The responses to the comments of the referee in our direct reply (shown below) and within the revised manuscript (see marked copy) are provided. The pages and lines indicated below correspond to those in the marked copy.

Response to Referee 1 (Referee's comments are italicized)

1. Referee's comment: "*Although several caveats have been introduced noting that the peak assignments are speculative, the same interpretations follow. The speculation is ok, but there should be no further quantification or interpretation based upon that. Without further justification, the organic acids should not be identified as a single compound and their abundance should not be interpreted. Instead, please show them as masses, or as a sum of compounds. The figures may be very misleading by showing individual compounds as mixing ratios. If molecule names are used, then some simple tests ought to be performed to inform the identification of the masses. Can an HR-TOF be used with SF6- in a similar environment to see which compounds dominate? That would be far more powerful than the comparison with WSOCg.*"

Author response: We will agree that that with the exception of formic, acetic, oxalic and propionic acids, we do not have sufficient evidence to justify the assignment of other the organic acids. Hence, we will refer to organic acids with m/z 75, 87, 101, 103, 117 and 131 by their ion masses.

We are confident in our peak assignment of formic, acetic and propionic acids because the SF_6^- ion chemistry is selective to acidic species and these three acids do not have organic acid isomers and isobaric species. In addition, we are confident in our peak assignment of oxalic acid because the estimated gas-phase oxalic acid concentration make sense relative to its particle concentrations, which were also measured during the study. As explained in Nah et al. (2018), the gas-particle ratios of the organic acids depend of their thermodynamic conditions, which are dependent on the acid's physicochemical properties, ambient temperature, particle water and pH. In the case of oxalic acid, the measured gas-particle partitioning ratios are in good agreement with their corresponding thermodynamic predictions, thus indicating that our assignment of the m/z 89 ion to oxalic acid is reasonable.

The manuscript has been revised as follows:

Page 18 line 546: "3.2.3. Larger organic acids

In addition to formic and acetic acid, eight other ions were monitored during the field study: m/z 73, 75, 87, 89, 101, 103, 117 and 131. These ions were chosen as they had significant signals when ambient air was sampled and were not obviously formed from SF_6^- reaction with water vapor or O_3. Since the CIMS utilized in this study only had unit mass resolution, these ions are the sum of all organic acid isomers and isobaric organic acids of the same molecular weight as well as other product ions from species that might react with SF_6^-. We will refer to organic acids with m/z 75, 87, 101, 103, 117 and 131 by their ion masses. We assign the m/z 73 ion as the X^- ion of propionic acid because it does not have organic acid isomers and isobaric species at that m/z. In addition, real-time ion chromatography measurements of aerosol composition performed during the field study demonstrated the presence of particulate oxalic acid (Nah et al., 2018). For this reason, we assign the m/z 89 ion as the X^- ion of oxalic acid. As shown in Nah et al. (2018), the gas-particle ratios of the

organic acids depend of their thermodynamic conditions, which are dependent on the acid's physicochemical properties, ambient temperature, particle water and pH. Since the measured gas-particle partitioning ratios of oxalic acid (calculated using the CIMS and ion chromatography measurements) are in good agreement with their corresponding thermodynamic predictions (Nah et al., 2018), this indicated that our assignment of the m/z 89 ion to oxalic acid is reasonable. In addition, the high sensitivity of SF_6^- to oxalic acid also helps limit interferences due to other acids. Particulate formic acid and acetic acid were also detected by ion chromatography during the field study, but were at much lower concentrations relative to the gas phase (Nah et al., 2018).

Figures 5 and S5 show the time series and diurnal profiles of oxalic and propionic acids and organic acids with ions m/z 75, 87, 101, 103, 117 and 131 measured during the field study. These organic acids displayed very similar day-to-day variability as formic and acetic acids, with higher concentrations (or ion signals) being measured on warm and sunny days. The diurnal profiles of all the measured organic acids have similar diurnal trends, with their concentrations (or ion signals) reaching a maximum between 17:30 and 19:30 and rapidly decreasing after sunset."

Page 24 line 798: "The SF_6^- CIMS method was deployed for measurements of gas phase organic acids in a mixed forest-agricultural area in Yorkville, Georgia from Sept to Oct 2016. The organic acids measured in the field study were formic, acetic, propionic and oxalic acids."

Discuss., in review, 10.5194/acp-2018-373, 2018.

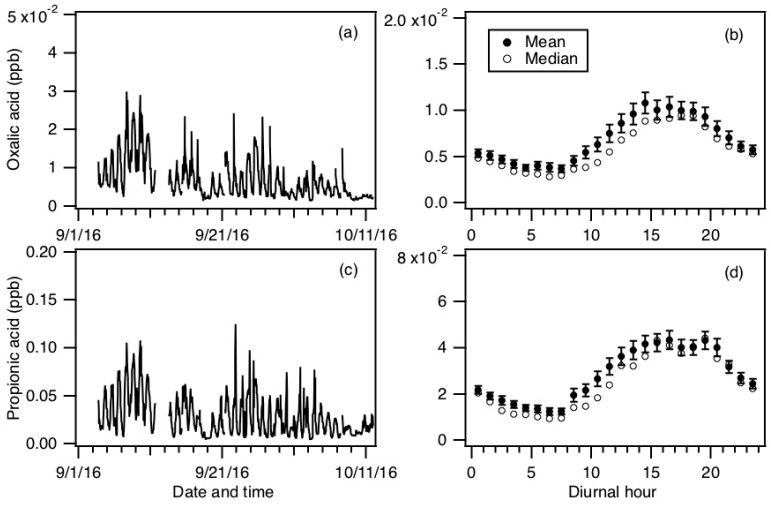

Figure 5: Time series of concentrations of (a) oxalic and (c) propionic acids measured during the field study. All the data are displayed as 1-hour averages. Their corresponding diurnal profiles are shown in (b) and (d), respectively. The diurnal profile concentrations represent averages in 1-hour intervals and the standard errors are plotted as error bars.

