**Abstract.** Many processes in the lower atmosphere including transport, turbulent mixing and chemical conversions happen on time scales of the order of seconds (e.g. at point sources). Remote sensing of atmospheric trace gases in the UV and visible spectral range (UV/Vis) commonly uses dispersive spectroscopy (e.g. Differential Optical Absorption Spectroscopy, DOAS). The recorded spectra allow for the direct identification, separation and quantification of narrow band absorption of trace gases.

5 However, these techniques are typically limited to a single viewing direction and limited by the light throughput of the spectrometer setup. While two dimensional imaging is possible by spatial scanning, the temporal resolution remains poor (often several minutes per image). Therefore, processes on time scales of seconds cannot be directly resolved by state of the art dispersive methods.

We investigate the application of Fabry-Perot Interferometers (FPIs) for the optical remote sensing of atmospheric trace gases  
10 in the UV/Vis. By choosing a FPI transmission spectrum, which is optimised to correlate with narrow band (ideally periodic) absorption structures of the target trace gas, column densities of the trace gas can be determined with a sensitivity and selectivity comparable to dispersive spectroscopy, using only a small number of spectral channels (FPI tuning settings). Different from dispersive optical elements, the FPI can be implemented in full frame imaging setups (cameras), which can reach high spatio-temporal resolution. In principle, FPI Correlation Spectroscopy can be applied for any trace gas with distinct absorption  
15 structures in the UV/Vis.

We present calculations for the application of FPI Correlation Spectroscopy to SO<sub>2</sub>, BrO and NO<sub>2</sub> for exemplary measurement scenarios. Besides high sensitivity and selectivity we find that the spatio temporal resolution of FPI Correlation Spectroscopy can be more than two orders of magnitude higher than state of the art DOAS measurements.

As proof of concept we built a one-pixel prototype implementing the technique for SO<sub>2</sub> in the UV. Good agreement with  
20 our calculations and conventional measurement techniques are demonstrated and no cross sensitivities to other trace gases are observed.

## 1 Introduction

Within the last decades, progress in optical remote sensing of atmospheric trace gases led to a better understanding of many important processes including air pollution, ozone and halogen chemistry, and the evolution of volcanic plumes. Narrow band structures in the trace gas molecule's absorption spectrum are used to identify and quantify the amount of a trace gas integrated along a line of sight, i.e. its column density (CD, typically in units of molec cm<sup>-2</sup>) and to separate its absorption signal from interfering gas absorptions and scattering processes.

Differential Optical Absorption Spectroscopy (DOAS, see Platt and Stutz, 2008, for details) has become a well established technique for atmospheric trace gas remote sensing in the UV/Vis with high sensitivity (detection limits within the ppb to ppt range for atmospheric light paths of a few kilometers). A spectrometer and a telescope with narrow field of view (FOV) are used to record spectra  $I(\lambda)$  of scattered sunlight, which are compared to a reference spectrum  $I_0(\lambda)$ . Beer Lambert's law describes the corresponding spectral optical density  $\tau(\lambda)$  with  $\sigma_i(\lambda)$  and  $c_i(l)$  being the absorption cross section and the concentration of trace gas species  $i$  along a line of sight  $L$ , respectively:

$$\tau(\lambda) = -\log \frac{I(\lambda)}{I_0(\lambda)} = \int_0^L \sum_i \sigma_i(\lambda) c_i(l) dl + \text{scattering at molecules and aerosols} \quad (1)$$

Atmospheric UV/Vis optical densities are dominated by trace gas absorption and scattering processes at air molecules or aerosols. The known absorption cross sections of the trace gases together with a polynomial, which accounts for the broad band absorption and scattering effects are fitted to the measured spectral optical density. The fit coefficients represent the CDs  $S_i = \int_0^L c_i(l) dl$ , i.e. the integrated trace gas concentration along the light path difference of  $I(\lambda)$  and the reference  $I_0(\lambda)$ . In principle, spatial distributions of trace gases (images or height profiles) can be recorded by scanning of viewing angles with a narrow FOV telescope (e.g. Multi-Axis DOAS, Hönninger et al., 2004). More complicated optical setups allow to record spectra of an entire image column at once by using a two dimensional detector array (e.g. Imaging DOAS, Lohberger et al., 2004). Images can then be recorded by column by column (push broom) scanning. The acquisition times of these techniques are rather high (often several minutes per image or profile for typical trace gas CDs) limiting their application to processes that are spatially homogeneous on that time scale or processes with very high trace gas CDs.

