General Comments Low cost sensors (LCS) playing an emerging role in the urban environmental monitoring with respect to the possibility of setting up a densely populated gridded network. Nevertheless, the detection limit, the stability and the real-time calibration were in general of question or with difficulty to overcome. In this study, the authors try to use the machine learning (ML) method to enhance of the data quality of LCS which is in general fit the effort of the community to improve the data quality of LCS. The paper is within the scope of AMT and I have the following comments for the authors to consider before publication.

Printer-friendly version

Discussion paper

C1. The machine learning method is used to improve the data quality of the LCS. The improvement is clear but still without in-depth explanations. The scientific paper shall not be looks like simply magic. I will be convinced if the authors can provide much more examples as the authors also wrote in their conclusions. Moreover, I did see much better comparison results from LCS (the Cambridge group for the same campaign) with the CAPS instrument on NO<sub>2</sub> and other parameters like O<sub>3</sub>, CO, etc. So, I wonder if the results presented in this paper can be improved further.

C1. Author's response We thank the reviewer for this comment, as this is something we really wanted to avoid and have therefore added more detail in order to try and be more explicit about this. During the analysis section of this work the authors made sure that the ML techniques used provided outputs on the decisions they made that could then be compared with laboratory experiments and previous sensor studies, in order to make the methods used not seem like black boxes. This was underpinned by our choice of ML techniques; BRT was chosen because of the function to extract out the variables gain contributions, GP could produce the uncertainty for each predicted data point and the weights associated with each variable can be extracted from the BLR algorithm (see C4 with Figs. 4 and 5 of this document). The manuscript aimed to compare results from using different techniques on the same dataset and therefore, fully comprehensive explanations of different ML techniques is beyond the scope of this paper. However, we recognise that this was not made clear enough in the manuscript so have added some more detail in the text and some more citations to detailed descriptions of the techniques.

With respect, the authors have not seen any publications from the Cambridge group on this and cannot comment on unpublished work. Whilst there are many references to studies where LCS have been used successfully in the field, the scope of this manuscript relates to the improvement of low-cost sensor performance for deployment over longer periods of time and possible calibration strategies that would enable this.

C1. Changes to manuscript Gaussian process reference inserted: Gaussian process

for time series modelling, S. Roberts, M. Osborne, M. Ebden, S. Reece, N. Gibson and S. Aigrain (Roberts et al., 2013) Page 7, line 27.

XGBoost reference inserted: Greedy function approximation: a gradient boosting machine (Friedman, 2001). Page 7, line 17.

C2. Sect. 3.2: during the training period, what kind of regression method is used to calibrate the sensors? According to Cantrell, 2008 (Cantrell, C. A.: Technical Note: Review of methods for linear least-squares fitting of data and application to atmospheric chemistry problems, Atmos. Chem. Phys., 8, 5477–5487, 2008.), bivariate regression algorithm is required to retrieve the robust slope.

C2. Author's response Thanks for bringing to our attention that the SLR method described in Section 3.2 was unclear. More text has been added to better describe the linear regression process. There were four different types of analytical techniques used in turn to examine the performance of ML versus simple linear regression (SLR). In section 3.2, SLR was used to calibrate the EC sensors against their respective reference instruments.

Using NO<sub>2</sub> as an example, linear parameters in the form of  $y = mx + c$  were determined using a linear least squares fit between the NO<sub>2</sub> CAPS reference instrument and the median NO<sub>2</sub> EC sensor. This linear relationship was calculated for the first five days of the deployment – the same five days that were used as the training period for the ML analysis.

Text has been added on Page 6 lines 6 – 10, to provide further detail about SLR.

The training period for the NO<sub>2</sub> EC sensors and NO<sub>2</sub> reference measurements was also re-analysed using bivariate regression (Ordinary Least Squares) and the resulting model was applied to the median NO<sub>2</sub> sensors over the testing period. This produced a bivariate regression NO<sub>2</sub> prediction, shown in green in Figure 1. The regression was performed using the Python statsmodels package.

The RMSE was calculated between the BR NO<sub>2</sub> prediction and the NO<sub>2</sub> reference measurements in the testing period and was found to be 14.6 ppb. The bivariate regression prediction therefore contains more error than the simple linear regression in the manuscript (10.42 ppb). This does not change the outcome of the paper which aims to use ML to improve the quality of the NO<sub>2</sub> sensors by correcting for cross interferences and therefore has not been added to the manuscript. The SLR was used to show the calibration of the sensors using linear regression and essentially set a baseline for the improvements.

C2. Changes to manuscript Using the NO<sub>2</sub> EC as an example, linear parameters in the form of  $y = mx + c$  were determined using a linear least squares fit between the NO<sub>2</sub> CAPS reference instrument and the median NO<sub>2</sub> EC sensor for the first five days of the sensor instrument deployment. Once trained in this manner, these linear calibration factors based on SLR were used to calibrate the median NO<sub>2</sub> sensor and were unchanged for the remainder of the experiment.

C3. Figure 4, Panel A is with linear scale, Panel B-D is with logarithmic scale. Why the authors want to have two different scales?

C3. Author's response Figure 4a uses a linear scale to compare the uncalibrated median NO<sub>2</sub> EC sensor to the co-located reference NO<sub>2</sub> measurement. The NO<sub>2</sub> sensor signal differed from the reference measurement sufficiently to allow this to be on a linear scale and to show the reader that the NO<sub>2</sub> sensor was able to detect the general trend of the NO<sub>2</sub> concentration patterns, but that there was still a large amount of discrepancy between the two measurements.