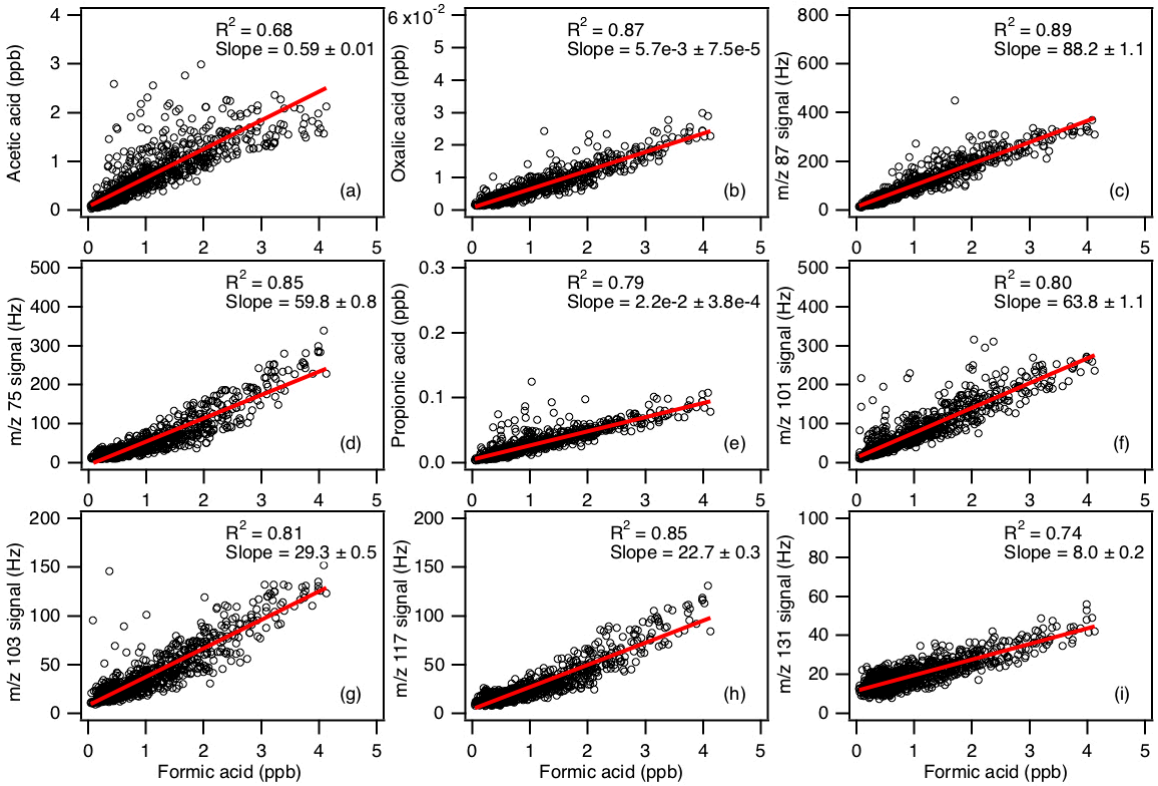

Figure 7: Scatter plots of concentrations (or ion signals) of the measured organic acids with formic acid concentration. All the data are displayed as 1-hour averages. Red lines shown are linear fits to the data.

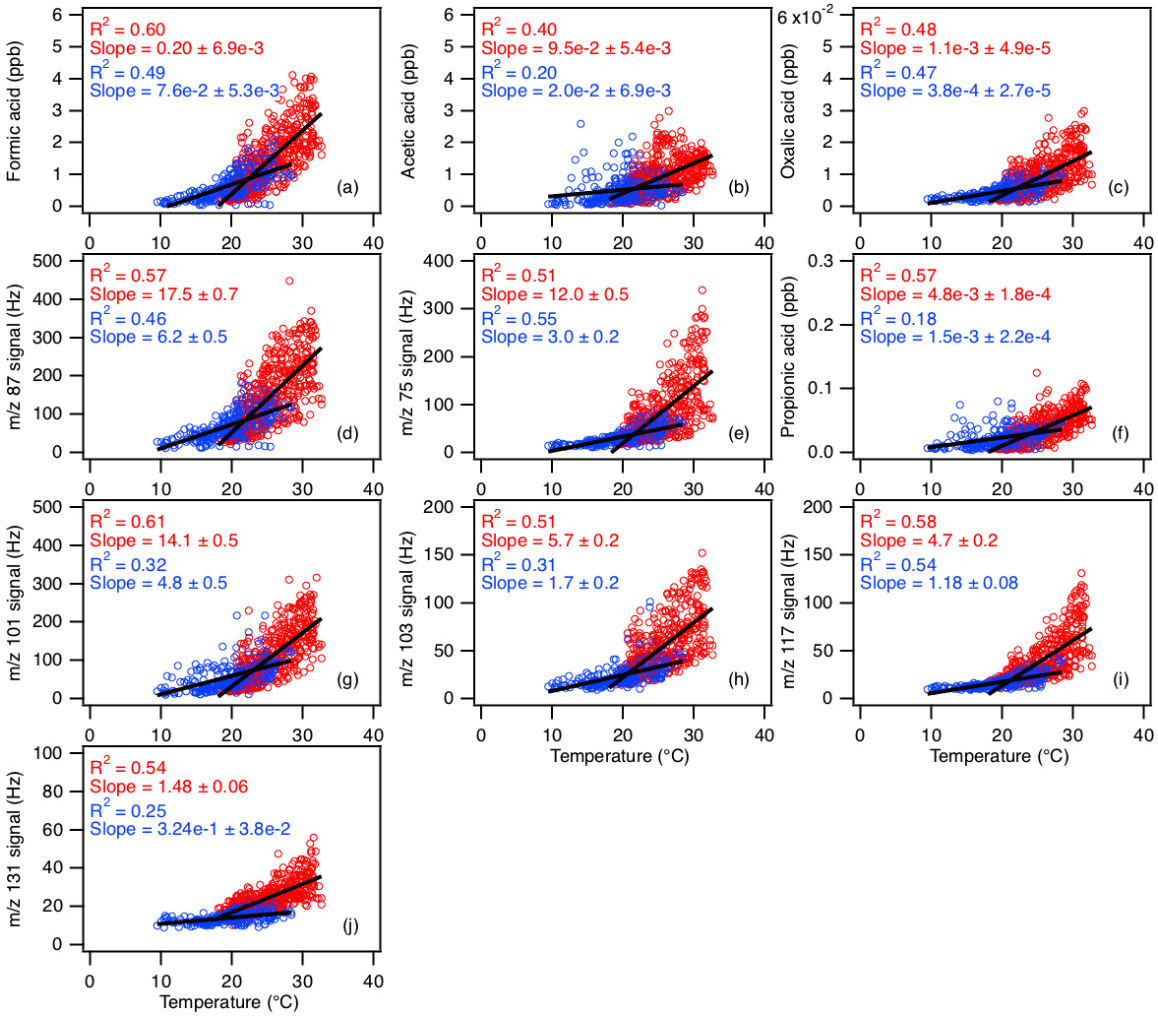

Figure 8: Scatter plots of concentrations (or ion signals) of the measured organic acids with ambient temperature. The red symbols are data collected from 3 to 27 Sept, while the blue symbols are data collected from 28 Sept onwards. All the data are displayed as 1-hour averages. Black lines shown are linear fits to the datasets.

