10 **Abstract**

11 Carbon dioxide and oxygen are tightly coupled in land-biospheres CO₂ - O₂ exchange
12 processes, while they are not coupled in oceanic exchange. For this reason, atmospheric
13 oxygen measurements can be used to constrain the global carbon cycle, especially oceanic
14 uptake. However, accurately quantifying the small (~1-100 ppm) variations in O₂ is
15 analytically challenging due to the very large atmospheric background which constitutes
16 about 20.9 % (~209500 ppm) of atmospheric air. Here we present detailed description of the
17 analyzer and its operating principles as well as comprehensive laboratory and field studies for
18 a newly developed high-precision oxygen mixing ratio and isotopic composition analyzer
19 (Picarro G-2207) that is based on cavity ring-down spectroscopy (CRDS). From the
20 laboratory tests, we have calculated a short-term precision (standard error of one-minute O₂
21 mixing ratio measurements) of < 1 ppm for this analyzer based on measurements of eight
22 standard gases analyzed for two hours consecutively. In contrast to the currently existing
23 techniques, the instrument has an excellent long-term stability and therefore a calibration
24 every 12 hours is sufficient to get an overall uncertainty of < 5 ppm. Measurements of

25 ambient air were also conducted at the High-Altitude Research Station, Jungfrauoch and the
26 Beromünster tall tower in Switzerland. At both sites, we observed opposing and diurnally
27 varying CO₂ and O₂ profiles due to different processes such as combustion, photosynthesis
28 and respiration. Based on the combined measurements at Beromünster tower, we determined
29 height dependent O₂:CO₂ oxidation ratios varying between -0.98 to -1.60 , which increase
30 with the height of the tower inlet, possibly due to different source contribution such as natural
31 gas combustion with high oxidation ratio and biological processes which are at the lower end.

32 **1. Introduction**

33 Atmospheric oxygen comprises about 20.9 % of the global atmosphere and in the past
34 decade its concentration decreased at a rate of ~ 20 per meg yr⁻¹ (Keeling and Manning, 2014)
35 mainly associated with the increase in fossil fuel combustion. Note that the variations in
36 atmospheric O₂ is expressed in units of per meg due to its small variations with respect to a
37 large background and to account for dilution effects from CO₂ or any other gas of relevant
38 amount change which is expressed as:

39

$$40 \quad \delta \left(\frac{O_2}{N_2} \right) (per\ meg) = \left(\frac{\left(\frac{O_2}{N_2} \right)_{sample}}{\left(\frac{O_2}{N_2} \right)_{reference}} - 1 \right) \cdot 10^6 \quad (1)$$

41 In contrast, the global average atmospheric CO₂ mixing ratio increased to 405.0 ppm
42 averaged over 2017 since its preindustrial value of 280 ppm (Le Quéré et al., 2017). As the
43 variability of atmospheric oxygen is directly linked to the carbon cycle, both its short and
44 long-term observations can be used to better constrain the carbon cycle. For example, since
45 first suggested by Keeling and Shertz (1992) the long-term trends derived from concurrent
46 measurements of atmospheric CO₂ and O₂ have been widely used to quantify the partitioning
47 of atmospheric CO₂ between the land-biosphere and oceanic sinks (Battle et al., 2000; Goto et

48 al., 2017; Manning and Keeling, 2006; Valentino et al., 2008). This method hinges on the
49 linear coupling between CO₂ and O₂ with an oxidation ratio (OR defined as the stoichiometric
50 ratio of exchange during various process such as photosynthesis and respiration) of 1.1 for the
51 terrestrial biosphere photosynthesis-respiration processes (α_b) and 1.4 for fossil fuel
52 combustion (α_f) while they are decoupled for oceanic processes. Meanwhile, the short-term
53 variability in atmospheric oxygen can be used to estimate marine biological productivity and
54 air-sea gas exchange (Keeling et al., 1998; Nevison et al., 2012). However, the accuracy of
55 these estimates is primarily linked to the accuracy and precision of atmospheric O₂
56 measurements and the assumed ORs for the different processes which are highly variable in
57 contrast to atmospheric CO₂ that can be well measured within the precision guidelines set by
58 the Global Atmospheric Watch (GAW) (± 0.1 ppm for the northern hemisphere).

59 Currently there are several techniques mostly custom built that can measure
60 atmospheric O₂ variations as oxygen concentration based on interferometric, paramagnetic,
61 UV absorption and fuel cell technology (Keeling, 1988a; Manning et al., 1999; Stephens et
62 al., 2007) or as O₂/N₂ ratios to account for the large background effect using gas
63 chromatography with thermal conductivity detector (GC-TCD) or gas chromatography
64 coupled to mass spectrometry (GC-MS) (Bender et al., 1994; Tohjima, 2000). Despite the fact
65 that these techniques have been used for more than two decades, accurate quantification of
66 atmospheric oxygen variability remains challenging primarily because the small ppm-level
67 atmospheric oxygen signal rides on a $\sim 210,000$ ppm background, which places stringent
68 requirements on the precision and drift of the analysis methods especially for continuous
69 monitoring (Note that the GAW recommendation for the measurement precision of O₂/N₂ is 2
70 per meg). The techniques listed above struggle to routinely achieve the necessary performance
71 for various reasons, including i) instability over time that requires frequent measurement

72 interruption for calibration, ii) measurement bias with ambient and sample temperature and/or
73 pressure, and/or iii) systematic errors in the measurement due to other atmospheric species.
74 Further, some techniques require the use of consumables and rely on high vacuum, which
75 complicates field deployment.

76 In this manuscript we describe a new high precision oxygen concentration and isotopic
77 composition analyzer by Picarro Inc., Santa Clara, USA (G-2207) based on CRDS
78 technology. Here, we will introduce the analyzer design principles in details, describe the
79 unique features of the analyzer and evaluate its performance based on various independent
80 laboratory and field tests by comparing it with currently existing techniques. Then, we will
81 present and interpret our observations based on field measurements. Finally, we will conclude
82 its overall performance and provide recommendations and possible improvements.

