9 **Abstract**

10   Low concentrations of ice nucleating particles (INPs) are thought to be important for the properties of mixed-

11   phase clouds, but their detection is challenging. While instruments to quantify INPs online can provide relatively

12   high time resolution data, they typically cannot quantify very low INP concentrations. Furthermore, typical online

13   instruments tend to report data at a single defined set of conditions. Hence, there is a need for instruments where

14   INP concentrations of less than 0.01 L^{-1} can be routinely and efficiently determined. The use of larger volumes of

15   suspension in drop assays increases the sensitivity of an experiment to rarer INPs or rarer active sites due to the

16   increase in aerosol or surface area of particulates per droplet. Here we describe and characterise the InfraRed-

17   Nucleation by Immersed Particles Instrument (IR-NIPI), a new immersion freezing assay that makes use of IR

18   emissions to determine the freezing temperature of individual 50μL droplets each contained in a well of a 96-well

19   plate. Using an IR camera allows the temperature of individual aliquots to be monitored. Freezing temperatures

20   are determined by detecting the sharp rise in well temperature associated with the release of heat caused by

21   freezing. In this paper we first present the calibration of the IR temperature measurement, which makes use of the

22   freezing period after initial nucleation when wells warm and their temperature is determined by the ice-liquid

23   equilibrium temperature, i.e. 0°C when the water activity is ~1. We then tested the temperature calibration using

24   ~100 μm chips of K-feldspar, by immersing these chips in 1 μL droplets on an established cold stage (μL-NIPI)

25   as well as in 50 μL droplets on IR-NIPI; the results were consistent with one another indicating no bias in the

26   reported freezing temperature. In addition we present measurements of the efficiency of the mineral dust NX-illite

27   and a sample of atmospheric aerosol collected on a filter in the city of Leeds. NX-illite results are consistent with

28   literature data and the atmospheric INP concentrations were in good agreement with the results from the μL-NIPI

29   instrument. This demonstrates the utility of this approach, which offers a relatively high throughput of sample

30   analysis and access to low INP concentrations.

31   **1 Introduction**

32   Cloud droplets can freeze homogeneously below about -33°C (Herbert et al., 2015), but the presence of ice-

33   nucleating particles (INPs) can induce freezing at much warmer temperatures (Kanji et al., 2017). The glaciation

34   of clouds at these warmer temperatures has a substantial impact on a cloud's reflective properties, lifetime and

35   therefore the overall climate of the planet, but is poorly represented in many models (Hoose and Möhler, 2012;

36   Vergara-Temprado et al., 2018). INPs can cause nucleation through a number of pathways (Vali et al., 2015), but

37   in mixed-phase clouds it is thought that the pathways where particles become immersed in droplets is most

38   important (Hoose et al., 2010; Murray et al., 2012). Even small concentrations of INPs can influence cloud

39   properties; for example, in a modelling study of Southern Ocean shallow mixed-phase clouds, Vergara-Temprado

40   et al. (2018) showed that while concentrations of INPs greater than ~1 L^{-1} cause profound changes in cloud

41   properties, clouds are sensitive to concentrations many orders of magnitude smaller.

42   The ability to quantify INP spectra (INP concentrations as a function of temperature) and test the efficiency of

43   proxy materials for ice-nucleating efficiency is invaluable for improving our understanding of cloud glaciation.

44   However it is not a trivial task, in part because INP concentrations are low and the sites on surfaces which cause

45   nucleation at warm temperatures are rare. There are several different methods of conducting ice nucleation

46   experiments that include Continuous Flow Diffusion Chambers (CFDC's) e.g. (Salam et al., 2006; Rogers et al.,

47   2001), cloud expansion chambers e.g. (Niemand et al., 2012; Cotton et al., 2007), wind tunnels e.g. (Pitter and

48   Pruppacher, 1973; Diehl and Mitra, 1998) and droplet freezing assays e.g. (Knopf and Alpert, 2013; Vali, 2008;

49   Murray et al., 2011; Budke and Koop, 2015; Whale et al., 2015; Beall et al., 2017). Each of these systems has its

50   limitations and advantages which must be understood and accounted for when conducting an experiment and

51   interpreting the results. For example CFDCs cannot be used for measurements at temperatures warmer than about

52   -11°C but they do allow for specific saturation conditions to be controlled, something which other instruments

53   cannot achieve. For more information on the capabilities and limitations of the various techniques see the

54   comprehensive review and intercomparison which was conducted by Hiranuma *et al.* (2015).