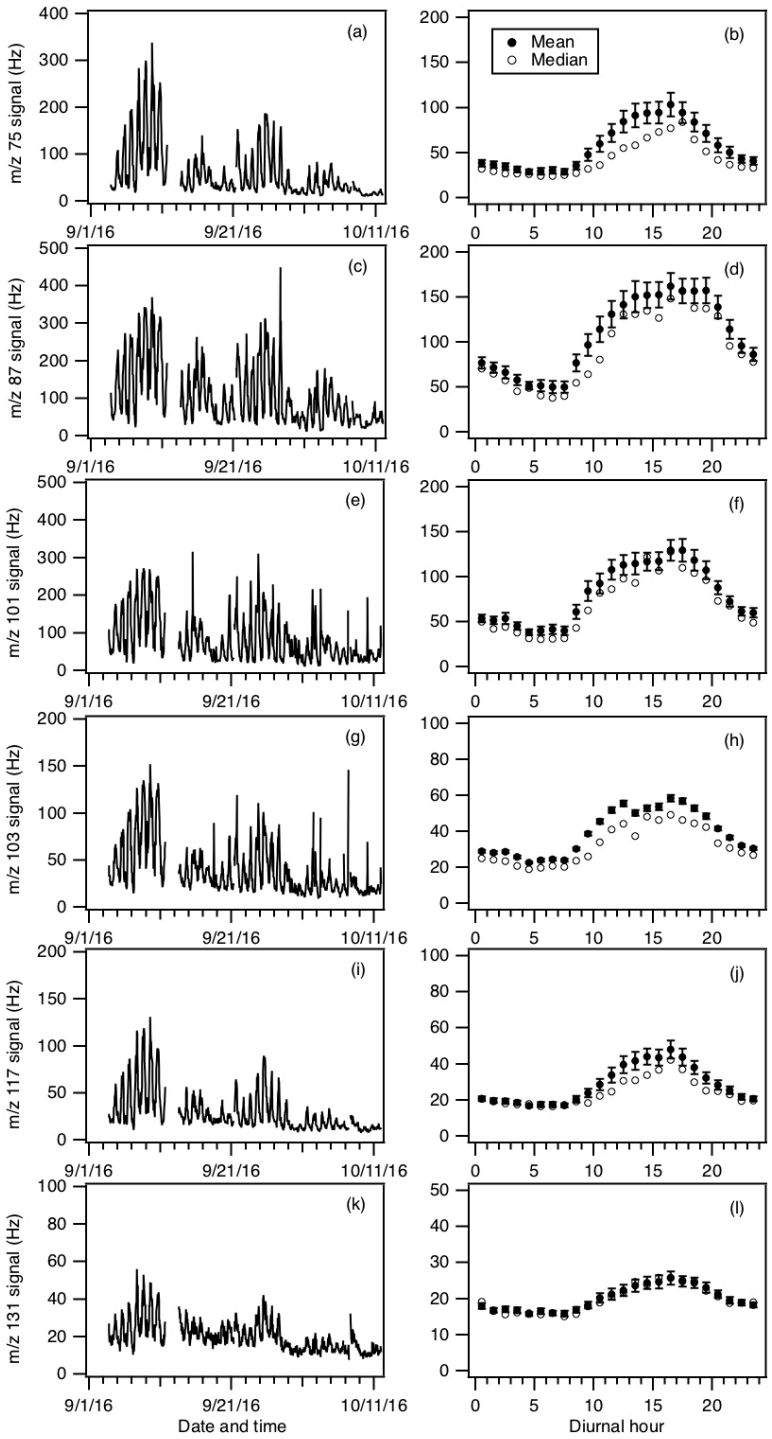

Figure S5: Time series and diurnal profiles of ion signals of organic acids with m/z 75, 87, 101, 103, 117 and 131 measured during the field study. The data are displayed as 1-hour averages. All the signals represent averages in 1-hour intervals and the standard errors are plotted as error bars.

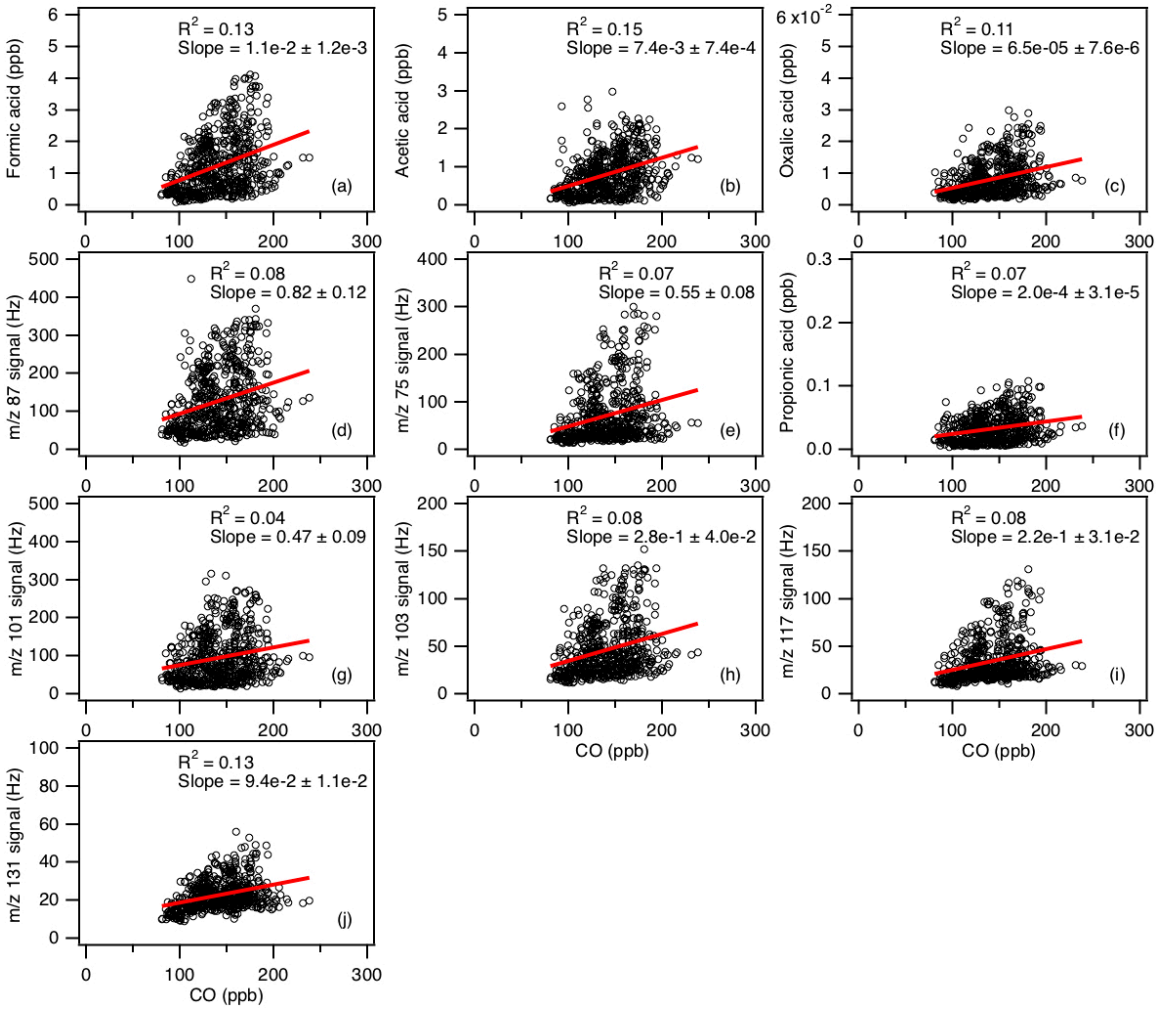

Figure S7: Scatter plots of concentrations (or ion signals) of the measured organic acids with CO concentration. All the data are displayed as 1-hour averages. Red lines shown are linear fits to the data.