Determination of two dimensional atmospheric trace gas distributions with high time resolution at time scales of the order of seconds, i.e. fast imaging of atmospheric trace gases is possible with techniques recording all spatial pixels of an image at once for a low number of spectral channels (see e.g. Platt et al., 2015). This allows studying phenomena which are not accessible to conventional scanning methods. With fast trace gas imaging techniques sources and sinks of trace gases can be identified and quantified on much smaller spatial and temporal scales than with conventional remote sensing techniques. This allows for instance to gain insight into small scale mixing processes and to distinguish chemical conversions from transport.

Most of the presently used atmospheric trace gas imaging schemes either use a set of two band pass filters (e.g. SO<sub>2</sub> Camera, ~ 1 Hz for volcanic emissions, see e.g. Mori and Burton, 2006; Bluth et al., 2007; Kern et al., 2010; Platt et al., 2018) or a tuneable band pass filter as wavelength selective element (e.g. NO<sub>2</sub> Camera, ~ 3 min per image for stack emissions of power plants Dekemper et al., 2016). These techniques either involve intricate optical set-ups with low light throughput or yield a

rather coarse spectral resolution which might result in strong cross interferences (see e.g. Lübcke et al., 2013; Kuhn et al., 2014).

Here we study the application of Fabry-Perot Interferometers (FPIs) as wavelength selective elements for trace gas imaging in the UV/Vis. The periodic FPI transmission spectrum is matched to the spectral absorption structures of trace gases that often show a similar periodicity. Due to the high correlation of the transmission spectrum of the wavelength selective element and the trace gas absorption spectrum a high sensitivity can be reached and cross interferences with other absorbers are minimized, even if only a small number of spectral channels (FPI tuning settings) is used (see Kuhn et al., 2014, and the discussion in Sect. 3.2 below). Air spaced FPI etalons are very robust devices and allow for simple optical designs that can easily be implemented in imaging sensors. We present a model study on the sensitivity and selectivity of FPI Correlation Spectroscopy applied to SO<sub>2</sub>, BrO and NO<sub>2</sub> (Sect. 3). For exemplary measurement scenarios, we infer the possible spatio-temporal resolution of these measurements for a specific instrument implementation. We find that for the three gases imaging with spatio-temporal resolutions by around two orders of magnitude higher than state of the art methods should be possible. In addition, we present a proof of concept study of the technique for volcanic sulphur dioxide SO<sub>2</sub>, validating the expected high accuracy and sensitivity of the technique (Sect. 4).

## 2 Fabry-Perot Interferometer Correlation Spectroscopy

### 2.1 Fabry Perot Interferometer

The FPI is a fundamentally very simple optical device, known for more than a century (e.g. Perot and Fabry, 1899). In principle, it consists of two plane parallel surfaces each with reflectance  $R$ , separated by a distance  $d$  (see Fig. 1). The medium between the plates has the index of refraction  $n$ . Incident light (angle of incidence  $\alpha$ ) is split up in partial beams with different optical path lengths between the two surfaces. Due to interference of the transmitted partial beams, the spectral transmission of the FPI is characterised by periodic transmission peaks, referring to constructive interference. For high enough orders of interference, the free spectral range (FSR)  $\Delta_\lambda$  between two transmission peaks in units of wavelength  $\lambda$  is approximately given by:

$$\Delta_\lambda(\lambda) \approx \frac{\lambda^2}{2nd \cos \alpha} \quad (2)$$

The finesse  $F$  of a FPI represents the ratio of FSR to the full width half maximum (FWHM)  $\delta_\lambda$  of a transmission peak:

$$F = \frac{\Delta_\lambda}{\delta_\lambda} \quad (3)$$

The finesse is a measure for the number of effectively interfering partial beams and therefore increasing with the surface reflectance. However, it is also depending on the alignment and quality of the surfaces.

The spectral transmission as a function of  $\lambda$  and the FPI's instrument parameters is given by:

$$T_{FPI}(\lambda) = \left[ 1 + \frac{4R}{(1-R)^2} \sin^2 \left( \frac{2\pi dn \cos \alpha}{\lambda} \right) \right]^{-1} \quad (4)$$

Despite its simple design, the challenge in manufacturing FPI devices lies in creating a stable set-ups keeping  $d$  stable to a fraction of a wavelength across the effective aperture.

## 2.2 Detection principle

The concept of using FPI correlation to detect atmospheric trace gases is described in Kuhn et al. (2014). The correlation of periodic absorption structures of atmospheric trace gases and the FPI transmission is exploited. An apparent absorbance  $\tilde{\tau}_i$  of a trace gas  $i$  is calculated from the optical densities of an on-band  $\tau_A$  and off-band  $\tau_B$  channel:

$$\tilde{\tau}_i = \tau_A - \tau_B = \log \frac{I_{A,0}}{I_A} - \log \frac{I_{B,0}}{I_B} = (\bar{\sigma}_{A,i} - \bar{\sigma}_{B,i}) S_i = \Delta \bar{\sigma}_i S_i \quad (5)$$

$S_i$  denotes the CD of a trace gas  $i$ . For the on-band channel, the spectral pattern of the FPI transmittance is chosen to correlate with the absorption band structure of the target trace gas, while for the off-band channel the FPI is tuned to show minimum correlation with the target trace gas absorption. The apparent absorbance is - for low trace gas optical densities - proportional to the CD of the trace gas. The proportionality is  $\Delta \bar{\sigma}$ , representing the difference of the effective absorption cross section seen by channel A and channel B.