83 **2. Analyzer design principles**

84 The analyzer described here is derived from the Picarro G2000 series of CRDS
85 analyzers. The basic elements have been described elsewhere (Crosson, 2008; Martin et al.,
86 2016; Steig et al., 2014): briefly, the instrument is built around a high-finesse, traveling-wave
87 optical cavity, which is coupled to either of two single-frequency Distributed Feedback-
88 stabilized semiconductor lasers. One cavity mirror is mounted on a piezoelectric translator
89 (PZT) to allow fine tuning of the cavity resonance frequencies. A semiconductor optical
90 amplifier between the laser sources and the cavity boosts the laser power and serves as a fast-
91 optical switch. The cavity body is constructed of invar and enclosed in a temperature
92 stabilized box ($T = 45^\circ \text{C}$, stabilized to approximately 0.01°C) for dimensional and
93 spectroscopic stability. A vacuum pump pulls the gas to be sampled through the cavity and a
94 proportional valve between the cavity and the pump maintains the sample pressure in the
95 cavity at a value of 340 hPa, with variations on the order of 1 Pa. The instrument has a

96 wavelength monitor, based upon measurements of interference fringes from a solid etalon,
97 which is used to control the laser wavelength by adjusting the laser temperature and current.
98 A high-speed photodiode monitors the optical power emerging from the cavity. The
99 instrument's data acquisition system sweeps the laser frequency over the spectral feature to be
100 measured, modulates the laser output to initiate ring-downs, and fits the ring-down signal to
101 an exponential function to generate a spectrogram of optical loss versus laser frequency. For
102 this instrument the empty cavity ring-down time constant is about 39 μs . Subsequent program
103 modules compare the measured loss spectrum to a spectral model, using non-linear least-
104 squares fitting (Press et al., 1986) to find the best-fit model parameters and thereby obtain a
105 quantitative measure of the absorption due to the target molecule, and finally apply a
106 calibration factor to the optical absorption to deduce the molecular concentration. When
107 operating in its normal gas analysis mode, the instrument acquires about 200-300 ring-downs
108 per second and achieves a noise equivalent absorption of typically about $10^{-11} \text{ cm}^{-1} \text{ Hz}^{-1/2}$,
109 with some variation between instruments.

110 The primary goal when designing this analyzer was to measure the molecular oxygen
111 concentration with few-per-meg level precision and stability. In this context operational
112 stability is as important as signal-to-noise. Our experience has been that the most stable
113 operation of the analyzer is achieved when the optical phase length of the cavity is held as
114 nearly constant as possible. In this case the free spectral range (FSR, 0.0206 cm^{-1}) of the
115 temperature stabilized, invar ring-down cavity provides a better optical frequency standard
116 than the etalon-based wavelength monitor, which in turn allows more consistent
117 measurements of absorption line width and integrated absorption line intensity (Steig et al.,
118 2014). For a small, field-deployable instrument, it is not practical to stabilize the absolute
119 frequencies of the cavity modes to an optical frequency standard (Hodges et al., 2004) but the

120 oxygen lines themselves, under conditions of constant temperature and pressure, provide an
121 adequate frequency reference. The oxygen spectrum was also used to calibrate the FSR, by
122 comparing a wide (approximately 10 cm^{-1}) FSR-spaced spectrum with the Hitran database
123 (Rothman et al., 2013).

124 To determine molecular oxygen concentration, the analyzer measures absorption of the
125 Q13Q13 component of the $a^1\Delta_g \leftarrow X^3\Sigma_g^-$ band, at a frequency of $7878.805547\text{ cm}^{-1}$,
126 according to the latest edition of Hitran (Gordon et al., 2017). This is one of the strongest
127 near-infrared lines of oxygen, well separated from other oxygen lines, and reasonably free of
128 spectral interference from water, carbon dioxide, methane, and other constituents of clean air.
129 The spectral model for this line was developed using reference spectra of clean, dry, synthetic
130 air that were acquired with the same hardware as in the field-deployable analyzer, but with
131 special-purpose software that allows it to operate as a more general spectrometer.

132 Recently, considerable work has been done to advance the understanding of spectral
133 line shapes and to define functional representations that better describe the processes that
134 determine spectral line shapes than does the Voigt model (Hartmann et al., 2008; Tennyson et
135 al., 2014, Tran et al., 2019). Line shape studies have been published for the $1.27\text{ }\mu\text{m}$ band of
136 O_2 (Fleisher et al., 2015; Lamouroux et al., 2014), though not to our knowledge for the Q
137 branch. The apparatus used here is not capable of spectroscopic studies of comparable
138 precision; the absolute temperature and pressure monitoring and especially the frequency
139 metrology are far too crude for that purpose. Our goal is merely to define a simple model of
140 the Q13Q13 line that is adequate for least-squares retrievals of the O_2 absorption under the
141 limited range of conditions (stabilized temperature and pressure) that the operational analyzer
142 experiences in the field. The CRDS analyzers use the Galatry function (Varghese and Hanson,
143 1984), which is distinctly better than the Voigt and still easily and quickly evaluated for line

144 shape modeling. Ultimately, the usefulness of the spectral model is to be evaluated by the
 145 precision and stability of the O₂ measurements when compared with established techniques.
 146 Ultimately, the usefulness of the spectral model is to be evaluated by the precision and stability of
 147 the O₂ measurements when compared with established techniques. For spectral model
 148 development, this spectrometer has the drawback that the cavity FSR, is too large to reveal
 149 much detail of the absorption line shape, even with the simplifying assumption of a Galatry
 150 line shape. We therefore acquired a set of four interleaved spectra, with the PZT-actuated
 151 mirror moved to offset the cavity modes of the individual FSR-spaced spectra by one-fourth
 152 of an FSR. The precise offsets were determined from fits to the strong and well-isolated O₂
 153 lines in the spectra. From the consistency of the fitted line centers, we estimate that the
 154 positioning of the interleaved spectra was accurate to approximately 10 MHz. The spectrum
 155 of the Q13Q13 line acquired in this manner is shown in Figure 1, together with the best-fit
 156 Galatry function. It stands out that the residuals are largely odd in detuning from the line
 157 center: this shows the limitations of the Galatry model in this case, since the Galatry function
 158 is purely even about the line center. The shape of the absorption line in this model is specified
 159 by two dimensionless parameters: the collisional broadening parameter

$$160 \quad y = \gamma / \sigma_D \quad (2)$$

161 and the collisional narrowing parameter

$$162 \quad z = \beta / \sigma_D \quad (3)$$

163 where γ is the frequency of broadening transitions, β is the velocity change collision rate, and
 164 σ_D is the 1/e Doppler half-width of the transition, given by

$$165 \quad \sigma_D = \nu_0 (2k_B T / M c^2)^{1/2} \quad (4)$$

166 where ν_0 is the transition frequency, k_B is Boltzmann's constant (J. K⁻¹), T is the sample
 167 temperature (K), M is the molecular mass (amu), and c is the speed of light (m/s). Figure 2

168 shows the values of y and z obtained from spectra acquired in the same way as Figure 1, as a
169 function of cavity pressure. The values depend linearly on pressure, as expected from the
170 Galatry model, but the unconstrained linear fits do not go precisely through the origin. It is
171 not clear whether this represents a breakdown of the Galatry model or simply reflects the
172 limited quality of the data set. The slope of y can be converted to an air-broadened collisional
173 width $\gamma_{\text{air}} = 0.0442 \text{ cm}^{-1}/\text{atm}$, which agrees with the Hitran value of $0.0460 \text{ cm}^{-1}/\text{atm}$ (Gordon
174 et al., 2016) to within the uncertainty estimate stated by Hitran (uncertainty code 4 for γ_{air}
175 corresponding to 10% --20% relative uncertainty). The slope of z can be interpreted in terms of
176 the optical diffusion coefficient (Fleisher et al., 2015), yielding $D = 0.285 \text{ cm}^2 \text{ s}^{-1}$, compared
177 to the literature value of $0.233 \text{ cm}^2 \text{ s}^{-1}$ for O_2 in air at $45 \text{ }^\circ\text{C}$ (Marrero and Mason, 1972).
178 Although the anticipated use of the analyzer is for ambient air samples having a very small
179 range of O_2 concentrations, we did investigate the variation of the line shape in binary
180 mixtures of O_2 and N_2 shown in Figure 3. The error bars are taken from the output of the
181 Levenberg-Marquardt fitting routine (Press et al., 1992). The dependence of the collisional
182 broadening parameter z on O_2 mole fraction was considered too small to be significant, but
183 the variation in y was used in the subsequent analysis of the air samples. Note that Wójtcwicz
184 et al. (Wójtcwicz et al., 2014) also found collisional broadening coefficients for nitrogen to be
185 slightly larger than for oxygen in measurements of one O_2 line in the B-band.