55   A significant challenge in sampling INPs in the atmosphere is their low concentration. At present there is a dearth

56   of published, atmospherically relevant, INP measurements globally (Vergara-Temprado et al., 2017). Not only is

Atmospheric
Measurement
Techniques
Discussions

57 the global spatial and temporal coverage of INPs inadequate, but the range of activation temperatures and INP

58 concentrations covered in any one set of measurements is typically limited. No single instrument has the

59 capability of measuring INP concentrations over the full range of conditions relevant to mixed-phase clouds.

60 Online instruments, such as CFDCs, do precisely this, but their detection limit is limited to ~10^{-1} L^{-1} (Eidhammer

61 et al., 2010). This can be improved with aerosol concentrators, but is still above the INP concentrations models

62 suggest influence the properties of certain cloud types, such as shallow cold-sector clouds in the Southern Ocean

63 (Vergara-Temprado et al., 2018). The alternative approach is therefore to increase the number of particles within

64 each aliquot of water. In principle, if the ice-nucleating properties of the aerosol particles in question are

65 insensitive to mixing state, then increasing the amount of aerosol per droplet will scale with inverse proportionality

66 to the INP concentration, thereby allowing quantification of lower INP concentrations. To increase the number of

67 aerosol particles per volume of liquid the time period over which an atmospheric sample is collected can be

68 extended, but in doing so temporal resolution would be lost. An alternative method of increasing the sensitivity

69 of an immersion mode technique is to increase the volume of suspension used in each aliquot. This has been done

70 in the past e.g. (Vali, 1971; Bigg, 1953), and has been the strategy employed in the development of some recent

71 instruments e.g. (Beall et al., 2017; Du et al., 2017).

72 Here we propose a new technique, the IR Nucleation by Immersed Particle Instrument (IR-NIPI), for the detection

73 of INPs using large volumes of sample in the immersion mode. This instrument is part of the NIPI suite of

74 instruments that includes the µL-NIPI and when used together these devices allow measurements to be taken over

75 a very wide range of INP concentrations. The use of an infrared camera allows temperature measurements to be

76 made for individual droplets which helps reduce errors from horizontal gradients across the array of droplets and

77 the effect of heat release on the temperature of neighbouring wells. The unique design, in combination with a

78 Stirling engine chiller, is also compact making it ideal for field-based measurements and the use of multiwell

79 plates lends itself to future automation.

80 **2   Instrument Design**

81 **2.1   Operating principle**

82 Drop assays have been used extensively for ice nucleation experiments e.g.(Vali, 1971; Vali, 1995; Conen et al.,

83 2011; Knopf and Forrester, 2011; Garcia et al., 2012; Stopelli et al., 2014; Whale et al., 2015; Budke and Koop,

84 2015). This is partly due to their simplicity compared to other techniques but also the ability to scale the amount

85 of nucleator with droplet size. In brief, aqueous suspensions are prepared and droplets of a well quantified size

86   are placed onto a substrate or immersed in oil. These droplets tend to be monodispersed but polydispersed

87   experiments are also possible (Vali, 1971; Murray et al., 2011). The system is then cooled and the fraction of

88   droplets frozen is recorded. The cooling can be conducted at a constant rate or with a stepped rate to hold the

89   droplets at a specified temperature for a period of time (i.e. isothermally) to explore the time dependence aspect

90   of ice nucleation (Herbert et al., 2014; Vali, 1994; Sear, 2014). The droplets are monitored and the freezing

91   temperature of each droplet is recorded. The fraction of the droplet population frozen throughout the explored

92   temperature range can then be determined, from which other expressions of the ice-nucleating properties or INP

93   concentrations can be derived (Vali et al., 2015).

94   If the surface area of nucleant per droplet is known then it is common to express the nucleating ability of a material

95   as the density of active sites per unit surface area of nucleator, $n_s(T)$ (Connolly et al., 2009; DeMott, 1995). This

96   approach is based on the assumption specific sites on a nucleator's surface are responsible for ice formation. n_s is

97   a cumulative term, i.e. as you move to cooler temperatures there are more features which may behave as an active

98   site as the energy barrier for ice formation decreases. $n_s(T)$ is calculated via equation (1).