In practice, a wavelength range of high correlation of spectral trace gas absorption and FPI transmission is preselected with a band pass filter (BPF). Within this spectral range the FPI physical parameters are optimised, particularly the Finesse is chosen to maximise the signal to noise ratio.

Here we apply FPI Correlation Spectroscopy for passive imaging of a trace gas in the atmosphere. This means that the light source is scattered sky radiation that is measured within an imaging FOV (e.g. 20° aperture angle). We assume in the following that a reference  $I_0$  (i.e. a part without trace gas) is always present within the image, so that  $S$  denotes the differential trace gas CD compared to that reference.

## 3 Model study for SO<sub>2</sub>, NO<sub>2</sub> and BrO

FPI Correlation Spectroscopy can be applied to every trace gas species that yields sufficiently strong spectral absorption structures in the regarded wavelength range. In this section we present exemplary model studies for imaging of SO<sub>2</sub>, NO<sub>2</sub> and BrO. For each target trace gas we regard a typical exemplary measurement scenario (Tab. 1). For the target species BrO and SO<sub>2</sub> we use typical measurement scenarios of volcanic emissions in the UV spectral range. For SO<sub>2</sub> we assume CDs that are typically measured in volcanic plumes of a comparably weak volcanic emitter or an already highly diluted plume (1e17 molec cm<sup>-2</sup>, see Tab. 1). We additionally chose a high and probably disturbing NO<sub>2</sub> CD (1e17 molec cm<sup>-2</sup>) in order to make the scenario also applicable to SO<sub>2</sub> measurements at e.g. ship or industrial stack emissions. Existing filter based SO<sub>2</sub> cameras are subject to strong cross interferences in this CD range (see e.g. Lübcke et al., 2013; Kuhn et al., 2014). In the scenario for BrO we assume a relatively strong but not uncommon volcanic emitter, with BrO mixing ratios of tens to hundreds ppt within the plume (1e14 molec cm<sup>-2</sup>, see Tab. 1) and high SO<sub>2</sub> CDs (3e18 molec cm<sup>-2</sup>). Gradients in the BrO distributions can give insight into in-plume halogen chemistry (see e.g. Bobrowski et al., 2007; von Glasow, 2010; Roberts et al., 2014). The NO<sub>2</sub>

scenario (blue spectral range) is applicable to measurements of stack emissions at e.g. a coal power plant (see e.g. Dekemper et al., 2016) but also to local gradients induced by traffic ( $1e16 \text{ molec cm}^{-2}$ , see Tab. 1).

We calculate the sensitivities and study the cross interference of the apparent absorbance with other atmospheric absorbers for typical differential CDs for the respective measurement scenario. Table 1 lists the assumed differential CDs of the trace gases absorbing in the same spectral range as the trace gases under investigation. For these potentially interfering trace gases we chose relatively high values, so that the indicated cross interferences correspond to upper limits. The listed CDs represent differential CDs across a typical image FOV ( $\sim 20^\circ$ ), assuming that within the image always a reference region  $I_0$  without the target trace gas is present.

In a second step, we calculate the corresponding photon budgets in order to infer the approximate achievable spatial and temporal resolution of the respective imaging measurement.

### 3.1 Description of the Model

The apparent absorbance is calculated from radiances  $I_k$  (in  $[\text{photons s}^{-1} \text{ mm}^{-2} \text{ sr}^{-1}]$ ) of scattered solar radiation transmitted by the respective spectral channel  $k = A, B$  (on-band and off-band FPI setting) :

$$I_k = \int d\lambda I_0(\lambda) e^{-\sum_i \sigma_i(\lambda) S_i} T_{FPI,k}(\lambda) T_{BPF}(\lambda) \quad (6)$$