186 The primary goal in designing the analyzer was to achieve high enough precision to
187 make meaningful measurements of O_2 in clean atmospheric samples. Although the current
188 best practice for such high-precision measurements is to work with dried samples, we decided
189 to include high precision measurements of water vapor. There were two reasons for this
190 decision: one is to serve as a monitor for residual water vapor, which is difficult to remove

191 completely from the ring-down cavity and associated sample handling hardware, and the
192 second and more ambitious reason was to see how well the effect of water vapor could be
193 corrected for measurements of undried ambient air. While it was considered unlikely that
194 measurements of undried air could compete in accuracy with those of dried air, it might be
195 possible to correct for water vapor well enough to enable useful measurements in some
196 circumstances without the expense and inconvenience of drying the sample. For this purpose,
197 a second laser was added, which probes the $7_{1,6} \rightarrow 8_{4,5}$ component of the $2\nu_3$ band of water
198 vapor, at a frequency of $7816.75210 \text{ cm}^{-1}$ (Gordon et al., 2017). The Galatry model was used
199 to fit spectra of synthetic air humidified to various levels of water vapor concentration. These
200 fits also included two other nearby, very weak water lines, with intensities less than 1% of the
201 strong transition, in order that their absorption should not perturb the line shape of the main
202 transition. Results for the shape of the $7816.75210 \text{ cm}^{-1}$ line are shown in Figure 4. At the
203 level that we can measure, only the y -parameter has a meaningful variation with water
204 concentration. From the linear fit one obtains a pressure broadening coefficient for air, $\gamma_{\text{air}} =$
205 $0.0752 \text{ cm}^{-1}/\text{atm}$, in reasonable agreement with the Hitran value $\gamma_{\text{air}} = 0.0787 \text{ cm}^{-1}/\text{atm}$
206 (Gordon et al., 2017), and a self-broadening coefficient $\gamma_{\text{self}} = 0.413 \text{ cm}^{-1}/\text{atm}$, to be compared
207 with the Hitran value $\gamma_{\text{self}} = 0.366 \text{ cm}^{-1}/\text{atm}$. Since the uncertainty estimate for the Hitran
208 values is 10 % to 20 %, this level of agreement seems reasonable.

209 We also looked at absorption from water near the Q13Q13 absorption line of O_2 .
210 These spectra were measured in a background of pure nitrogen to reveal the very weak lines
211 interfering with the O_2 measurement. Without the strong O_2 lines, it was impossible to
212 interleave FSR-spaced spectra, so in this case the frequency axis comes from the analyzer's
213 wavelength monitor. The upper panel of Figure 5 shows the spectrum of saturated water vapor
214 in nitrogen, together with a fit to a Voigt model of the molecular lines. The measurement was

215 made at a pressure of 340 hPa and temperature of 45° C. The main features are the Q13Q13 line
216 from trace contamination of oxygen in the sample and several lines that arise from normal water
217 ($^1\text{H}_2^{16}\text{O}$, AFGL abbreviation 161) and deuterated water ($^1\text{H}^2\text{H}^{16}\text{O}$, AFGL abbreviation 162, also
218 abbreviated HDO). The lower panel of Figure 5 shows the lines tabulated in Hitran.
219 Immediately after the data in Figure 5 were acquired, measurements were also made at
220 $7816.85210\text{ cm}^{-1}$, to establish the relationship between the absorption strengths in the two
221 spectral regions. The relative intensities of the 161 and 162 lines change with variations in the
222 isotopic composition of the water, but fortunately the direct interference with the oxygen Q13Q13
223 lines comes entirely from the 161 isotopologue, with the strongest 162 line being separated by
224 approximately 8 line widths (FWHM) from the Q13Q13 line. Hitran simulations for molecules
225 other than water that are expected to be present in clean, ambient air indicate that direct
226 interference with the Q13Q13 line should be negligible at the level of precision considered
227 here. In the case of CO_2 , the dilution of oxygen due to 400 ppm of CO_2 is significant, and
228 larger than any direct spectral interference.

229 Finally, we investigated the influence of water vapor on the shape of the O_2 Q13Q13
230 line. Switching between the two lasers sources, we acquired FSR-spaced spectra of
231 humidified synthetic air, alternately covering the 7817 cm^{-1} and 7878 cm^{-1} regions. Individual
232 spectra were acquired in less than 2 s, so changes in water vapor concentration between
233 spectra were small. These spectra, with frequency resolution of 0.0206 cm^{-1} , were analyzed by
234 nonlinear least-squares fitting with the following spectral models: the 7817 cm^{-1} spectra were
235 modeled as the sum of an empty-cavity baseline having an adjustable offset level and slope
236 and three water peaks and the two weak perturbing peaks. The molecular absorption of the
237 main peak was expressed as an adjustable amplitude, A_w , multiplying a dimensionless, area-
238 normalized Galatry function (Varghese and Hanson, 1984). The weak perturbers were

239 modeled by Voigt profiles with amplitudes and line widths that constrained to be in fixed
240 ratios to the strong line, and therefore added no new degrees of freedom to the fitting
241 procedure. Since the amplitude A_w multiplies an area-normalized shape function, it is
242 essentially equivalent to the area of the absorption line, to the extent that the Galatry model
243 provides a valid description of the line shape. The Doppler width of the Galatry function was
244 fixed based on the measured cell temperature, the y-parameter was allowed to vary, and the z-
245 parameter was constrained to be proportional to y, based on measurements summarized in
246 Figure 2. In addition, the center frequency of the Galatry function was adjusted to match the
247 data set, giving a total of five free parameters for this fit. The 7878 cm^{-1} spectra were modeled
248 with an adjustable baseline offset and slope and molecular absorption amplitude, A_{O_2} ,
249 describing the Q13Q13 O_2 line. Here, too, the y-parameter and centration of the O_2 lines were
250 allowed to adjust, and the z-parameter was constrained to be proportional to y. The weak
251 water lines interfering with oxygen absorption were included in the model, but with no
252 additional free parameters, rather the amplitudes were preset based on the measured water
253 absorption at 7817 cm^{-1} and the previously determined amplitude relationships between the
254 water lines. This procedure does not account for variations in HDO abundance, which may introduce
255 some systematic error into the water vapor correction for samples of unusual isotopic composition,
256 but it should accurately model the most important lines that interfere with the oxygen
257 measurement. Collisional broadening of the Q13Q13 O_2 line by water vapor is shown in
258 Figure 6. From the linear fit one obtains a coefficient for collisional broadening of the
259 Q13Q13 line by water vapor of $\gamma_{\text{water}} = 0.0442\text{ cm}^{-1}/\text{atm}$. We are not aware of previous
260 measurements of this quantity.