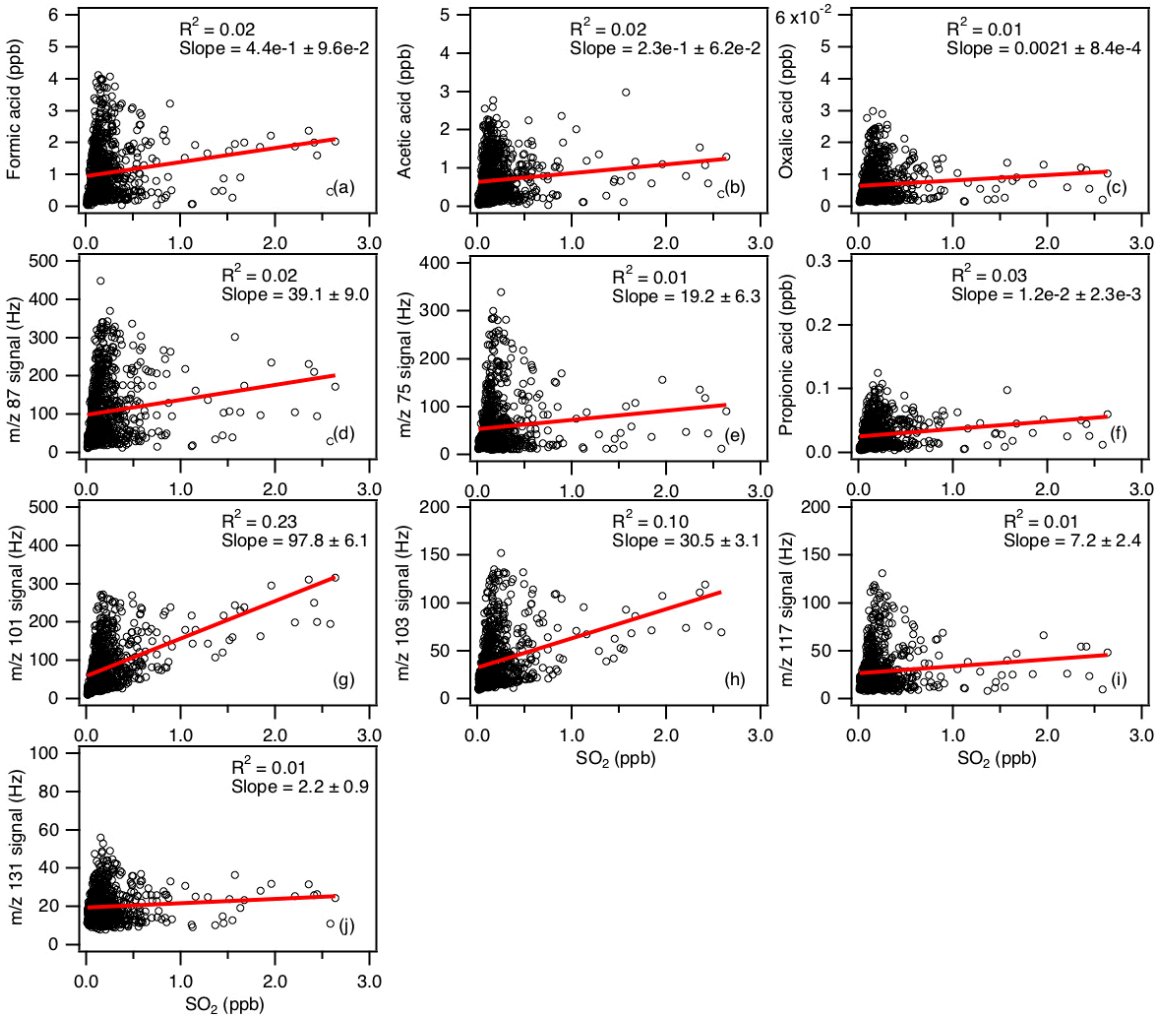

Figure S8: Scatter plots of concentrations (or ion signals) of the measured organic acids with SO_2 concentration. All the data are displayed as 1-hour averages. Red lines shown are linear fits to the data.

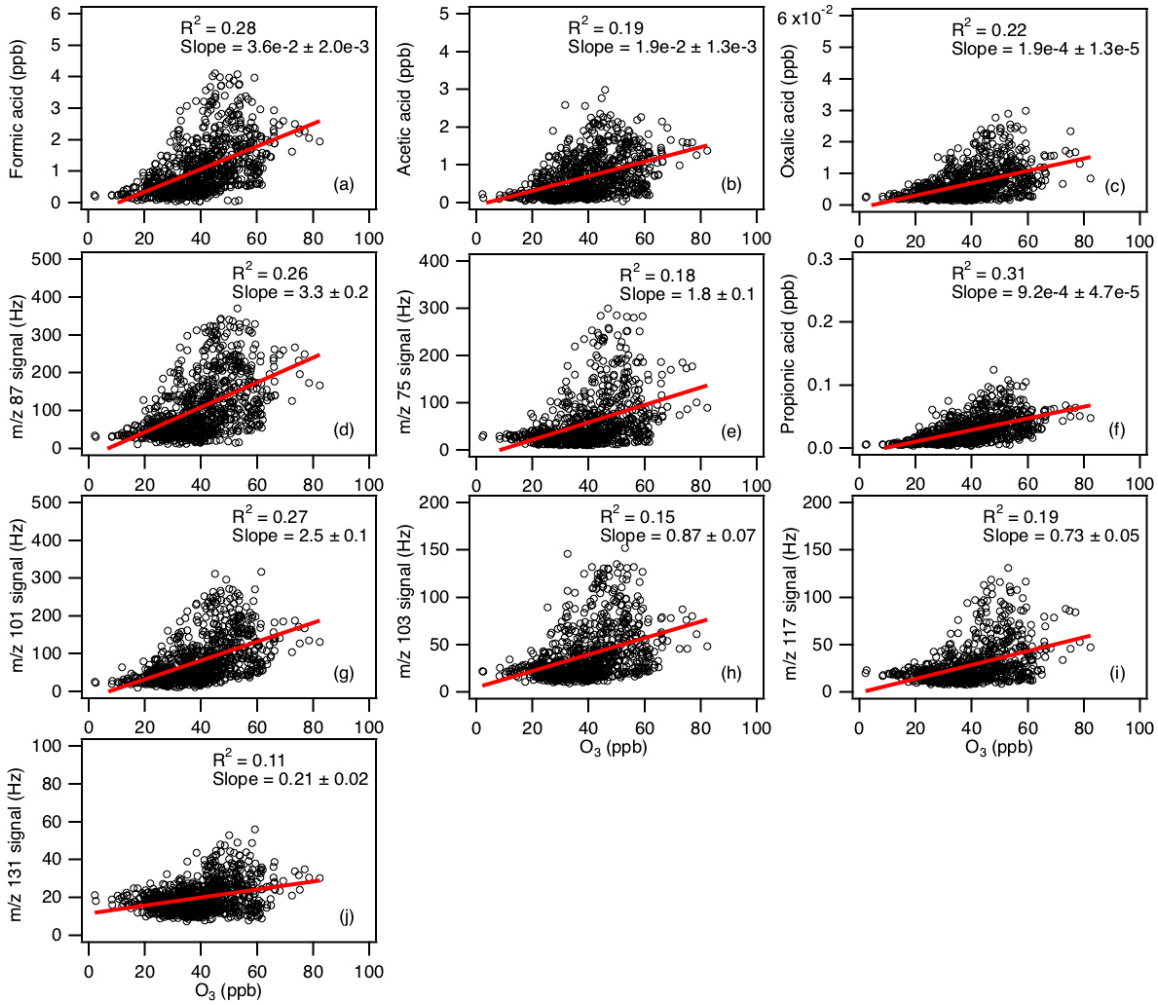

Figure S9: Scatter plots of concentrations (or ion signals) of the measured organic acids with O_3 concentration. All the data are displayed as 1-hour averages. Red lines shown are linear fits to the data.