A spectrum recorded at a clear day in Heidelberg with a solar zenith angle of  $73^\circ$  ( $160^\circ$  relative solar azimuth,  $89^\circ$  viewing zenith angle) was used to approximate the spectral radiance  $I_0(\lambda)$ .  $I_0(\lambda)$  was scaled with scattered sky radiance measurements from (Blumthaler et al., 1996). The radiance measurements were performed in Innsbruck in February, 1995 with a solar zenith angle of  $68^\circ$ . For our calculations we used the values for  $180^\circ$  relative solar azimuth and  $70^\circ$  viewing zenith angle.  $S_i$  is the CD of an absorbing gas species  $i$  with spectral absorption cross section  $\sigma_i(\lambda)$ .  $T_{FPI,k}$  is the FPI transmittance in configuration  $k$  (see Eq. (4)) and  $T_{BPF}$  the transmittance of the BPF isolating the measurement wavelength range for the respective target trace gas.  $T_{BPF}$  was modeled with a higher order Gaussian function:

$$T_{BPF}(\lambda) = P e^{-\left(\frac{(\lambda_{BPF}-\lambda)^2}{2c^2}\right)^p} \quad (7)$$

with a FWHM of

$$\delta\lambda_{BPF} = 2c\sqrt{2(\log 2)^{\frac{1}{p}}} \quad (8)$$

$P$  describes the peak transmission at a central wavelength  $\lambda_{BPF}$ . An order  $p = 6$  was used to approximate interference filter transmission profiles.

With Eq. (5) and the intensities  $I_k$  from Eq. (6), the apparent absorbance  $\tilde{\tau}_i$  can be calculated, allowing to study the sensitivity and selectivity of the detection of a trace gas  $i$  for given FPI instrument settings.

In addition, we approximate the respective detection limits based on photon shot noise. In order to calculate the number of photons that reach the detector of the imaging device, we need to know the etendue (product of entrance area  $A$  and aperture

solid angle  $\Omega$ ) of the employed optics. Kuhn et al. (2014) suggest several optical setups for FPI Correlation Spectroscopy imaging implementations. Here, we chose the setup in which, with help of an image space telecentric optics (see Fig. 5), the incident radiation from the imaging FOV is parallelised before traversing the FPI and BPF. In order to avoid strong blurring of the FPI transmission spectrum due to different incidence angles, the divergence  $\Theta$  of the light beams traversing the FPI should not be much larger than  $\Theta = 1^\circ$ . With a lens of focal length  $f$  this condition limits the maximum aperture radius  $a$  to:

$$a = f \tan \frac{\Theta}{2} \quad (9)$$

The FPI clear aperture radius  $a_{FPI}$  determines the imaging FOV aperture angle

$$\gamma_{FOV} = 2 \arctan \frac{a_{FPI}}{f} \quad (10)$$

The etendue per pixel  $E_{pix}$  is determined by the spatial resolution of the recorded image, which can be varied by binning individual pixels. For  $n_{pix}$  being the number of pixels along a column of a square detector array, the approximate etendue per pixel of the instrument is:

$$E_{pix} = A_{pix} \Omega_{pix} \approx a^2 \sin^2 \left( \frac{\gamma_{FOV}}{2n_{pix}} \right) \pi^2 \quad (11)$$

The detectors quantum efficiency and losses within the optics are considered to be not wavelength dependent in the regarded spectral ranges and combined in a loss factor  $\eta$ . We chose a somewhat lower loss factor for the UV (0.25 for  $\text{SO}_2$  and  $\text{BrO}$ ) compared to the Vis (0.5 for  $\text{NO}_2$ ) due to the higher quantum efficiency of commonly used detectors. Each FPI channel (on-band and off-band setting) requires one image acquisition. We assume a photon electron shot noise limited measurement, where for an exposure time  $\Delta t$  the number of counted photo electrons per pixel and image is

$$N_{phe,pix} = I E_{pix} \eta \Delta t \quad (12)$$

with an uncertainty of  $\Delta N_{phe,pix} = \sqrt{N_{phe,pix}}$ . The uncertainty in the apparent absorbance  $\tilde{\tau}$  is then

$$\Delta \tilde{\tau} \approx \sqrt{\frac{2}{N_{phe,pix}}} \quad (13)$$

assuming the intensities  $I_k$  for the two FPI settings  $k = A, B$  are similar and that the reference intensities  $I_{0,k}$  have to be recorded only once.

Note, that the used sky radiances, loss factors and dimensions of the optics (see Tab. 2) represent conservative assumptions. For instance the light throughput could be enhanced by more than an order of magnitude by choosing a different optical setup (see Kuhn et al., 2014). There, the FPI is placed in front of the lens using the full clear aperture and the full aperture angle of the FPI and the optics. Each viewing direction of the FOV, however, will have a different incidence angle onto the FPI and therefore a different FPI transmission spectrum, which has to be accounted for in the data analysis. Alternatively, simply a larger FPI could be used. The results of the following calculations for the image space telecentric optics, therefore, represent lower limits of the performance.