261 The alternating measurements at 7817 cm^{-1} and 7878 cm^{-1} also calibrated the
262 relationship between water mole fraction and the absorption at 7817 cm^{-1} , using a dilution

263 analysis described by Filges et al. (Filges et al., 2018), who showed that the results obtained
264 this way agree well with water vapor fractions measured with a conventional hygrometer.
265 Figure 7 shows the measured amplitudes of the water and oxygen lines for samples of variable
266 humidity. Since the air came from a tank of constant composition, the oxygen concentration
267 changes due to dilution of oxygen when water is added. Assuming that this is the sole cause
268 of the change in measured absorption, since the line shapes were being constantly adjusted to
269 account for changes in collisional broadening, it is straightforward to deduce the relation
270 between the water fraction and the absorption amplitude. This calibration was used to
271 generate the water fraction axes in Figures 4 and 6. We note that we did not take particular
272 care to control or measure the quantity of dissolved gases, especially oxygen and carbon
273 dioxide, in the water used for this experiment. While these gases would not significantly
274 affect the water calibration, they may affect the water vapor correction of the oxygen
275 measurement at the ppm level. More work needs to be done to investigate the water vapor
276 correction of the oxygen measurement.

277 The observations described above were used to design a method to measure oxygen
278 concentration in ambient air. Gas from the inlet to the analyzer is drawn through the cavity at
279 a rate of about 100 sccm (standard cubic centimeter per minute) and the conditions in the
280 cavity are held stable at 340 hPa and 45° C. In its analysis mode the analyzer alternately
281 measures ring-downs in the 7817 cm^{-1} and 7878 cm^{-1} regions. At 7878 cm^{-1} measurements are
282 made at 11 different frequencies, spaced by one FSR of the cavity and centered at the peak of
283 the Q13Q13 line. Multiple ring-down measurements are made to improve the precision of the
284 loss determination, with a total of 305 ring-downs allocated to one spectrum. In the 7817 cm^{-1}
285 region measurements are also made at 11 distinct frequencies at FSR spacings. Only 35 ring-
286 downs are allocated to this spectral region, since the measurement of O_2 is much more

287 important than water vapor. The data sets are analysed using a Levenberg-Marquardt fitting
288 routine, which adjusts five free parameters in each region to find the best agreement to a
289 spectral model based on Galatry line shapes, as described above. One of the outputs of the
290 7878 cm^{-1} fit is the frequency offset of the FSR grid from the center of the Q13Q13 line. This
291 information is used to adjust the position of the PZT actuated mirror to keep the
292 measurements centered on the line, effectively stabilizing the optical path length of the cavity
293 to the frequency of the O_2 line. The reported water fraction is obtained by multiplying the
294 fitted amplitude of the water line by a calibration constant derived from the dilution
295 experiment as explained above. For the O_2 fraction a slightly more complicated procedure is
296 followed. It was observed that the least-squares fitting of the data gives highly correlated
297 results for the amplitude of the absorption line and the line width parameter γ . The correlation
298 may be due in part to the fitting procedure itself (Press et al., 1992) and it may also have a
299 contribution from pressure variations that the pressure sensor is unable to detect. The ratio
300 A_{O_2}/γ can be determined from the fit much more precisely than A_{O_2} alone and so gives a more
301 sensitive measurement of molecular absorption. It also has the advantage of being
302 independent of sample pressure, to the extent that the Galatry model applies (Figure 2).
303 However, using the ratio A_{O_2}/γ as a metric for absorption adds more complications if
304 measurements are to be made over a range of O_2 and water concentrations, because the O_2/N_2
305 ratio and water concentration affect the line width independently of pressure and O_2
306 concentration alone. To minimize systematic errors due to these broadening effects, we define
307 a nominal γ -parameter based on the measured amplitudes of the O_2 and water lines and the
308 line broadening dependences shown in Figures 3 and 4. The measured ratio A_{O_2}/γ is
309 normalized by the nominal γ to obtain a quantity that is ideally independent of pressure and
310 water concentration, and this is the quantity that is multiplied by a calibration constant to give

311 the reported O₂ fraction. In addition, a dry mole fraction is reported for O₂, defined as the
312 directly measured mole fraction corrected for water dilution.

313 The main goal in developing this instrument was to make high precision
314 measurements of O₂ mole fraction, based on absorption by the dominant ¹⁶O₂ isotopologue.
315 The absorption lines of the rarer isotopologues are also present nearby, so a mode of operation
316 was included in which one laser is scanned over neighboring lines of ¹⁶O₂ and ¹⁶O¹⁸O and the
317 ratio of amplitudes is used to derive an isotopic ratio, reported in the usual delta notation. In
318 this case the operating pressure was reduced to 160 hPa to improve the resolution of the
319 nearby lines. The lines measured were the Q3Q3 line of ¹⁶O₂, at 7882.18670 cm⁻¹, and the
320 Q9Q9 line of ¹⁶O¹⁸O, at 7882.050155 cm⁻¹. The measurement procedure is very much like
321 that for the O₂ fraction measurement, so it will not be described in detail, only the main
322 differences will be noted. One is that in determining an isotopic ratio there is no advantage to
323 be obtained from normalizing absorption amplitudes to line widths, instead we simply take
324 the ratio of amplitudes to compute delta. Although the Q9Q9 line and its neighbor Q8Q8 are
325 the strongest ones in this band, absorption by ¹⁶O¹⁸O is still very weak, only about 5x10⁻⁹ cm⁻¹
326 at the line center under the conditions we used. Consequently, the signal-to-noise that can be
327 achieved with this analyzer is not adequate to determine both the amplitude and the width of
328 the ¹⁶O¹⁸O line with useful precision, so in the fitting step the y-parameter of the ¹⁶O¹⁸O line
329 is constrained to be a constant factor times the fitted y-parameter for the ¹⁶O₂ line.
330 Additionally, because of the weakness of the rare isotopologue absorption, the majority of
331 ring-downs in each spectrum is devoted to measuring ¹⁶O¹⁸O i.e. 232 ring-downs in each
332 spectrum versus only 40 for ¹⁶O₂. This implies that the mole fraction measurement in the
333 isotopic mode is much less precise than when the analyzer measures the Q13Q13 line alone.