99    $$n_s = \frac{(-\ln(1-\frac{n(T)}{N}))}{A} \qquad (1)$$

100   Where $n(T)$ is the number of droplets frozen at a given temperature and N is the total number of droplets. A is the

101   surface area of nucleator within each droplet. Nucleation is a time-dependent stochastic process, but in

102   determining $n_s(T)$ the time dependence is neglected. This assumption is justified for many materials because the

103   diversity in activity of active sites leads to a much greater spread in freezing temperatures than the shift in freezing

104   temperatures associated with changes in cooling rate (Vali, 2008; Herbert et al., 2014).

105   **2.2   IR-NIPI design**

106   In brief an aqueous suspension is prepared and aliquots pipetted into the wells of a 96 multiwell plate which is

107   then placed on a temperature controlled stage. The cold stage and multiwell plate are enclosed by a Perspex cover

108   with an infrared camera mounted in its lid (Figure 1). The system is cooled at ~ -1°C min⁻¹ until all droplets are

109   frozen (typically in a temperature range of 0 to -30°C). The temperature of the individual aliquots is monitored

110   using the IR camera which records a temperature map every 20 seconds. The temperature map is then analysed

111   with a semi-automated process using custom Python code to yield the freezing temperatures of individual wells.

112   The IR-NIPI has been designed around an Asymptote Ltd. VIA Freeze™ stirling cryocooler (Figure 1). The VIA

113   Freeze uses a Stirling engine to provide a convenient means of cooling without refrigerants or circulating liquids

114   and was primarily designed for use in cryopreservation applications. This chiller can achieve temperatures of -

115   90°C, hence it has more than enough cooling capacity for our application, and has sufficiently low power

116   requirements that allow it to be run from an automotive 12 V inverter. It also features an onboard datalogger and

117   internal computer with touch screen control. The VIA Freeze has been developed to accommodate multiwell

118   plates onto its aluminium cooling stage, which are ideal for large volume drop assays as they hold up to 200 μL

119   per aliquot (for the 96 well plates), allow the separation of droplets to reduce interference across cells and can be

120   supplied medically sterile. These multiwell plates have anywhere from 12-1536 (with maximum working volumes

121   of 6.9 mL to 2 μL, respectively). The most useful for this freezing assay are the 96 x 200 μL or 384 x 50 μL

122   aliquot arrays and in the tests reported here 50μL droplets are used in 96 well plates. We have used both

123   polystyrene (Corning, CLS3788) and polypropylene plates (Greiner, M8060) and observed no difference in

124   freezing results between the two. To aid thermal contact between the multiwell plate and the VIA Freeze a

125   thermally conductive gap pad (RS components, 7073452) is located between the cold plate and the multiwell

126   plate, while a clamping system with screw threads applies mechanical pressure to the multiwell plate to push the

127   wells into the pad (Figure 1). A specially designed Perspex hood then encloses the system to reduce contamination

128   from the surroundings. The IR camera slots into the hood and captures an image of the multiwell plate every 20

129   seconds (Figure 2a), storing the corresponding temperature data (Figure 2b) on a removable memory card. The

130   IR camera used here is a Fluke Ti9 Thermal Imager with 160 x 120 pixels. The Stirling engine is then set to cool

131   down at 1.3°C min^{-1} which corresponds to 1°C min^{-1} ± 0.06°C in the wells due to a measured offset between the

132   plate and aliquot temperatures. This ramp rate was selected based on preliminary runs and justification for this

133   cooling rate being equivalent to 1°C min^{-1} can be seen in the well temperatures over time (Figure 2b). Once the

134   system has initially cooled to 5°C the temperature is held for 5 min to allow time for the system to equilibrate.

135   Following this the system continues to ramp down in temperature while recording IR heat maps of the multiwell

136   plate.

137   In order to determine the temperature of individual wells, the analysis code locates a pixel centred in the middle

138   of each well, reporting this temperature as the well temperature. Profiles of temperature versus time are shown in

139   Figure 2b/c. The freezing temperature of each individual well is determined by comparing each temperature

140   reading, for a certain well, with the temperature recorded 20 seconds prior. If the temperature reading increases

141   by more than 2°C this is recorded as a freezing event (Figure 2c). The 2°C threshold occasionally needs to be

142   optimised to capture freezing events while eliminating false positive detection of freezing. For example, samples

143   that freeze within ~3°C of melting are more difficult to detect since the maximum temperature of an aliquot of

144   water-ice is 0°C and the threshold has to be reduced to below 2°C; manual inspection is required in this

145   temperature regime. The code then prints out the number of events recorded, along with a time vs temperature

146   plot (Figure 2b) and the corresponding event temperatures for the user to quality control check and then exports

147   the data as a '.csv' file.