### 3.2 Results of the simulations

The FPI Correlation Spectroscopy technique allows for numerous different realisations regarding the used spectral window and FPI instrument parameters that can be chosen according to e.g. measurement conditions or availability of optical components (FPI, BPF). Here, we identified spectral windows in which the target trace gas absorption cross sections exhibit approximately periodic structure and appropriate FPI parameters were determined in order to maximise the correlation of FPI transmission and trace gas absorption according to the procedures described in Kuhn et al. (2014). Table 2 lists the parameters for the exemplary setups we use in this work.

The results for SO<sub>2</sub>, BrO and NO<sub>2</sub> are summarized in Fig. 2, 3 and 4, which show the differential optical densities of the target trace gas and the potentially interfering trace gases for the respective measurement wavelength ranges (panels a). In the lower panels, the transmitted spectral radiances of the respective FPI spectral channels (on-band, off-band) are plotted. The SO<sub>2</sub> and NO<sub>2</sub> trace gas optical density clearly dominate the total differential optical density for the targeted detection limits. For BrO the other trace gases exhibit differential optical depths on the same order of magnitude as BrO. In the b) panels of the same figures, the respective simulated calibration curves are plotted, where the dashed lines indicate the impact of the individual interfering gases for the assumed amounts. For all three gases these impacts are well below the targeted detection limit. Especially for the case of BrO this illustrates, how FPI Correlation Spectroscopy can effectively separate the absorption structure of a single trace gas from a multitude of trace gas optical densities of the same order of magnitude. By using more than two FPI settings, the selectivity can be enhanced even further.

Table 3 summarises the results of the photon budget calculations. We calculated the maximum possible spatial resolution of the imaging measurement for a 10 s exposure time and the instrument parameters listed in Tab. 2. For this, spatial pixels are co-added until the targeted detection limit was reached. We find that for the targeted detection limits the spatial resolutions of the imaging measurements for the chosen parameters are 226 by 226 pixels for SO<sub>2</sub>, 51 by 51 pixels for BrO and 252 by 252 pixels for NO<sub>2</sub> for a temporal resolution of 10 s. The temporal resolution could be enhanced at the expense of the spatial resolution or vice versa. For instance, cutting the linear spatial resolution in half (e.g. from 226 by 226 to 113 by 113 pixels for SO<sub>2</sub>), would reduce the temporal resolution to 5 s for the same detection limit.

When comparing to corresponding DOAS measurements the enormous increase of spatio-temporal resolution becomes evident. A state of the art DOAS measurement takes around 1 s to reach a detection limit of  $1 \cdot 10^{14}$  molec cm<sup>-2</sup> BrO for one spatial pixel. To scan the ca. 2600 pixels of the assumed BrO image would take 2600 s. An imaging DOAS instrument (e.g. Lohberger et al., 2004) does simplify the scanning process but will not improve the light budget. Our results show that FPI Correlation Spectroscopy can be more than two orders of magnitude faster than a DOAS measurement while maintaining a similar degree of selectivity and interference suppression.

The presented results of the exemplary calculations for SO<sub>2</sub>, BrO and NO<sub>2</sub> suggest that FPI Correlation Spectroscopy can also be implemented for other trace gases with similarly strong and structured absorption, such as e.g. O<sub>3</sub>, HCHO, IO, or OCIO.

#### 4 Proof of concept: Field measurements of volcanic SO<sub>2</sub>

The above model study on trace gas detection with FPI Correlation Spectroscopy was validated in a proof of concept field study for volcanic SO<sub>2</sub>. In a one-pixel prototype a single photodiode was used as detector. A BPF ( $\lambda_{BPF} \approx 310$  nm,  $\delta_{\lambda, BPF} \approx 10$  nm) was used for the preselection of a wavelength range, where the SO<sub>2</sub> differential absorption is strong and approximately

5 periodic. A FPI (air-spaced etalon from *SLS Optics Ltd.*) with a FSR of 2.1 nm and a Finesse of 7 across a clear aperture of 20 mm was tilted by a servo motor in order to tune it to the on-band and off-band transmission settings. The individual plates of the FPI have a finite thickness and two surfaces, the outer surfaces have an anti-reflective coating and are slightly wedged from the inner surfaces of the plates, so their influence can be neglected here. The optical setup behind FPI and BPF consists of a fused silica lens ( $f = 50$  mm), which projects light from a narrow FOV ( $\sim 0.8^\circ$  aperture angle) onto the photodiode.

10 Radiances for the on-band and off-band channel were recorded, delivering an apparent absorbance measurement with 0.42 Hz. A telescope ( $\sim 0.5^\circ$  aperture angle) was co aligned with the one pixel FPI setup and connected to a temperature stabilized spectrometer (spectral resolution  $\sim 0.8$  nm). The recorded spectra ( $\sim 0.13$  Hz) were evaluated with the DOAS algorithm.