334 **3. Results and Discussions**

335 **3.1. Laboratory tests at Picarro, Santa Clara**

336 3.1.1. Temperature and pressure sensitivity

337 One set of tests was done to determine how well the goal was met of minimizing the
338 susceptibility of the concentration measurements to uncontrolled noise or drift of the sample
339 temperature and pressure. For these tests the analyzer sampled dry synthetic air from a tank
340 and the temperature and pressure setpoints of the cavity were adjusted upward and downward
341 from the nominal values, to obtain an estimate of the differential response. We express the
342 sensitivity to experimental conditions in relative form, that is the derivative with respect to
343 temperature or pressure divided by the signal under nominal conditions.

344 From these experiments, we determined a temperature sensitivity of $-2.1 \times 10^{-4} \text{ K}^{-1}$ and
345 a pressure sensitivity of $+9.8 \times 10^{-6} \text{ hPa}^{-1}$. The temperature sensitivity is somewhat larger than
346 expected based on a calculation using Hitran data to estimate the temperature dependences of
347 all the quantities that go into the measured absorption of the Q13Q13 line. The pressure
348 sensitivity is strikingly small, indicating a good cancelation of the pressure dependence of
349 absorption amplitude and line width. Both temperature and pressure sensitivities are small
350 enough to have a negligible effect on short-term precision of measurements made with the
351 stabilized ring-down cavity, though long-term drifts in the sensors are always a matter of
352 concern.

353 3.1.2. Measurement precision and Drift

354 Measurement precision was evaluated by analyzing synthetic air containing nominal
355 atmospheric concentrations of CO_2 and CH_4 from an aluminum Luxfer cylinder over a period
356 of several days. The tank, oriented horizontally and thermally insulated (though not
357 controlled), was connected directly to the instrument (S/N TADS2001) with a 2-stage
358 regulator and stainless-steel tubing and reducing the flow with an additional orifice to about

359 55 sccm. For the isotopic mode of operation, the precision of the measurement was also tested
360 by making repeated measurements from a tank of clean, dry synthetic air.

361 Figure 8 shows the time series of the precision test data, displaying the reported
362 oxygen concentration, the height of the oxygen absorption peak, the width of the oxygen
363 absorption peak and the ambient temperature. The residual error of the analyzer, although
364 small, is nevertheless significant given the stringent targets set forth by the WMO-GAW
365 program. Possible sources of error include: temperature drifts due to sensor drift or gradients;
366 pressure errors due to sensor drift; optical artifacts such as parasitic reflections, higher order
367 cavity mode excitation, and/or loss nonlinearity that can distort the reported oxygen spectrum.
368 More work is required to identify and eliminate these small drifts.

369 The Allan standard deviation of the reported O₂ fraction is shown in Figure 9. The
370 ordinate on this plot is the square root of the Allan variance of reported mole fraction, so 1
371 ppm in these units corresponds to about 5 per meg in the ratio of O₂/ N₂. The precision of
372 averaged measurements improves as $\tau^{-1/2}$ for approximately 5000 s and reaches 1 ppm in less
373 than 10 minutes and remains below 1 ppm for time scales on the order of about 1 hour.

374 Figure 10 shows the precision of $\delta(^{18}\text{O})$ (uncalibrated) derived from the ratio of lines
375 measured at 7882 cm⁻¹. Because of the weak signal from the ¹⁶O¹⁸O line, it is necessary to
376 average for more than 20 seconds or more to achieve 1‰ precision on the isotopic ratio. As
377 for the concentration measurement, averaging improves the measurement precision for times
378 scale up to about 1 hour.

379 **3.2. Laboratory measurements at the University of Bern**

380 3.2.1. Measurements of standard gases

381 The performance of the instrument was tested by analyzing eight standard gases with
382 precisely known CO₂ and O₂ compositions (Table 1) using the CRDS analyzer and comparing

383 it to parallel measurements with a paramagnetic oxygen sensor (PM1155 oxygen transducer,
384 Servomex Ltd, UK) embedded to a commercially available Oxzilla fuel cell oxygen analyzer
385 (OXZILLA II, Sable Systems International, USA) (Sturm et al., 2006) as well as with an
386 isotope ratio mass spectrometer (IRMS, Finnigan Delta^{Plus}XP). The design of the
387 measurement set-up is shown in Figure 11. Standard gases were directly connected to the
388 pressure controlling unit, and a multi-port valve (V2) was used to select among the standard
389 gases. The flow from each cylinder was adjusted to about 120 ml min⁻¹ which was eventually
390 directed to a selection valve (V1), allowing switching between ambient air and standard gases.
391 Flow towards and out of the Oxzilla was controlled by the pressure controlling unit. The O₂
392 mixing ratio of this incoming gas was first measured on the Paramagnetic O₂ sensor and then
393 directed towards a non-dispersive infrared analyzer (NDIR) (Li-7000, LICOR, USA) for
394 measuring CO₂ and H₂O. The outflow from this analyzer (100 ml min⁻¹) returns to the
395 pressure controlling unit and was eventually divided between the CRDS analyzer (which uses
396 about 75-80 ml min⁻¹) and the IRMS (~ 20 ml min⁻¹) via a Tee-junction. Each cylinder was
397 measured for two hours in each system controlled by a Lab VIEW program.

398 In priori, we investigated the influence of this Tee-junction, which splits the gas flow
399 between the CRDS and the IRMS, on the measured O₂ values. Manning (2001) showed that
400 the fractionation of O₂ in the presence of a Tee-Junction is strongly dependent on the splitting
401 ratios as well as temperature and pressure gradients. Hence, we measured and compared the
402 O₂ mixing ratios of two standard gases (CA07045 and CA060943) in two cases: i) in the
403 presence of a Tee-junction with different CRDS to IRMS splitting ratios and ii) without a
404 Tee-junction so that all gas flow is directed towards the CRDS analyzer. The splitting ratios in
405 these test experiments vary from 1:1 to 1:100, and reversed to change the major flow direction
406 either to the CRDS or the IRMS. Note that the experimental condition in this manuscript is

407 with a 4:1 splitting ratio (i.e. $\sim 80 \text{ ml min}^{-1}$ towards the CRDS analyzer and $\sim 20 \text{ ml min}^{-1}$
408 towards the IRMS).

409 In the cases of the smaller splitting ratios (1:1, 1:4 and 4:1), which are relevant for the
410 results presented in this study, only minor differences in the measured O_2 mixing ratios were
411 observed when compared to case ii (i.e. without a Tee-junction). For these two cylinders
412 measured, the average differences in these cases were about 0.5 ppm, calculated as the mean
413 of the differences in the raw O_2 measurements of the last 60 seconds. The negligible
414 fractionation can indeed be the result of smaller splitting ratios while strong influence is
415 usually expected in case of larger splitting ratios (Stephens et al., 2007). For higher splitting
416 ratios, the result seems inconclusive without any dependence on the ratios due to the strong
417 decline in the cylinder temperature (specifically at the pressure gauge) caused by higher flow
418 to achieve the higher splitting ratios (as high as 1:100). Hence, these tests need to be
419 conducted in a temperature controlled condition and the results could not be discussed in this
420 manuscript.