148   The whole process from sample preparation to final analysis takes approximately 1 hour. In order to achieve

149   higher throughput of samples, albeit with a reduced number of replicates, multiple samples and internal blanks

150   can be placed within one multiwell plate. For example, when performing dilutions we might run 12 wells as a

151   handling blank and three lots of 28 wells that contain three different sample dilutions. This not only speeds up

152   analysis, it also reduces run-to-run variability and the aging of a sample in water.

153

154   **2.3   Temperature measurements with an Infrared camera**

155   By using an IR camera to view the thermal emission of each individual well of suspension we are able to obtain

156   temperatures associated with individual wells. This contrasts with the approaches adopted in other experiments

157   where the temperature is recorded, for example when employing a cold stage housing an embedded thermocouple

158   whose reading is assumed to be representative for all droplets. We note that in our system there was a lateral

159   gradient across the entire multiwell plate in the IR-NIPI of up to 6°C (in extreme cases). This is likely due to there

160   not being an even thermal contact of the multiwell plate with the underlying cold plate. The typical gradient was

161   4°C, hence temperature measurements of the individual wells was necessary.

162   **2.4   Temperature calibration**

163   Our calibration is based on the fact that when an aliquot of water in a multiwell plate freezes, the released latent

164   heat raises the temperature of the aliquot to the ice-water equilibrium temperature (0°C when the water activity

165   of the sample is ~1, as it is in these experiments). This is illustrated in Figure 2c which shows the phases of

166   crystallisation that the aliquots go through. Initially, the crystal growth is rapid with a rapid release of latent heat

167   and a corresponding rise in temperature of the aliquot within the 20 s time between frames. Visual inspection of

168   the IR camera output revealed that the temperature reached a maximum within 1 s. The temperature of an ice-

169   water mixture will necessarily be 0°C, hence the aliquot cannot warm above 0°C and the temperature will remain

Atmospheric
Measurement
Techniques
Open Access
Discussions
EGU

170   at 0°C until all of the water has frozen and no more heat is evolved. The rate of crystallisation in this regime is

171   determined by the loss of heat to the surroundings, in this case the cold stage, as well as to the surrounding droplets

172   and the multiwell plate. This stage of crystallisation takes longer at higher freezing temperatures where the

173   temperature differential between the cold stage and the aliquot is smaller. Hence, freezing when nucleation takes

174   place at -12°C takes around 100 s, whereas when nucleation takes place at -20°C freezing takes around 20-40 s.

175   Once all of the water has frozen the temperature of the aliquot decreases rapidly back to that of the multiwell plate

176   within 20-40 s. The fact that the aliquots spend 10s of seconds at 0°C provides a very useful calibration point for

177   each individual well. In the following we describe a novel method for calibrating the IR temperature measurements

178   that takes advantage of this process and proceed to justify this approach.

179   Using the analysis code, when an event is identified it uses the recorded temperature of the frame after the initial

180   event and calculates the difference of this value compared to 0°C to give an offset correction value. This offset

181   value is then subtracted from the temperature recordings for that specific well. The average correction value

182   calculated for the IR camera via this method is -1.9°C with a standard deviation 0.5°C.

183   We performed a number of experiments to test the IR temperature measurement calibrated using the above

184   method. In the first instance we used highly conductive individual aluminium wells for 50μL droplets. The

185   temperature of these wells were recorded independently using T type thermocouples embedded in the aluminium

186   wells to give a representative temperature of the well and aliquot of water (see inset in Figure 3). A standard

187   freezing experiment was then performed and the thermocouple data was contrasted to that of the IR camera which

188   was calibrated using the above method (Figure 3). The comparison in Fig 3a shows that the IR and thermocouple

189   temperature were in excellent agreement and this is also readily seen in residuals plotted in Fig 3b. The scatter

190   around the zero line in the residual plot is ± 0.9°C (two standard deviations) in the regime after the equilibration

191   at 5°C and before the first freezing event. We used this value as an estimate of the temperature uncertainty

192   associated with the IR technique generally.