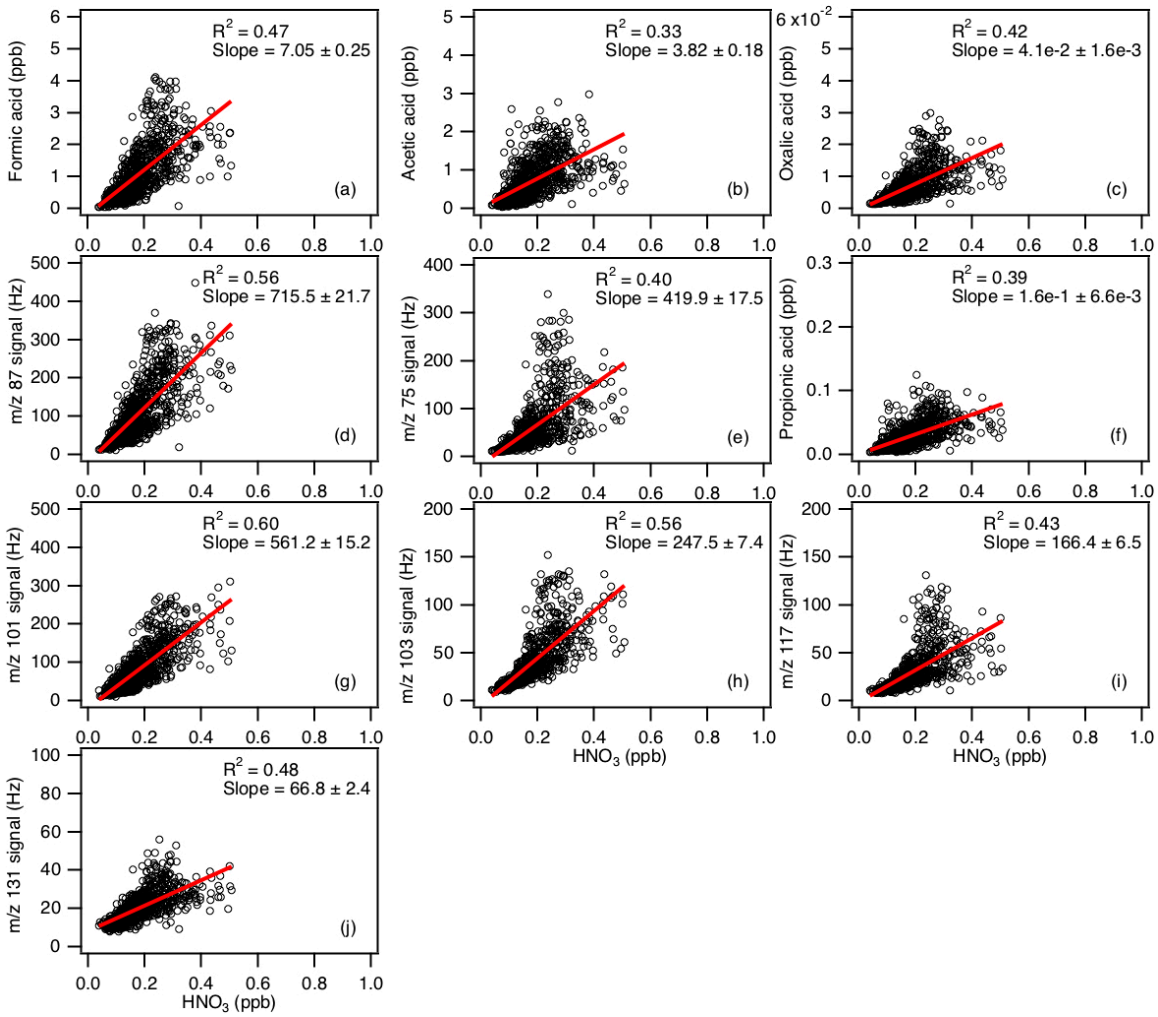

Figure S10: Scatter plots of concentrations (or ion signals) of the measured organic acids with HNO_3 concentration. To exclude periods when the site was affected by urban or power plant emissions, data where HNO_3 > 0.5 ppb are excluded from these scatter plots. All the data are displayed as 1-hour averages. Red lines shown are linear fits to the data.

2. Referee's comment: "*Comparison to aerosol composition (section 3.2.3) is not a compelling reason to choose the peak assignments. As is stated in the manuscript, the low volatility compounds measured in the particle phase are expected to have low gas phase concentrations. This could be used to argue that oxalic, malonic... that are present in the particle phase do not explain the signals measured in the CIMS. The IC aerosol measurements are never discussed quantitatively: Do the gas phase concentrations estimated here make sense relative to the particle concentrations?*"

Author response: As the IC aerosol measurements have been discussed in detail in another paper, they were not discussed quantitatively in this paper. We refer the referee to Nah et al. (2018) for detailed discussions of the IC aerosol measurements.

Although volatility is a factor, the gas-particle ratios of the organic acids is more complex than that. It depends on thermodynamic conditions, which are dependent on the acid's physicochemical properties (including volatility), ambient temperature, particle water and pH. As explained in detail

in Nah et al. (2018), the measured oxalic acid gas-particle partitioning ratios are in good agreement with their corresponding thermodynamic predictions. Hence, we are confident in our assignment of the m/z 89 ion to oxalic acid since its gas-phase concentrations estimated here make sense relative to its particle concentration. In the case of formic and acetic acids, their measured gas-particle partitioning ratios do not agree with their corresponding thermodynamic predictions, which may be due to mixing states or specific chemical forms of particle-phase formate and acetate (Nah et al., 2018).

Since thermodynamic modeling was not performed for the other organic acids, we are unable to determine if their estimated gas-phase concentrations make sense relative to their particle-phase concentrations. We refer the referee to our reply to comment 1 for revisions made to manuscript regarding the assignment of ions peaks to organic acids.

J.: Characterization of Aerosol Composition, Aerosol Acidity and Organic Acid Partitioning at an Agriculture-intensive Rural Southeastern U.S. Site, Atmos. Chem. Phys. Discuss., in review, 10.5194/acp-2018-373, 2018.

3. Referee's comment: "*It would be much more useful to further justify the technique, which may have some advantages over iodide ion chemistry. For example, the sensitivity to propionic acid is much better than iodide. Is the same true for other acids that iodide does not detect well, like acrylic acid? Iodide often suffers from a large lactic acid interference that compromises oxalic acid quantification. What is the sensitivity to lactic acid? Since the motivation was to quantify organic acids, further discussion of the advantages (possibly unique) of SF6 for quantifying organic acids would be particularly valuable.*"

Author response: Since the main purpose of this paper is to introduce SF_6^--CIMS as an alternative and promising approach in the detection of organic acids in ambient measurements, the manuscript focuses on the details of the SF_6^- ion chemistry and optimal instrument operation for the detection of such acids. Because this paper is not a comparison paper for the different CIMS techniques on the detection of organic acids, we did not conduct laboratory experiments to compare the SF_6^- vs. I^- sensitivities of different organic acids.

Our preliminary lab experiments showed that SF_6^- is less sensitive to lactic acid compared to oxalic acid because the SF_6^- + lactic acid reaction results primarily in the formation of SF_5^- ions, instead of X^- and X^-•HF ions. As already discussed in the manuscript, the production of SF_5^- does not allow for the selective detection of any atmospheric species. In addition, the larger the branching ratio of the SF_5^- channel, the lower the CIMS sensitivity to an individual acid since the effective rate constants for the X^- and X^-•HF channels are lower. In addition, we always used gloves when working on the CIMS during this study to limit contamination from emissions from human skin. We also kept people away from the front of the SF_6^--CIMS sampling inlet to minimize lactic acid interferences. Furthermore, as noted above, we believe that our assignment of the m/z 89 ion to oxalic acid is reasonable because our estimated gas-phase oxalic acid concentrations make sense relative to its particle concentration. As discussed in detail in Nah et al. (2018), the gas-particle ratios of the organic acids depend of their thermodynamic conditions, which are dependent on the acid's physicochemical properties, ambient temperature, particle water and pH. The measured

oxalic acid gas-particle partitioning ratios were shown to be in good agreement with their corresponding thermodynamic predictions. We refer the referee to our reply to comment 1 for revisions made to manuscript regarding the assignment of m/z 89 to oxalic acid.

Given that the main purpose of this paper is to introduce SF_6^--CIMS as an alternative and promising approach in the detection of organic acids in ambient measurements, we feel that we have sufficiently shown the unique advantages of SF_6^--CIMS over other reagent ions. As already stated in the manuscript in the introduction, the major advantage that SF_6^- has over I^- and $CH_3CO_2^-$ is that it allows for the detection of acetic acid and SO_2. CF_3O^- has a similar chemistry to SF_6^- and can detect organic acids but it also has issues due to hydrolysis and the ion precursor is not commercially available. Together, our measurements show that SF_6^--CIMS is a promising technique for the simultaneous detection of inorganic species (e.g., SO_2, HNO_3) and organic acids up to C_5 (valeric acid).

References:

Nah, T., Guo, H., Sullivan, A. P., Chen, Y., Tanner, D. J., Nenes, A., Russell, A., Ng, N. L., Huey, L. G., and Weber, R. J.: Characterization of Aerosol Composition, Aerosol Acidity and Organic Acid Partitioning at an Agriculture-intensive Rural Southeastern U.S. Site, Atmos. Chem. Phys. Discuss., in review, 10.5194/acp-2018-373, 2018.

Information regarding how we limited lactic acid contamination during the study has been added to the revised manuscript:

Page 6 line 184: "It should also be noted that we always used gloves when working on the CIMS during this study to limit contamination of lactic acid emissions from human skin. In addition, we kept people away from the front of the SF_6^--CIMS sampling inlet to minimize lactic acid interferences as well."