421 Figure 12 shows the standard gas measurements for the seven cylinders with known
422 CO_2 and O_2 mixing ratios (Table 1) using both the CRDS and the Paramagnetic analyzers.
423 Standard eight, which has too high O_2 , is not shown in the figure as the figure is zoomed-in to
424 better illustrate the change in O_2 for the remaining cylinders. While the first five cylinders
425 contain O_2 and CO_2 fractions comparable to ambient air values, standards 6 & 8 had either
426 very low and very high O_2 , respectively. In addition, standard 6 and 7 have very low and very
427 high CO_2 mixing ratios. Note that due to its very high CO_2 content ($\sim 2700 \text{ ppm}$), standard 7
428 was not measured on the IRMS and hence the O_2 mixing ratios are unknown. The measured
429 mixing ratios for the six standard gases between the two systems are in very good agreement
430 while cylinder 7 showed an opposing signal for the two analyzers compared to standard 6

431 (Figure 12). While the Paramagnetic analyzer showed a higher O₂ mixing ratio, the values
432 from the CRDS analyzer are lower in O₂. This can be associated with the very high CO₂
433 mixing ratio in standard 7, which leads to a strong dilution effect in the CRDS analyzer as it
434 does not include any correction function for dilution effect from CO₂. However, such high
435 CO₂ mixing ratios may not be that important for most atmospheric research. Yet, it should be
436 considered to include a parallel CO₂ mixing ratios measurement to the instrument as it will
437 further improve the accuracy. This would be especially important for biological or
438 physiological studies where a wide range of CO₂ and O₂ concentrations must be expected.

439 The measurement precision of the CRDS analyzer was calculated as the standard error
440 of the mean i.e. the standard deviation (1- σ) of the last 1-minute raw measurements divided
441 by the square root of the number of measurements (n = 60), and for all these cylinders the
442 values are usually between 0.5 ppm to 0.7 ppm. For parallel measurements of these cylinders
443 using a Paramagnetic analyzer, we obtained a precision of about 1 ppm, calculated exactly the
444 same way.

445 We also made a correlation plot to see which of the two instruments are in better
446 agreement with the assigned values based on IRMS measurements for the individual
447 cylinders. While similar correlation coefficients were observed for both analyzers, different
448 slopes were calculated (Fig. A.1). This is due to the fact that the IRMS measures the O₂ to N₂
449 ratio ($\delta(\text{O}_2/\text{N}_2)$) in per meg, while the CRDS and the Paramagnetic analyzers provide non-
450 calibrated O₂ mixing ratios in units of ppm and per meg, respectively. If we exclude the two
451 standard gases with the highest and lowest O₂ mixing ratios (standards 7 and 8) that are
452 subjected to strong dilution effects, both the slope and the r^2 values decrease from those
453 shown in Figure A.1. But this decrease is larger in the case of the Paramagnetic
454 measurements, implying a slightly better linearity of the CRDS analyzer.

455 3.2.2. Measurements of ambient air

456 Ambient air measurements were conducted from the roof top of our laboratory at the
457 University of Bern to evaluate the analyzer's performance under atmospheric variability.
458 Ambient air was continuously aspirated from the inlet at the roof of the building at a flow rate
459 of $\sim 250 \text{ ml min}^{-1}$ which is then dried using a cooling trap kept at $-90 \text{ }^\circ\text{C}$ towards the
460 switching valve (V1) and measured in similar way to the standard gases as explained above.
461 The measurement values obtained here were compared with the parallel measurements by the
462 Paramagnetic sensor to test the instruments stability and accuracy.

463 Figures 13 panels a & b show the 1-minute average ambient air measurements from the
464 rooftop inlet by the Paramagnetic and the CRDS analyzers at the beginning of the testing
465 period including standard gases measured every 12-hour. While the Paramagnetic analyzer
466 seems to be stable, the CRDS analyzer showed a strong drift for an extended period. This can
467 be due to unstable conditions in the CRDS measurement system as it started operating right
468 after it was unpacked. Hence, we looked into temperature inside the instrument chassis and
469 pressure records, which were stable within the manufacturer's recommended range during this
470 period. As the CRDS analyzer incorporates a water correction function, interference from this
471 species should be well accounted. Even comparing the analyzer's parallel water
472 measurements to water measurements by the NDIR system such a drift was not observed. It
473 should be noted that the two internal standard gases which were less frequently measured
474 (every 12 hours) during this period were also drifting in similar pattern. This implies that the
475 drift is associated with the analyzer. Interestingly, we observed that the two cylinders follow
476 exactly the same drift pattern that can be modeled using a polynomial function which can then
477 be used to correct for the observed drift in the ambient air measurements. After applying a
478 polynomial drift correction, we were able to fully account for the observed drift. However, the

479 manufacturer decided to further investigate possible causes of this drift. After further
480 improvements, we obtained the first commercial analyzer in September 2017 and repeated the
481 above tests (Figure 13 c & d). No such drift was observed any more in the standard gases or in
482 ambient air measurements.

483 A possible hypothesis for the cause of the drift can be an optical amplifier in the first system
484 and not anymore included in the design of the product which produced a significant amount of
485 broadband light that could fill the cavity (albeit with a low coupling coefficient), and would
486 ring down with a different (and generally much faster) time constant than the baseline loss of
487 the cavity. However, the ringdown time on the peak of the oxygen line is just 10
488 microseconds, such that the broadband light might have distorted the single exponential decay
489 of the central laser frequency, leading to the observed drift in the oxygen signal. However,
490 we were not able to confirm this hypothesis.

491 3.2.3. Water correction test

492 Measurements of oxygen are reported as both wet ($O_{2, \text{raw}}$) and dry ($O_{2, \text{dry}}$) mole
493 fractions by the CRDS analyzer as it also measures water vapor in parallel at its water
494 absorption line (7817 cm^{-1}), and corrects for the dilution effect based on an inbuilt numerical
495 function:

$$496 \quad O_{2, \text{dry}} = \frac{O_{2, \text{raw}}}{1 - f_{\text{H}_2\text{O}}} \quad (5)$$

497 where $f_{\text{H}_2\text{O}}$ is the measured water mole fraction.

498 The efficiency of water correction by this function was assessed in two ways: i) by comparing
499 the water vapor content in standard air measured by this analyzer with similar measurements
500 by the NDIR analyzer and ii) by comparing the oxygen mixing ratios between non-dried

501 ambient air measured and corrected for water dilution by the CRDS analyzer with dried air
502 measured using a paramagnetic analyzer.

503 Figure 14 shows the water vapor content for standard gases measured continuously for
504 two days by the CRDS and the NDIR analyzers. Note that the two data sets are manually
505 fitted to each other as the measured water values by the NDIR analyzer are not calibrated.
506 Based on these plots, the two analyzers are in very good agreement although there are small
507 differences during very dry conditions (low water content).