193   We also tested the IR temperature measurement using T type thermocouples distributed in specific wells of a

194   polypropylene multiwell plate. The IR camera could not take an accurate reading of wells that had a thermocouple

195   placed inside them, therefore neighbouring unfrozen wells were assumed to be representative of each other (see

196   inset in Figure 4). As mentioned above there is a gradient across the entire plate and so a series of preliminary

197   experiments were undertaken to find suitable placement locations for the thermocouples in which the surrounding

198   wells displayed similar temperature readings compared to one another. The thermocouples were placed in the base

199   of the well along with 50 μL of Milli-Q grade water and four surrounding well temperatures were measured using

200   the IR system. The thermocouple wire crossed one of the four IR measured wells and so only three wells adjacent

201   to the thermocouple monitored well were used for comparison.

202   A total of six IR measurements were recorded with the corresponding thermocouple readings over a series of

203   experiments spanning a temperature range of 20°C to –25°C. An example of a thermocouple measurement

204   contrasted to three IR measurements can be seen in Figure 4a.The residual temperatures for all six thermocouple

205   temperatures are also shown (Figure 4b). The IR temperature uncertainty derived from the aluminium well

206   experiment is also plotted and shows that the data is consistent across both strategies with an uncertainty of ±

207   0.9°C.

208

209   **3**   **Test experiments and analysis**

210   **3.1**   **Control experiments**

211   In larger volume freezing assays (10s of microliters) it is extremely challenging to remove all background INPs

212   from the water and substrates, hence freezing is typically observed at temperatures well above what one would

213   expect for homogenous freezing (Koop and Murray, 2016). Homogeneous nucleation is expected to result in 50%

214   of 50 μl droplets freezing at around -35°C see, whereas 50% of the Milli-Q water droplets froze around -22°C in

215   our control experiments (Figure 5). Filtering of the Milli-Q water to 0.22 μm reduced the temperature at which

216   pure water droplets froze. Blanks were run initially with entire 96 well plates and then 12 wells of each experiment

217   thereafter were allocated for an internal blank when testing samples of INPs (i.e. 12 aliquots of Milli-Q water and

218   84 aliquots of sample suspension). Comparison of fraction frozen curves for typical IR-NIPI blanks with curves

219   obtained for droplets containing various ice-nucleating materials (discussed below) show that there is a clear

220   heterogeneous freezing signal (Figure 5). We hope to improve the baseline in the future (Polen et al., 2018) but

221   for the purpose of these experiments the nucleants tested were active at sufficiently warm temperatures to be well

222   above the baseline.

223   **3.3**   **Feldspar chips**

224   To further test the temperature readings from the IR-NIPI instrument a set of experiments was performed where

225   each droplet contained a single ~100 μm sized grain of K-feldspar, a mineral known to exhibit excellent ice-

226   nucleating properties (Atkinson et al., 2013; Harrison et al., 2016). This experiment was adapted from the

227   procedure described by Whale *et al*. (2018) and involved taking feldspar chips from a bulk rock of pegmatite and

228   selecting individual grains. Pegmatite is an igneous intrusive rock rich in felsic minerals (including alkali

229   feldspars) with grain sizes often being larger than 2.5cm. The feldspar chips were selected after sorting them by

230   eye. A total of 20 grains were collected, assigned a number and their position tracked through the course of each

231   experiment. The same feldspar chips were tested in both the μL-NIPI and the IR-NIPI. For the IR-NIPI

232   experiments single grains of feldspar were placed into the bottom of a multiwell plate and 50 μL of Milli-Q water

233   was then pipetted into each well. The experiment was then carried out as normal and the freezing temperatures of

234   the wells were recorded. The grains were then used in the μL-NIPI experiment by placing the grains onto a glass

235   cover slip atop a cold plate and pipetting 1 μL droplets onto the grains, before carrying out a standard μL-NIPI

236   experiment as described by Whale *et al*. (2015). Briefly, the temperature of the cold plate was reduced at 1°C min^{-1}

237   and the temperature of the droplet freezing events recorded via a camera. The resulting fraction frozen plot for

238   this experiment can be seen in Figure 6. The two instruments yielded similar fraction frozen curves, with the

239   agreement between the two suggesting that the temperature measurement and calibration of the IR-NIPI were

240   robust. The agreement also further justified the use of the calibration method developed for the IR camera. The

241   observation that the feldspar grains in the two experiments gave rise to similar results suggests that the IR camera

242   is reporting a representative temperature, within the quoted temperature uncertainties.