We have added the following sentences to the revised manuscript to emphasize the high sensitivity of SF_6^--CIMS to oxalic, propionic and glycolic acids which are expected to be present at low concentrations in the atmosphere:

Page 23 line 772: "It should be noted that the SF_6^- CIMS method is particularly sensitive to oxalic, propionic and glycolic acids, which are expected to be present at low concentrations in the atmosphere."

4. Referee's comment: "*I don't understand the normalization to F2SO2. F2SO2 has a water dependence that the organic acids do not, so the normalization is not appropriate, even if the water dependence is later adjusted (which I didn't understand). Why not normalize to the reagent ion signal, as is common in most other CIMS papers? This would make the work more easily compared to other CIMS techniques, and avoid correcting and then uncorrecting the signals by using F2SO2 normalization.*"

Author response: We understand the referee's point regarding the normalization of signals to F_2SO_2. While is it true that some research groups do normalize their measured signals to the reagent ion signal, this was not carried out in this paper because the SF_6^- reagent ion signals were in a region of non-linearity (i.e., at or close to signal saturation) for the entire field study. While we could have corrected for the non-linearity in the SF_6^- reagent ion signal prior to normalization,

doing so introduces uncertainties to our measurements. As a point of reference, we can only count linearly to a few hundred thousand ions per second and our counter/detector saturates at about a million ions per second. These numbers are not precise and depend on the particular combination of preamplifier and detector. So, we avoid normalization but instead calibrate often or even continuously.

Although we could have normalized our measured CIMS signals to the sensitivities of the formic or acetic acid calibrant gases, the formic and acetic acid sensitivities were not measured for the entire study because their perm tubes were shared with another CIMS during the study. In contrast, $^{34}SO_2$ was the main calibrant gas and its sensitivity was measured during every calibration period for the entire field study. Consequently, the CIMS instrument sensitivity measured by the $F_2{}^{34}SO_2^-$ ion signal was applied to all the measured species (except for formic and acetic acids during periods when their perm tubes were used for calibration purposes by the SF_6^--CIMS) using relative sensitivities determined in laboratory studies.

5. Referee's comment: "*With the removal of speculation in sections 3.24 and 3.3, there is room to emphasize some of the measurement technique accomplishments. The reagent ion signal is never mentioned in the text, though it is stated in the authors comments. Achieving a signal of 9 MHz is extraordinary given the low activity of the ionizer. Few CIMS do any better than this, so lines 352-354 are not correct in general. The paper should detail how the large reagent ion signal was achieved, as this seems to be a major new advance.*"

Author response: We disagree that the SF_6^- reagent ion signal is extraordinarily high and that lines 352 to 354 are incorrect. It may be true that some commercial CIMS can't achieve such high levels of reagent ion signal, but our group has achieved this level of SF_6^- and I^- reagent ion signals (>10^6 Hz) with our custom-built CIMS for many years. We refer the referee to Fig. 5 of Slusher et al. (2004) for an example of the I^- reagent ion signal (~10^6 Hz) obtained during a previous field study in 2002. In this example, the I^- signal was also saturated at an apparent signal of 10^6 Hz and was probably more on the order of 10 MHz if it could be counted accurately.

The obtainment of such high levels of reagent ion signals by our CIMS is probably due to the evolution of the design of our CIMS. This has been documented extensively, and we refer the referee to Liao et al. (2011) (or other previous papers from our group) for a more detailed description of our instrument.

6. Referee's comment: "*Likewise, the high sensitivity to acetic acid and possible insensitivity to lactic acid are important. The former is discussed, but it would be more powerful to have a table that compares the sensitivities here for all the acids to other CIMS techniques.*"

Author response: We disagree with the referee's assertion on the need for a table that compares the SF_6^- sensitivities of all the organic acids to other reagent ions. The main purpose of this paper is to introduce SF_6^--CIMS as an alternative and promising approach in the detection of organic acids in ambient measurements. This paper is not a comparison paper for the different CIMS techniques on the detection of organic acids. In addition, we think a table comparing sensitivities is likely to be misleading as instruments are constantly developing and being used in different configurations. Hence, the manuscript focuses on the details of the SF_6^- ion chemistry and optimal instrument operation for the detection of such acids.

Given the main purpose of this paper, we strongly feel that we have sufficiently shown the advantages of SF_6^--CIMS over other reagent ions such as $CH_3CO_2^-$, I^- and CF_3O^- to justify it being a promising technique in the detection of ambient organic acids. As already stated in the manuscript and in our previous reply to comment 1 from referee 2, the major advantage that SF_6^- has over I^- and $CH_3CO_2^-$ is that it allows for the detection of acetic acid and SO_2. CF_3O^- has a similar chemistry to SF_6^- and can detect organic acids but it also has issues due to hydrolysis and the ion precursor is not commercially available. Together, our measurements show that SF_6^--CIMS is a promising technique for the simultaneous detection of inorganic species (e.g., SO_2, HNO_3) and organic acids up to C_5 (valeric acid).

The referee's comment regarding the SF_6^- sensitivity to lactic acid is addressed in our replies to comment 1 and 3.

7. Referee's comment: "*The 1/e2 time decays are given, but the time response for most of the system is very fast. It looks like 1/e is <13s. Where does the time response come from? It is slower than many other CIMS measurements, even though there is a very large flow through the flow tube, and the inlet appears to be only 25 cm and with a large flow. Do the high dilution or reduced pressure affect time response?*"

Author response: Determination of the time response of our CIMS is limited by the CIMS sampling time. As stated in the manuscript, the sampling conditions of the CIMS during the study resulted in 13 s time resolution data. Hence, it is not possible to accurately determine the times for the various signals to decay to 1/e since it appears that the times all appear to be ≤ 13 s. We did not put this in the first version of the paper for these reasons and only did so at the suggestion of a reviewer. In addition, as stated in the manuscript, we report 1-hour averaged ambient concentrations (not 13 s ambient concentrations), which is sufficient for the purpose of this ground-based field study where the concentrations of measured species do not change rapidly (unlike airborne campaigns). Hence, we do not expect the time response of our CIMS to affect our results and conclusions.

However, the high dilution and reduced pressure do not affect the CIMS time response relative to other configurations of our CIMS. Instead, we expect the CIMS time response to a species to be governed primarily by the species' propensity to adhere to surfaces. This information has been added to the revised manuscript:

Page 15 line 450: "The CIMS time response to a compound is governed primarily by the compound's propensity to adhere to surfaces. The decays in the formic and acetic acid ion signals and times required for them to reach steady state after the removal of calibration gases during the switch from standard addition calibration to ambient sampling were used to determine the CIMS response time."

8. Referee's comment: "*line 242: what were the impurities in glyoxylic?*"

Author response: We were unable to identify the impurities in our glyoxylic acid. Although the purity of the sample was listed as 98 % by the manufacturer (Sigma Aldrich), the impurities were not listed. Some of these m/z peaks appeared at masses larger than glyoxylic acid, suggesting that they may be polymers.

9. Referee's comment: "*line 244: what are the vapor pressures? would heating generate sufficient vapor pressure?*"

Author response: The vapor pressures of malonic, succinic and glutaric acids are 5.73×10^{-4}, 1.13×10^{-4} and 4.21×10^{-4} kPa at 298 K, respectively (Booth et a., 2010). Although the referee is correct in stating that heating the malonic, succinic and glutaric acid samples will likely generate sufficient vapors for calibration, this method of generating calibrant gases for calibration purposes is subjected to errors caused by the vapors condensing out and adhering onto surfaces at room temperature prior to introduction into the CIMS. It is very difficult to maintain all parts of the tubing, inlet, and CIMS at an elevated temperature which would be required if we used a heated sample. This information has been added to the revised manuscript:

Page 9 line 249: "We attempted to generate calibration plots for malonic (Sigma Aldrich, ≥ 99.5 %), succinic (Sigma Aldrich, 99 %) and glutaric (Sigma Aldrich, 99 %) acids by passing N_2 over their solid samples at room temperature. However, it was not possible to generate large enough gas phase concentrations for calibration since these organic acids have very low vapor pressures. The vapor pressures of malonic, succinic and glutaric acids are 5.73×10^{-4}, 1.13×10^{-4} and 4.21×10^{-4} kPa at 298 K, respectively (Booth et al., 2010), which are at least 2 orders of magnitude lower than the organic acids that we calibrated for. Although heating up the malonic, succinic and glutaric acid samples will likely generate sufficient vapors for calibration, this method of generating calibrant gases will lead to large measurement uncertainties due to vapors condensing out and adhering onto surfaces at room temperature prior to introduction into the CIMS."