508 The water correction test was conducted by measuring dried ambient air (Figure 15a)
509 into both analyzers as well as allowing non-dried air to the CRDS analyzer only (Figure 15b)
510 and comparing the difference in O₂ measurements in both cases. Figures 15c & 15d show the
511 water contents of dried ambient air measured in both analyzers (note that the CRDS uses its
512 in-built water correction function). The measurements of the Paramagnetic analyzer were
513 scaled to ppm units by applying the correlation equation obtained from the six standard gas
514 measurements of the two analyzers (Fig. A.1). Note that the CRDS measurements were
515 corrected for the observed drift using the polynomial fit to the two standard gas measurements
516 stated above.

517 In the first period of the measurement when both analyzers measured dried ambient
518 air, the absolute differences between the 1-minute averages measured over two days by the
519 two analyzers were mostly within 15 ppm and symmetrically distributed around zero.
520 However, when wet air was admitted to the CRDS analyzer and the in-built water correction
521 was applied, a stronger variability was observed in the calculated differences. This implies
522 stronger short term variability in the CRDS analyzer measurement values (as nothing was
523 changed for the Paramagnetic measurement system) when wet samples were analyzed. The
524 more negative values in the differences can also be associated with overestimation of the O₂

525 mixing ratios by the CRDS originating from an overestimated water correction. However,
526 detailed evaluation of the analyzer's water correction function is beyond the scope of this
527 study.

528 **3.3. Field Measurements**

529 After a series of tests at University of Bern, we conducted multiple field measurements
530 at the High Altitude Research Station Jungfrauoch and the Beromünster tall tower sites in
531 Switzerland described below.

532 3.3.1. Tests at the High Altitude Research station Jungfrauoch

533 The High Alpine research station Jungfrauoch is located on the northern ridge of the
534 Swiss Alps (46° 33' N, 7° 59' E) at an elevation of 3580 m a.s.l. It is one of the global
535 atmospheric watch (GAW) stations well-equipped for measurements of numerous species and
536 aerosols. The site is above the planetary boundary layer most of the time due to its high
537 elevation (Henne et al., 2010; Zellweger et al., 2003). However, thermally uplifted air from
538 the surrounding valleys during hot summer days or polluted air from the heavily industrialized
539 northern Italy may reach at this site (Zellweger et al., 2003). The Division of Climate and
540 Environmental Physics at the University of Bern has been monitoring CO₂ and O₂ mixing
541 ratios at this site based on weekly flask sampling and continuous measurements since 2000
542 and 2004, respectively (Schibig et al., 2015). The CO₂ mixing ratio is measured using a
543 commercial NDIR analyzer (S710 UNOR, SICK MAIHAK) while O₂ is measured using the
544 Paramagnetic sensor (PM1155 oxygen transducer, Servomex Ltd, UK) and fuel cells (Max-
545 250, Maxtec, USA) embedded within a home-built controlling unit. Similar to the comparison
546 tests at the University of Bern, we have conducted parallel measurements between the CRDS
547 analyzer and the paramagnetic cell at this high altitude site during 03 – 14 February 2017. The
548 measurement of ambient air at the Jungfrauoch system is composed of sequential switching

549 between a low span (LS) and high span (HS) calibration gases followed by a target gas (T)
550 measurement (once a day) to evaluate the overall system performance and finally a working
551 gas (WG) measurement before switching back to ambient air.

552 Figure 16 (top panel) shows the calibrated 1-minute averaged O₂ mixing ratios
553 measured at this high altitude site in comparison with the Paramagnetic oxygen analyzer
554 already available at the site. While a strong variability was observed during the measurement
555 period of 10-days by both analyzers, a very good agreement was observed between them.

556 Figure 16 (bottom panel) shows the absolute difference of 1-minute averages in
557 atmospheric O₂ measured at Jungfraujoch between the two analyzers which are mostly within
558 ± 5 ppm range (but sometimes going as high as ± 10 ppm) without an offset. However, for
559 generally reported 10-minutes, half-hourly or hourly means these values correspond to < 1.5
560 ppm, < 1 ppm and < 0.65 ppm.

561 3.3.2. Tests at the Beromünster tall tower site

562 The Beromünster tower is located near the southern border of the Swiss Plateau, the
563 comparatively flat part of Switzerland between the Alps in the south and the Jura mountains
564 in the northwest (47° 11' 23" N, 8° 10' 32" E, 797 m a.s.l.), which is characterized by intense
565 agriculture and rather high population density. A detailed description of the tower
566 measurement system as well as a characterization of the site with respect to local
567 meteorological conditions, seasonal and diurnal variations of greenhouse gases, and regional
568 representativeness can be obtained from previous publications (Berhanu et al., 2016; Berhanu
569 et al., 2017; Oney et al., 2015; Satar et al., 2016). The tower is 217.5 m tall with access to five
570 sampling heights (12.5 m, 44.6 m, 71.5 m, 131.6 m, 212.5 m) for measuring CO, CO₂, CH₄
571 and H₂O using Cavity Ring Down Spectroscopy (Picarro Inc., G-2401). By sequentially
572 switching from the highest to the lowest level, mixing ratios of these trace gases were

573 recorded continuously for three minutes per height, but only the last 60 seconds were retained
574 for data analysis. The calibration procedure for ambient air includes measurements of
575 reference gases with high and low mixing ratios traceable to international standards (WMO-
576 X2007 for CO₂ and WMO-X2004 for CO and CH₄), as well as target gas and more frequent
577 working gas determinations to ensure the quality of the measurement system. From two years
578 of data a long-term reproducibility of 2.79 ppb, 0.05 ppm, and 0.29 ppb for CO, CO₂ and
579 CH₄, respectively was determined for this system (Berhanu et al., 2016).

580 Between 15.02.2017 and 02.03.2017, we have connected the new CRDS oxygen
581 analyzer in series with the CO₂ analyzer (Picarro G-2401) and measured the O₂ mixing ratios
582 at the corresponding heights. Similar to the CO₂ measurements, O₂ was also measured for
583 three minutes at each height. During this period, we have evaluated the two features (isotopic
584 mode and concentration mode) of the CRDS analyzer. In the isotopic mode, the CRDS
585 measures the $\delta^{18}\text{O}$ values as well as the O₂ concentration while in concentration mode only
586 the latter was measured.

587 During the tests conducted at this tower site, we first evaluated the two operational
588 modes (concentration vs isotopic modes) of the CRDS analyzer. Ambient air measurements
589 on isotopic mode over a 4-days period showed a strong variability in the measured oxygen
590 mixing ratios and it was not possible to distinguish the variability in the O₂ mixing ratios
591 among the five height levels. The calculated 1-minute standard error for ambient air
592 measurements was as high as 10 ppm while a standard error of less than 1 ppm was
593 determined from similar measurements in the concentration mode. Additionally, comparing
594 the O₂ values between the two modes, frequent short time variation in ambient air O₂ (~ 200
595 ppm) was observed in the isotope mode measurements while the variation in the concentration
596 mode is significantly smaller (~ 30 ppm). This precision degradation is due to the weaker ¹⁶O

597 oxygen line used for the isotopic mode, and the fact that far more ring-downs are collected on
598 the rare isotopologue in isotopic mode Hence, we have conducted the remaining test
599 measurements in concentration mode.