243

244   **3.4   NX-illite**

245   The mineral dust NX-illite was chosen as a test sample as it has been used in an extensive intercomparison study

246   (Hiranuma et al. 2015) and contains some common components which are found in atmospheric mineral dusts

247   (Broadley et al., 2012). NX-illite was taken from the same batch as that used by the Leeds group in the Hiranuma

248   *et al*. (2015) intercomparison and no further processing of the material was carried out. Aqueous suspensions of

249   the sample were prepared by weighing a known amount of material and suspending it in a corresponding volume

250   of water to make up a weight percent suspension (i.e. 0.1 g of mineral in 9.9 g of water to yield a 1 wt%

251   suspension). NX-illite concentrations of 0.01, 0.1 and 1 wt% were prepared in this manner, and in each case a

252   Teflon-coated magnetic stirrer bar was used to keep the particles suspended whilst the sample was pipetted into

253   the wells of the multiwell plate. Each concentration of NX-illite was tested using the IR-NIPI and the resultant

254   fraction frozen curves are shown in Fig. 5.

255   By employing a suspension of known concentration and composed of a material with a known specific surface

256   area, the surface area of nucleator per droplet can be calculated and used alongside the fraction frozen curves to

257   determine $n_s(T)$, as described in equation (1). The $n_s(T)$ values derived from the IR-NIPI for 0.01, 0.1 and 1 wt%

258   NX-illite are shown in Figure 7a. The results demonstrated good agreement with each other and exhibited the

259   expected trend of the lower wt% droplets freezing at lower temperatures and having higher $n_s(T)$ values than the

260   droplets having higher wt% suspensions. Further to this, a freeze-thaw experiment of a 0.1 wt% NX-illite

261   suspension was conducted wherein the sample was frozen once, thawed and then frozen again (see Figure 8). The

262   two runs froze at similar temperatures, as expected, showing good reproducibility with the IR-NIPI technique.

263

264   The n_s derived from IR-NIPI with 0.01, 0.1 and 1 wt% NX-illite are shown in Figure 7a. They are in good

265   agreement with one another with lower wt% suspensions yielding data at lower temperatures and higher n_s values,

266   as expected. Further to this a freeze thaw experiment of 0.1wt% suspension was conducted where the sample was

267   frozen once, thawed and then frozen again (see Figure 8). The agreement between the two runs show that the

268   material did not alter on freezing.

269   The values of $n_s(T)$ for NX-illite derived from 0.01-1 wt% suspensions are shown in Figure 7a, and is illustrated

270   together with the literature data for this material in Figure 7b. This material has also been investigated by Beall *et*

271   *al*. (2017) using an instrument that also takes advantage of 50μL droplets: the Automated Ice Spectrometer (AIS).

272   The results of Beall *et al.* (2017) are therefore directly comparable to the results from the IR-NIPI. All of the wet

273   suspension techniques have been grouped together in black in Fig. 7b, apart from the AIS data shown in green

274   and the IR-NIPI data in red. Both the IR-NIPI and AIS data were in good agreement with one another. It can be

275   seen that the larger volume assays (IR-NIPI and AIS) gave results towards the upper spread of literature data but

276   are still consistent with other results (Figure 7b). Dry dispersed techniques have also been plotted as unfilled blue

277   squares in Fig. 7b, but none of these techniques were sensitive in the range of $n_s(T)$ seen by the large droplet

278   instruments. The new data from the IR-NIPI has extended the dataset for NX-illite to warmer temperatures than

279   in previous measurements, illustrating the utility of the technique.

280   It should be noted that in preliminary experiments some discrepancies between dilutions of NX-illite were

281   observed which highlighted the importance of accurately making up suspensions. In the flowing we note some

282   issues that had to be solved. In some initial experiments the dilutions of a suspension would yield a higher than

283   expected $n_s(T)$. On further investigation this issue was resolved via gravimetrically weighing suspensions (i.e.

EGU

284 preparing a known mass of a sample in a known mass of water) rather than diluting a bulk stock suspension.

