-3}), and the concentration measured by a condensation particle counter y (particles cm^{-3}).

Case	Equation
CPC 7	$y = x - 2 \times 10^{-6}x^2$
CPC 8	$y = 40000 \operatorname{erf}\left(\frac{x}{32000\sqrt{2}}\right)$
CPC 9	$y = 20000 \operatorname{erf}\left(\frac{x}{16000\sqrt{2}}\right)$
CPC 10	$y = 10000 \operatorname{erf}\left(\frac{x}{8000\sqrt{2}}\right)$

1059

Table 5 Total concentrations used in theoretical aerosol distribution for CPC operation at high concentration and CCN-derived κ_{app} artifacts.

CPC Distribution	CCN Case	Total Concentration (particles cm⁻³)
CPC Distribution 1	CCN 1	5×10^6
CPC Distribution 2	CCN 2	1×10^5
CPC Distribution 3	CCN 3	1×10^4
CPC Distribution 4	CCN 4	2×10^3