600 As this tower has five sampling height levels, we first followed three minutes of
601 switching per inlet level, which enables four measurements per hour at a given level.
602 However, we noticed hardly any difference among the different levels due to strong short
603 term variability in O₂ mixing ratios between the consecutive heights. Hence, we switched to a
604 longer sampling period of six-minutes per height. Figure 17 shows the diurnal CO₂ and O₂
605 variations at the lowest (12 m) and highest (212.5 m) sampling heights of the tower. These
606 two heights were selected simply to better illustrate the difference in the mixing ratios. The
607 CO₂ mixing ratios on the top panel show higher values at the 12 m inlet than the highest level
608 most of the day due to its closeness to sources except during the afternoon (11:00 - 17:00
609 UTC) when both levels show similar but decreasing CO₂ mixing ratios. This is due to
610 presence of a well-mixed planetary boundary layer (PBL) (Satar et al., 2016). The lag in CO₂
611 peak between the two height levels by about two hours indicates the duration for uniform
612 vertical mixing along the tower during winter 2017. The opposite variability patterns are also
613 clearly visible in the O₂ mixing ratios shown in the lower panel with a clear distinction
614 between the two height levels during early in the morning and in the evening while similar O₂
615 values were observed in the afternoon. These opposing profiles are expected as CO₂ and O₂
616 are linearly coupled with a mean oxidation ratio of -1.1 ± 0.05 (Severinghaus, 1995) for land-
617 biospheric processes (photosynthesis and respiration) and -1.44 ± 0.03 for fossil fuel burning
618 (Keeling, 1988b).

619 Table 2 shows the oxidation ratios derived as the slopes of the linear regression
620 between CO₂ and O₂ mixing ratios at the different height levels measured on 25 February

621 2017. Accordingly, height dependent slopes were observed with a slope of -0.98 ± 0.06 at the
622 lowest level, close to the biological processes induced slope but slightly lower than its mean
623 value. For the highest level, we calculated a slope of -1.60 ± 0.07 a value close to fossil fuel
624 combustion oxidation ratio. Note that depending on fossil fuel type the oxidation ratio can
625 range between -1.17 and -1.95 for coal and natural gas, respectively (Keeling, 1988b). While
626 the slopes derived for the two other levels (44.6 m and 131.6 m) show similar values between
627 the highest and lowest height levels, possibly from mixed sources, the middle level showed a
628 slightly higher slope than these two levels but still in the large range between the lowest and
629 highest inlet heights.

630 3.4. Evaluation of the $\delta^{18}\text{O}$ measurements

631 To further evaluate the analyzer's performance in measuring stable oxygen isotopes,
632 we conducted ambient air isotopic composition measurements as well as analyzed a standard
633 gas without CO_2 which has a known $\delta^{18}\text{O}$ value. The choice of this CO_2 -free air standard gas
634 is twofold: one it has a known $\delta^{18}\text{O}$ value and second as it has no CO_2 possible interference
635 from band overlap. For this test three 0.5 L glass flasks were preconditioned and filled with
636 this standard gas to ambient pressure. These flasks were attached before or after the water trap
637 (Fig. 11) and measured similar to ambient air measurements. These measurements were then
638 compared with $\delta(^{34}\text{O}/^{32}\text{O})$ values obtained by parallel measurements using our IRMS.

639 Figure 18 shows the $\delta^{18}\text{O}$ values of ambient air from the roof top with three
640 consecutive measurements of glass flasks filled with CO_2 -free air in-between followed by a
641 fourth flask filled with breath air. An excellent agreement was observed for measurements
642 from both instruments for the three flasks filled with a standard gas. However, the fourth flask
643 with breath air showed a signal opposite to the measurements by the IRMS. As breath air
644 contains large amount of water and CO_2 in addition to O_2 , which can possibly interfere with

645 the CRDS analyzer measurements, we have removed H₂O and CO₂ by using a cryogenic trap
646 (-130 °C) and in an additional experiment using Schütze reagent to remove both CO and CO₂.
647 However, we have not observed any improvement towards an agreement with the IRMS
648 measurements. Therefore, any other gas component in the breath air must be relevant for the
649 interference. Based on the absorption lines in the spectral range of the instrument (7878 cm⁻¹)
650 retrieved from HITRAN database, we expect interference either from carbon monoxide (now
651 excluded by the tests) or methane or VOCs including acetone, ethanol, methanol or isoprenes,
652 all of which have been measured in breath air (Gao et al., 2017; Gottlieb et al., 2017; Mckay
653 et al., 1985; Ryter and Choi, 2013; Wolf et al., 2017). Further investigations have to shed light
654 on these interferences in order to take corresponding action to surpass these shortcomings in
655 the isotope analysis based on cavity ring-down spectroscopy.

656 **4. Conclusions**

657 We have thoroughly evaluated the performance of a new CRDS analyzer which
658 measures O₂ mixing ratios and isotopic composition combining laboratory and field tests.
659 Even if a drift in the analyzer was observed at the beginning of this study, which if it appears
660 can be easily corrected by calibration, the recent analyzers built by the manufacturer did not
661 show such instrumental drift. However, prior tests are recommended to see the analyzer's
662 stability.

663 The T-split tests for the current measurement setup based on the measurements of two
664 standard gases showed a difference within the measurement uncertainty. However, this effect
665 may become significant while applying larger splitting ratios and we recommend conducting
666 further experiments to accurately quantify this influence for larger splitting ratios.

667 We have observed a strong influence of dilution in the measured O₂ values during the
668 presence of high CO₂ mixing ratios. Even if such an influence may not be critical for the

669 present study, such an effect might be significant in other studies where higher CO₂ mixing
670 ratios might be present and we recommend following a correction strategy based on parallel
671 CO₂ measurements. This also applies for more accurate analysis.

672 The water correction applied by the instrument's in-built function seems to sufficiently
673 correct for the water vapor influence. However, a larger variability of the difference was
674 observed between the CRDS analyzer and the Paramagnetic cell when dried samples were
675 used in both systems. This can possibly be due to an overcorrection by the water correction
676 function of the CRDS analyzer when dried samples were used. This is particularly true for the
677 very low water vapor range (< 100 ppm). However, we believe that it is important to further
678 investigate this issue and identify an improved water correction strategy.

679 Based on the analysis of O₂ mixing ratios in the concentration and isotopic modes, we
680 have observed about a significant decrease in precision (about ten-fold) in the latter
681 measurement mode. The measured $\delta^{18}\text{O}$ values for the standard air by the CRDS analyzer are
682 in excellent agreement with the IRMS values. However, such measurements for a breath air
683 showed a contrasting signal, possibly due to interference from other gases as breath air
684 contains CO₂, CH₄ and CO in addition to oxygen. Hence, we recommend further investigation
685 on such possible contaminants and how to possibly remove them while conducting ambient
686 air measurements. However, we believe that this analyzer can be used for tracer experiments
687 where artificially enriched isotopes are used to study biological processes such as
688 photosynthesis in plants using isotopically labelled CO₂ and H₂O.

689