J.: Solid state and sub-cooled liquid vapour pressures of substituted dicarboxylic acids using Knudsen Effusion Mass Spectrometry (KEMS) and Differential Scanning Calorimetry, Atmos. Chem. Phys., 10, 4879-4892, 10.5194/acp-10-4879-2010, 2010.

10. Referee's comment: "*line 353: how much higher can the sensitivity and Po210 activity go?*"

Author response: A new commercial ^{210}Po ion source typically has 20 mCi activity. We estimate that the sensitivities may increase by as much as a factor of 5 with a new ^{210}Po ion source. This information has been added into the revised manuscript:

Page 12 line 382: "A weak ^{210}Po ion source (< 1 mCi) was used by SF_6^--CIMS instrument during the field study, hence these sensitivities will be substantially higher if a stronger radioactive source is used. Post-field laboratory work suggest that the sensitivities may increase by as much as a factor of 5 for a new commercial 20 mCi ^{210}Po ion source."

11. Referee's comment: "*line 393: replace "noticeable increase" with "xx% increase".*"

Author response: As requested, this information has been added into the revised manuscript:

Page 14 line 425: "There is a ~50 % increase in the $F_2{}^{34}SO_2^-/{}^{34}SF_6^-$ ion signal ratio on 28 Sept 2016, indicating an increase in the CIMS instrument sensitivity."

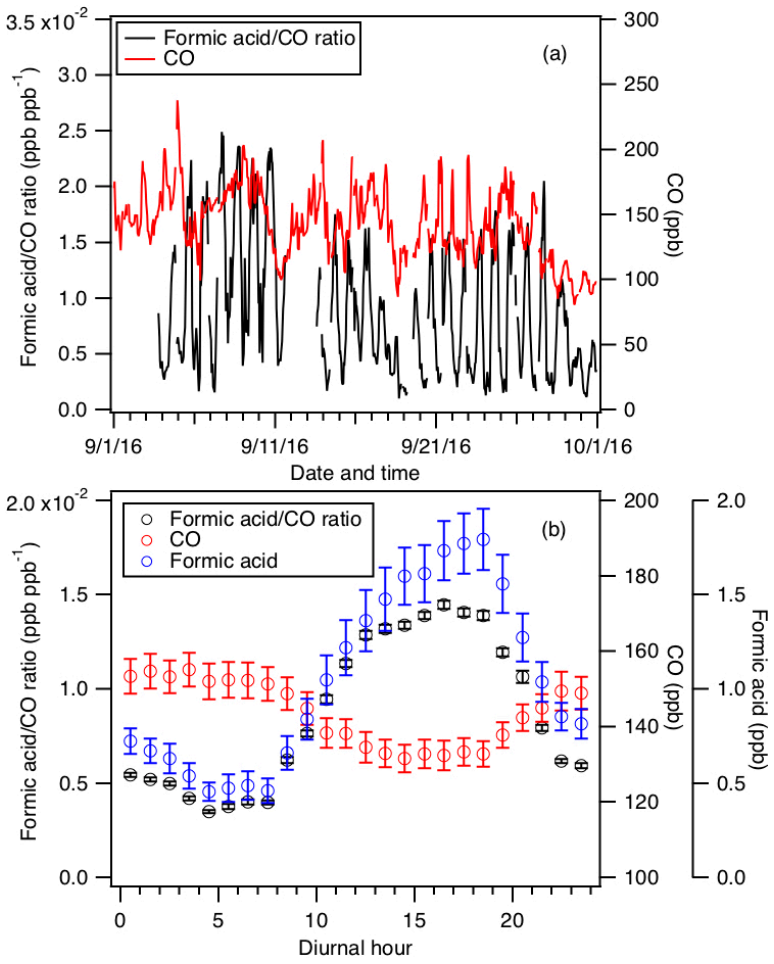
12. Referee's comment: "*line 406: how was water vapor dependence accounted for?*"

Author response: The water vapor dependence was accounted for using the linear relationship between the $F_2{}^{34}SO_2^-$ ion sensitivity and ambient water vapor concentration shown in Fig. S2c. This information has been added into the revised manuscript:

Page 14 line 438: "We accounted for water vapor dependence of the $F_2{}^{34}SO_2^-$ ion signal using the linear relationship between the $F_2{}^{34}SO_2^-$ ion sensitivity and ambient water vapor concentration (Fig. S2c) in our post-field calibrations, where the response of the CIMS acid signals were measured relative to the of the $^{34}SO_2$ sensitivity."

13. Referee's comment: "*section 3.2.1: ratios to CO may be helpful, in case transported air explains increase.*"

Author response: The formic acid/CO ratios ranged from 1.0 x 10^{-3} to 2.5 x10^{-2} ppb ppb^{-1}, with an average of 8.7 x 10^{-3} ± 5.8 x 10^{-3} ppb ppb^{-1}. The CO concentrations were consistently low during the study and ranged from 80 to 240 ppb, with consistent diurnal trends (see Fig. a below). Since the CO concentrations and diurnal profile have been published in another paper (Nah et al. 2018), they were not shown in this manuscript. Based on the diurnal profile of the formic acid/CO ratio (see Fig. b below), the formic acid/CO ratio peaks in the mid-afternoon, which coincides with when formic acid and CO reach their maximum and minimum, respectively.



Given that 1) the CO concentration did not spike during the field study, 2) the formic acid has a consistent diurnal profile, and 3) the formic acid/CO ratio time series is consistent with the diurnal trends of CO and formic acid, it is unlikely that the increase in that the increase in formic acid during the day can be explained by transported CO. This information has been added to the revised manuscript:

Page 21 line 702: "Formic acid/CO ratios (which have been used in some studies to determine the contribution of polluted air masses) ranged between 1.0 x 10^{-3} to 2.5 x10^{-2} ppb ppb^{-1}. The ratio peaked consistently in the mid-afternoon, which coincided with when formic acid and CO reached their maximum and minimum, respectively. In addition, there were no spikes in the formic acid/CO ratio during the study, suggesting that contributions of polluted air masses to the daily increase in formic acid are minimal."

14. Referee's comment: "*line 535: I don't understand comparison of organic ion signal to F2SO2 sensitivity. the ratio here isn't unitless.*"

Author response: We acknowledge that the units used are confusing. Hence, we will use the raw ion signals (Hz) of m/z 75, 87, 101, 103, 117 and 131 in the revised manuscript. The revised figures are shown in our reply to comment 1.

15. Referee's comment: "*line 559: what does zeroth order check mean?*"

Author response: It means that we checked that the estimated sum of organic carbon contributed by the measured organic acids is consistent with the total gas-phase water-soluble organic carbon ($WSOC_g$). Since the estimated carbon mass fractions of $WSOC_g$ comprised of these organic acids are generally less than 100 %, this suggests that our peak assignments are plausible. To remove any confusion, we have modified the aforementioned sentence in the revised manuscript:

Page 19 line 602: "This comparison primarily serves as a check to determine if the peak assignments are plausible by ensuring that the estimated sum of organic carbon contributed by these four organic acids is less than or equal to the measured $WSOC_g$."