285 Further to this great care was taken when sampling from the bulk NX-illite sample as to make sure no bias was

286 introduced when selecting material since a powder can separate on the basis of grain size. This was avoided by

287 shaking the container horizontally and selecting material from the centre of the bulk sample. Magnetic stirrer bars

288 were used to keep particles suspend but when it came to collecting the suspension using a pipette the suspension

289 was taken from the magnetic stirrer plate to stop the vortex within the vial. As the suspension was not stirring for

290 a short period of time it meant that particles did not have time to fallout of suspension and there was no longer a

291 vortex created by the stirrer bar which could bias particle distribution when sampling. The above emphasises the

292 importance of selecting samples in a repeatable way and may explain some of the variability between the literature

293 data seen in Fig. 7b.

294

295 **3.4   Atmospheric aerosol sample**

296 In order to demonstrate the utility of this approach for atmospheric aerosol samples, filter samples were collected

297 in Leeds as part of a field campaign held on the evening of the 5th November. Samples of atmospheric aerosol

298 were collected using a Mesa PQ100 air sampler for 100 min. An inlet head with an upper cut-off of 10μm was

299 utilised and air was sampled at 16.7 L min[-1] on to 0.4 μm polycarbonate track-etched Whatman filters, with a total

300 of 167 L of air sampled. The filters were then placed in to 6 mL of Milli-Q water and vortexed for 5 min to wash

301 the particles from the filter and into suspension.

302 The aqueous sample was then analysed on the IR-NIPI and μL-NIPI (Whale et al., 2015). The concentration of

303 INPs per litre of air, $[INP]_T$, was subsequently calculated using equation (2) (DeMott et al., 2016).

304 $$[INP]_T = -\ln\left(\frac{Nu(T)}{N}\right)\left(\frac{V_w}{V_a V_s}\right) \qquad\qquad (2)$$

305 Where $N_U(T)$ is the number of unfrozen droplets at a given temperature, N is the total number of droplets, V_w is

306 the volume of wash water, V_a is the volume of an aliquot and V_s is the volume of air sampled.

307 The resulting INP concentrations from the combination of these two instruments spanned four orders of magnitude

308 and covered a temperature range of 20°C (see Figure 9). The data from both instruments was in good agreement

309 and yielded complementary information. This illustrates how the IR-NIPI can be used to extend the measurements

310 of INP concentrations to higher temperatures and lower INP concentrations. Since modelling suggests that 0.1 to

311 1 INP L[-1] is a critical concentration and much lower concentrations still impact clouds (Vergara-Temprado et al.,

312   2018), measurements with IR-NIPI will be extremely useful, particularly in environments with low INP

313   concentrations.

4   Summary and conclusions

315   The IR-NIPI technique is a novel approach to measuring freezing events in immersion mode nucleation studies.

316   We demonstrate that IR thermometry is a sound method for determining the freezing temperature of 50 μL water

317   droplets in multiwell plates, overcoming potential distorting influences such as gradients, neighbouring wells

318   freezing and poor thermal contact. A novel calibration method has been proposed which relies on the return of

319   water droplets to the equilibrium melting temperature of water, 0°C, after initial freezing. This gives an individual

320   calibration for every run and every well. When comparing this calibration technique to thermocouple readings the

321   data is consistent to within ±0.9°C. The use of this calibration method is further supported when looking at

322   experiments using single grains of feldspar, with the results being consistent with those of the established μL-

323   NIPI instrument that employs 1μL droplets on a cold stage. Results for the ice nucleating ability of NX-illite with

324   the IR-NIPI, a mineral dust which has been the subject of an extensive inter-comparison, are consistent with

325   literature measurements. In particular, the IR-NIPI is in good agreement with another well-characterised large

326   droplet instrument (AIS) (Beall et al., 2017). However, it is unclear why both of these large volume instruments

327   produce n_s results at the high end of the range of n_s values reported previously. The utility of IR-NIPI for the

328   analysis of atmospheric samples was also demonstrated by collecting and analysing an aerosol sample in the

329   atmosphere of the city of Leeds, England. The sample was analysed simultaneously with the μL-NIPI instrument.

330   Results from the two instruments were in good agreement with one another. The IR-NIPI instrument extended the

331   range of INP concentrations shown by the μL-NIPI by two orders of magnitude, covering a regime critical for

332   cloud formation with a modest sampling time of just 100 mins at 16.67 L min^{-1}. The use of the multiwell plates

333   and the IR camera lends the IR-NIPI to the possibility of automating the system further and this is an objective

334   for future work.