However, plotting Fig. 4 b to d) on logarithmic axis shows the fit of the calibrated median NO<sub>2</sub> sensor with the reference measurement. The improvement of the NO<sub>2</sub> measurement across the deployment means that it was difficult to identify times where the concentration estimate contained more error and uncertainty, but the log scale shows this clearly. These higher-error/more uncertain measurements could then be

[Printer-friendly version](#)[Discussion paper](#)

justified by identifying when other variables exhibited measurements that were outside of their training period ranges. We would therefore like to keep the figure in its current state but are happy to change at the editor's request.

C4. Figure 5 is a nice way to explain the advantage from the ML method. Can the authors do the same for the other ML processing?

C4. Author's response The Boosted Regression Tree gain contributions for each variable was a major reason for using this as a calibration algorithm, and we are glad the reviewer liked Fig. 5. The gain contributions were also analysed for the OX EC BRT algorithm and have been added to the manuscript. This function of the BRT was advantageous as it allows the user to identify the key variables that impact the sensor signals which can then be compared with prior knowledge from laboratory experiments and other studies, thus removing some of the "black box" nature of these algorithms.

C4. Changes to manuscript: Gain contributions from OX BRT added to Figure 5 on page 21.

C4. Author's response Please note that the values used in the pie chart for the NO<sub>2</sub> concentration estimate gain contributions have been changed slightly. Whilst adding in the OX pie chart the authors noticed that the previous NO<sub>2</sub> plot was an old version, and this has now been changed to the most up-to-date chart. Where cited in the manuscript, values relating to these plots have been updated accordingly.

It is unfortunately not possible to extract the same information from the Gaussian Process implementation that was used in this work. This approach does however provide a prediction uncertainty, see Fig. 4b in manuscript, which is very useful when interpreting the predicted concentrations, in particular when they move into variable space outside of that experienced during the model training dataset.

Linear regression weights for variables can be extracted from the BLR algorithm. However, to make assumptions about the relative importance of each of the sensors to the

[Printer-friendly version](#)[Discussion paper](#)

algorithm, all the variables, including the reference observations were normalised to between 0 – 1. The BLR analysis was then repeated with the normalised data. This does not change the algorithm and the concentration estimates were identical to those used in the manuscript after the normalisation process.

The resultant weights can be used to indicate that, for the NO<sub>2</sub> BLR algorithm, the linear function describing the NO<sub>2</sub> sensor measurement contributed the most to the BLR algorithm. Equally, the linear component of the OX sensor measurement was the most important variable for determining the BLR algorithm when predicting the OX concentration estimate. The ability to extract these weights from the BLR analysis is useful for identifying relationships between the sensors, yet this was not included in the manuscript because it overcomplicated the analysis.

These weights output from BLR should not be directly compared to the gain contributions extracted from the BRT, because they are different metrics. The weights from BLR examine the linear relationships between variables whereas the gain contribution from BRT analysed the degree to which each variable contributed to the regression tree decisions – this includes non-linear functions. If the editor wishes, this can be included in the manuscript.

C5. The ML corrected LCS signal still significantly smaller than those measured by the reference instruments especially for the peak values of O<sub>x</sub>? Could the authors provide more discussions on this aspect and what could be the possible improvements on LCS or ML.

C5. Author's response Machine learning techniques are very powerful at data interpolation, but often fail when it comes to extrapolation beyond the training data variable space. It is for this reason that linear models can often outperform some ML techniques when using small training datasets. The performance of the ML techniques can be greatly improved by randomly distributing the training data throughout the full time-series in order to cover more variable space. However, this is not a realistic calibration

[Printer-friendly version](#)[Discussion paper](#)

strategy for low cost sensors and so was not pursued in this work. In Figure 6, at peak [OX] the BRT ML corrected OX concentration estimate does sometimes under-predict the concentration of OX, compared to the reference measurement. This is due to the median OX EC sensor reporting values at these times that are slightly higher than the maximum [OX] observed by the median OX EC sensor during the training period. The inability of the BRT algorithm to extrapolate caused the BRT predicted [OX] estimate to be lower than the reference measurements, in a similar manner to the BRT NO<sub>2</sub> prediction. To improve the comparison between the BRT OX concentration estimate and the OX reference measurements more training data is required. This will ensure that the concentration range of [OX] as measured by the EC sensors in the testing period is within the [OX] range in the training data. This was summarised by a few lines which were added to the text on page 9, lines 32 -34.

C5. Changes to manuscript, page 9, lines 32 -34 The ML technique with the lowest RMSE, BRT, brought the OX concentration estimate much closer to the reference observations, see Fig. 6, however, during peaks in OX concentration, the BRT predicted OX concentration estimate was underpredicted due to BRT's inability to extrapolate.

C6. Technical comments: In most cases, the multi-citations were not correctly implemented. For example, page 2 line 8, (Caron et al., 2016),(Jiao et al., 2016) should be (Caron et al., 2016; Jiao et al., 2016). This shall be revised throughout the paper.

C6. Author's response Thanks for notifying the authors about this error, this issue was addressed above in the Reviewer 1 Technical Comment 2.

C7. Figure 3 is not cited in the main text which I assume should appear somewhere in Sect. 3.2.

C7. Author's response Figure 3, showing how increasing the number of EC sensors from 1 to 6 within a cluster improves the agreement between the reference measurement and the median sensor signal, was cited within the manuscript in section 3.1 on Page 5, line 34.