The measurement was performed at the *Osservatorio Vulcanologico Pizzi Deneri* ( $37.766^\circ$  N,  $15.017^\circ$  E) at Mt. Etna on Sicily on the 30 July 2017. The device was pointed towards the volcanic plume of Mt. Etna with constant viewing angle ( $8^\circ$  viewing

15 elevation, azimuth  $280^\circ$  N). A plume free part of the sky was used for reference measurements. Fig. 6 shows the time series of the apparent absorbance of the FPI Correlation Spectroscopy prototype together with the SO<sub>2</sub> CD retrieved from the co-recorded spectra. The apparent absorbance shows high correlation with the retrieved SO<sub>2</sub> CD. In Fig. 7 the correlation plot is shown. For high SO<sub>2</sub> CDs the sensitivity of  $\tilde{\tau}_{SO_2}$  decreases slightly due to saturation effects. A simulation for the used instrument configuration (differing only by  $\lambda_{BPF} = 310$  nm from the above simulation) reproduces the recorded calibration

20 curve well. The remaining scatter of the values mainly originates from slight misalignment and the difference of the two narrow FOVs.

The recorded UV spectra also allow for evaluating the O<sub>3</sub> absorption. The lower panel of Fig. 6 shows the change of the differential O<sub>3</sub> CD during the measurement with respect to the reference. The observed increase of the O<sub>3</sub> CD by more than  $4 \cdot 10^{18}$  molec cm<sup>-2</sup> is due to the increasing stratospheric light path with increasing solar zenith angle ( $63.58^\circ$  to  $79.31^\circ$  during

25 the measurement sequence). Within an imaging FOV (of e.g.  $17^\circ$ ) much lower differential O<sub>3</sub> CDs are expected (see Tab. 2), since all pixels are similarly affected by the change in O<sub>3</sub> background. Even with this extreme change in O<sub>3</sub> CD no impact on the recorded SO<sub>2</sub> apparent absorbances is observed.

The one pixel prototype can be implemented in a full frame imaging instrument with e.g. the image space telecentric optical setup, used for the above calculations and shown in Fig. 5. In principle, the single pixel detector (photodiode) is replaced by

30 a two dimensional detector array (UV sensitive for SO<sub>2</sub> and BrO) and an aperture stop is added in the focal plane in front of the lens. This would, however, reduce the light throughput per pixel of the imaging setup compared to the one pixel prototype. Alternatively, the FPI could be placed in front of the lens using the full clear aperture and the full aperture angle of the FPI and the optics (see Kuhn et al., 2014). This leads to a much higher light throughput, however, the incidence angle of the incident light onto the FPI and thereby the FPI transmission spectrum becomes dependent on the pixel (i.e. the viewing direction within

the imaging FOV) and has to be accounted for in the data evaluation.

The data of the field study also indicate the potential of using an additional DOAS measurement for the absolute calibration of the apparent absorbance. The position of the narrow FOV of a DOAS telescope pointing into the wide imaging FOV can be retrieved from time series and used for an in-operation calibration as in the case of the SO<sub>2</sub>-camera (see e.g. Sihler et al., 2017; 5 Lübcke et al., 2013).

## 5 Conclusions

Many locally variable atmospheric processes are difficult to quantify with state of the art UV/Vis remote sensing methods (e.g. DOAS) due to the limited spatio-temporal resolution. This makes it difficult to e.g. quantify the emission of point sources or to separate the effects of transport and chemical conversion on local scales. Kuhn et al. (2014) proposed the FPI Correlation Spectroscopy for SO<sub>2</sub> in the UV wavelength range after similar approaches have been studied in infrared wavelength ranges 10 Spectroscopy for SO<sub>2</sub> in the UV wavelength range after similar approaches have been studied in infrared wavelength ranges (e.g. Wilson et al., 2007; Vargas-Rodríguez and Rutt, 2009). The major motivation is to reduce the number of spectral channels used for the trace gas detection in order to increase the spatio-temporal resolution of the measurement while maintaining its selectivity.

In a model study we investigated the sensitivity and determined the photon budget of FPI Correlation Spectroscopy for three 15 measurement scenarios for SO<sub>2</sub>, BrO and NO<sub>2</sub>. For SO<sub>2</sub> we assumed a scenario with rather low volcanic emissions, which is also representative for industrial stack or ship emissions. For BrO a scenario with stronger volcanic emissions was assumed, with BrO mixing ratios of 10 to 100 ppt within the volcanic plume and high SO<sub>2</sub> CDs. The NO<sub>2</sub> measurement scenario represents typical stack emissions of power plants and gradients of local air pollution induced by e.g. traffic.

For all three investigated gases, cross interferences with other trace gases absorbing in the preselected spectral ranges were 20 found to be very low, meaning that the selectivity of FPI Correlation Spectroscopy can be similar to the selectivity of conventional techniques (e.g. DOAS). In this study, we only used two FPI settings. A larger number of FPI settings could be used to further reduce possible cross interferences.

Using rather conservative assumptions regarding the intensity of the incoming radiation and the size of the instrument optics, we calculated the highest possible spatio-temporal resolution of the FPI Correlation Spectroscopy measurements for the dif- 25 ferent scenarios and found that they can be more than two orders of magnitude higher compared to state of the art DOAS measurements for the same trace gas CD. This means that in the same time period a conventional dispersive technique records a single viewing direction (i.e. a single spatial pixel), almost an entire image can be recorded with the FPI Correlation Spectroscopy. This strongly indicates that future instruments based on FPI Correlation Spectroscopy can provide unprecedented insight into short time or small scale processes in the atmosphere.

30 In the second part, we presented a proof of concept field study for FPI Correlation Spectroscopy applied to volcanic SO<sub>2</sub>, which confirms the model simulations by comparing the measured apparent absorbance to SO<sub>2</sub> CDs retrieved by a co-aligned DOAS measurement. One particularly important finding is that, as expected from the model study, no O<sub>3</sub> cross interference can be observed over a large O<sub>3</sub> CD range.

The extension of the one pixel prototype to a camera can be accomplished comparably easily by minor modifications of the optics and by using a UV sensitive detector array and should be the aim of future studies. By replacing the FPI and the BPF, the instrument is adjusted to measure different trace gases, e.g. BrO and NO<sub>2</sub> according to the model calculations performed in Sect. 3. A co-aligned narrow FOV DOAS measurement can be used for an in-operation calibration of the recorded apparent  
5 absorbance images.

The applications of UV/Vis FPI Correlation Spectroscopy mentioned in this work represent only some examples for and trace gases and phenomena that could be studied. Beyond the volcanological application, FPI imaging can for instance be used to study SO<sub>2</sub> in air pollution or BrO in salt pans (see e.g. Holla et al., 2015). The technique can also be applied to other trace gases with similarly strong and structured absorption, such as e.g. O<sub>3</sub>, HCHO, IO, or OCIO.

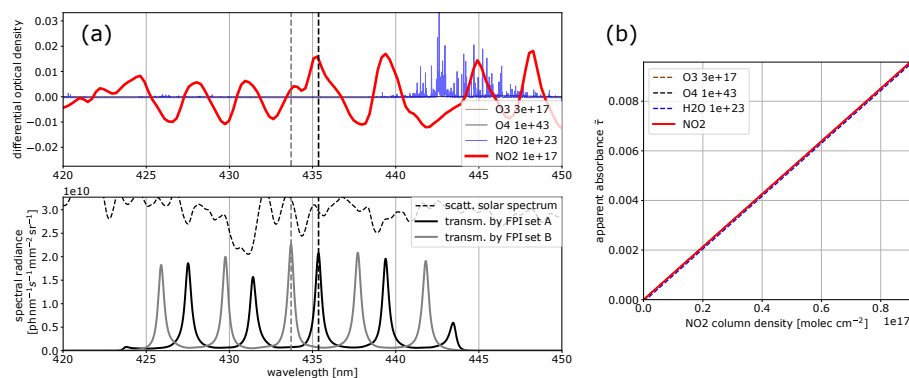

**Figure 1.** (a) FPI schematics indicating the splitting of incident radiation into partial beams that interfere to cause the FPI transmittance spectrum (b), which is characterised by periodic transmission maxima with a FWHM of  $\delta\lambda$  and a FSR of  $\Delta\lambda$ . The BrO absorption cross section (upper panel) shows approximately periodic structures allowing for a high correlation with spectral FPI transmittance.

**Figure 2.** Model results for  $\text{SO}_2$ : (a) the differential optical densities of the assumed differential trace gas CDs are plotted in the upper panel. The lower panel shows the spectral radiance of the sky (dashed line) and the transmitted spectral radiances of the FPI and BPF (drawn lines, on-band in black, off-band in gray). (b) shows the calculated calibration curve for  $\text{SO}_2$  only (drawn line) and with different interfering species included (dashed lines, CDs in  $[\text{molec cm}^{-2}]$  see legend and Tab. 1).

**Figure 3.** Model results for BrO: (a) the differential optical densities of the assumed differential trace gas CDs are plotted in the upper panel. The lower panel shows the spectral radiance of the sky (dashed line) and the transmitted spectral radiances of the FPI and BPF (drawn lines, on-band in black, off-band in gray). (b) shows the calculated calibration curve for BrO only (drawn line) and with different interfering species included (dashed lines, CDs in [molec cm<sup>-2</sup>] see legend and Tab. 1).

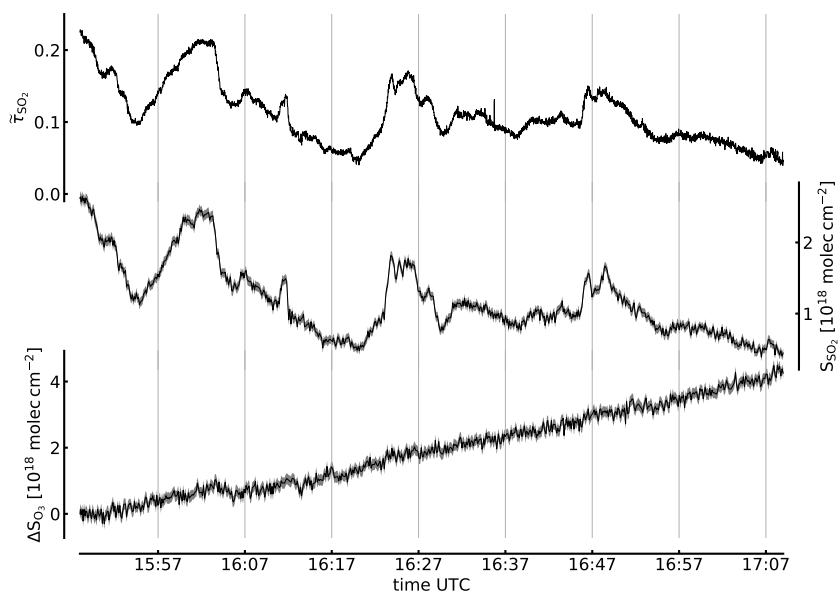

**Figure 4.** Model results for NO<sub>2</sub>: (a) the differential optical densities of the assumed differential trace gas CDs are plotted in the upper panel. The lower panel shows the spectral radiance of the sky (dashed line) and the transmitted spectral radiances of the FPI and BPF (drawn lines, on-band in black, off-band in gray). (b) shows the calculated calibration curve for NO<sub>2</sub> only (drawn line) and with different interfering species included (dashed lines, CDs in [molec cm<sup>-2</sup>] see legend and Tab. 1).

**Figure 5.** Image space telecentric optical setup for parallelising light from the imaging FOV before traversing the FPI and BPF.

**Figure 6.** Time series of the apparent absorbance of the one pixel FPI Correlation Spectroscopy prototype for SO<sub>2</sub> detection (top trace, left scale) recorded at Etna, Sicily on 30 July 2017. A co-aligned telescope was used to simultaneously record spectra for DOAS evaluation of SO<sub>2</sub> and O<sub>3</sub> (center and bottom traces and right and bottom left scales, respectively). The apparent absorbance nicely correlates with the SO<sub>2</sub> CD (see Fig. 7), while no O<sub>3</sub> impact is observable. The growth of the retrieved O<sub>3</sub> differential CD is expected due to the increasing stratospheric O<sub>3</sub> column for increasing solar zenith angle (see text).

**Figure 7.** Correlation plot of the recorded FPI Correlation Spectroscopy apparent absorbance and the  $\text{SO}_2$  CD retrieved by DOAS. A sensitivity of  $\Delta\bar{\sigma}_{\text{SO}_2}$  of  $10^{-19} \text{ cm}^2$  is reached for lower  $\text{SO}_2$  CDs. For higher CDs a flattening of the curve is observed that is induced by saturation effects due to the high  $\text{SO}_2$  optical densities at the absorption peaks. Also the simulation (as in Sect. 3 and Fig. 2 but with  $\lambda_{\text{BPF}} = 10 \text{ nm}$ ) reproduces the measurement very well.

**Table 1.** Differential CDs assumed for the different measurement scenarios. The values represent high values for CD variations within a typ. imaging FOV. The targeted detection limits are indicated in bold face.

differential CD across imaging FOV [ $\text{molec cm}^{-2}$ ]			
	SO <sub>2</sub> : volcanic emission (low) 300 - 315nm	BrO: volcanic emission (high) 330 - 355nm	NO <sub>2</sub> : stack emission 424 - 445nm
SO <sub>2</sub>	<b>1e17</b> (volcanic)	3e18 (volcanic)	-
BrO	1e14 (volcanic)	<b>1e14</b> (volcanic)	-
NO <sub>2</sub>	1e16 (bgr. pollution)	1e16 (bgr. pollution)	<b>1e16</b> (stack plume)
O <sub>3</sub>	3e17 (SZA change strat.)	3e17 (SZA change strat.)	3e17 (SZA change strat.)