16. Referee's comment: "*line 591: How long are these spikes? How close is the nearest power plant or urban area?*"

Author response: The SO_2 and HNO_3 spikes can last between 1 to 3 hours. The closest power plant was Plant Bowen, which was ~25 km north of the site. The closest urban center was Atlanta, which was ~55 km away. This information has been added to the revised manuscript:

Page 5 line 125: "Briefly, the Yorkville field site (33.931 N, 85.046 W) was located ~55 km northwest of Atlanta (the closest urban center), and was on a broad ridge in a large pasture where there were occasionally grazing cattle. The field site was surrounded by forest and agricultural land. There were no major roads near the field site and nearby traffic emissions were negligible. The closest power plant was Plant Bowen, which was located ~25 km north of the field site."

Page 20 line 669: "However, there were occasional periods when the site was impacted by anthropogenic pollution. In particular, there are spikes in both SO_2 and HNO_3 concentrations lasting between 1 to 3 hours throughout the study that corresponded to the site being impacted by power plant or urban emissions."

17. Referee's comment: "*line 663: what is a reasonable detection limit? give a number*"

Author response: Whether or not a detection limit is reasonable will depend on the species measured. In this study, our detection limits for the organic acids studied (1 to 60 ppt) are typically lower than the concentrations of the organic acids studied, allowing us to be reasonably confident of the concentrations measured. To remove any confusion, we have modified the aforementioned sentence in the revised manuscript:

Page 23 line 771: "Limits of detection ranged from 1 to 60 ppt for 2.5 min integration periods for the organic acids studied."

18. Referee's comment: "*Please define all acronyms at first use. I could not find definitions for m/z, slpm*."

Author response: These definitions have been added to the revised manuscript.

Real-time measurements of gas-phase organic acids using SF_6^- chemical ionization mass spectrometry

Abstract

The sources and atmospheric chemistry of gas-phase organic acids are currently poorly understood due in part to the limited range of measurement techniques available. In this work, we evaluated the use of SF_6^- as a sensitive and selective chemical ionization reagent ion for real-time measurements of gas-phase organic acids. Field measurements are made using a chemical ionization mass spectrometer (CIMS) at a rural site in Yorkville, Georgia from September to October 2016 to investigate the capability of this measurement technique. Our measurements demonstrate that SF_6^- can be used to measure a range of organic acids in the atmosphere. 1-hour averaged ambient concentrations of organic acids ranged from a few parts per trillion by volume (ppt) to several parts per billion by volume (ppb). All the organic acids displayed similar strong diurnal behaviors, reaching maximum concentrations between 5 and 7 pm local time. The organic acid concentrations are dependent on ambient temperature, with higher organic acid concentrations being measured during warmer periods.

Introduction

Organic acids are ubiquitous and important species in the troposphere. They are major contributors of free acidity in precipitation (Galloway et al., 1982; Keene et al., 1983; Keene and Galloway, 1984), and can also affect the formation of secondary organic aerosols (SOA) (Zhang et al., 2004; Carlton et al., 2006; Sorooshian et al., 2010; Yatavelli et al., 2015). As end products of oxidation, organic acids can also serve as useful tracers of air mass history (Sorooshian et al., 2007; Sorooshian et al., 2010). Organic acids are found in urban, rural and remote marine environments in the gas, aqueous and particle phases.

While organic acids are emitted directly from biogenic sources (e.g., microbial activity, vegetation and soil) and anthropogenic activities (e.g., fossil fuel combustion, vehicular emissions and biomass burning) (Kawamura et al., 1985; Talbot et al., 1988; Chebbi and Carlier, 1996; Talbot et al., 1999; Seco et al., 2007; Veres et al., 2010; Paulot et al., 2011; Veres et al., 2011; Millet et al., 2015), they can also be formed from photooxidation of non-methane volatile organic compounds and aqueous-phase photochemistry of semi-volatile organic compounds (Chebbi and Carlier, 1996; Hansen et al., 2003; Orzechowska and Paulson, 2005; Carlton et al., 2006; Sorooshian et al., 2007; Ervens et al., 2008; Paulot et al., 2011; Millet et al., 2015). The chemical aging of organic aerosols has also been proposed as a major source of organic acids (Molina et al., 2004; Vlasenko et al., 2008; Paulot et al., 2011). The relative importance of primary and secondary sources of organic acids are currently poorly constrained though their emissions likely depend on the magnitude of biogenic and anthropogenic activities and the meteorological conditions. Wet and dry deposition are the primary sinks of organic acids in the atmosphere (Chebbi and Carlier, 1996).

Formic and acetic acids are the dominant gas-phase monocarboxylic acids in the troposphere (Chebbi and Carlier, 1996). Due to their high vapor pressures, the gas-phase concentrations of formic and acetic acids are usually 1 to 2 orders of magnitudes higher than their particle-phase concentrations. Some field studies report strong correlations between formic and acetic acids, suggesting that these two organic acids have similar sources (Nolte et al., 1997; Souza and Carvalho, 2001; Paulot et al., 2011). A recent modeling study suggested that the dominant sources of formic acid in the southeastern U.S. are primarily biogenic in nature (Millet et al., 2015). These sources include direct emissions from vegetation and soil and photochemical production from biogenic volatile organic compounds (BVOCs). Currently, atmospheric formic and acetic acid concentrations are higher than those predicted by models, indicating that present model estimates of source and sink magnitudes are incorrect (Paulot et al., 2011; Millet et al., 2015). In the case of formic acid, deposition and secondary photochemical production via mechanisms such as photooxidation of isoprene and reaction of stabilized criegee intermediates need to be better constrained in models. Given that formic and acetic acids are major trace gases in the atmosphere, there is a need to resolve the discrepancy between measurements and

model predictions to close the atmospheric reactive carbon budget and improve our overall understanding of VOC chemistry in the atmosphere.

Currently, research on gas-phase organic acids has focused primarily on formic and acetic acids (Andreae et al., 1988; Talbot et al., 1988; Grosjean, 1991; Hartmann et al., 1991; Talbot et al., 1995; Talbot et al., 1999). This is due, in part, to the analytical difficulties in measuring gas-phase > C_2 organic acids and oxidized organic acids (i.e., containing more than 2 oxygen atoms) in real time. These organic acids have low vapor pressures and are generally present in low concentrations in the gas phase. For example, dicarboxylic acids typically have vapor pressures that are 2 to 4 orders of magnitude lower than their analogous monocarboxylic acids (Chebbi and Carlier, 1996), and are present mainly in the particle and aqueous phases. Rapid and accurate measurements of gas-phase > C_2 organic acids and oxidized organic acids are necessary for constraining the regional and global SOA budget since these acids can partition readily between the gas and particle and aqueous phases and subsequently affect SOA formation (Zhang et al., 2004; Carlton et al., 2006; Ervens et al., 2008; Sorooshian et al., 2010; Yatavelli et al., 2015).

Chemical ionization mass spectrometry (CIMS) is commonly used to selectively measure atmospheric trace gases in real-time with high sensitivity. CIMS measurements rely on reactions between reagent ions and compounds of interest present in the sampled air to produce analyte ions that are detected by a mass spectrometer. The subset of molecular species detected is determined by the reagent ion employed since the specificity of the ionization process is governed by the ion-molecule reaction mechanism. CIMS is a popular tool for atmospheric measurements since it is versatile and has high time resolution and sensitivity. It is also often a soft ionization technique with minimal ion fragmentation, thus preserving the parent molecule's elemental composition and allowing for molecular speciation. Recent developments in chemical ionization methods and sources have greatly improved our ability to measure atmospheric acidic species. Some of the CIMS reagent ions that have been used to measure atmospheric organic acids include acetate ($CH_3CO_2^-$), iodide (I^-) and CF_3O^- anions (Crounse et al., 2006; Veres et al., 2008; Lee et al., 2014; Brophy and Farmer, 2015; Nguyen et al., 2015). However, each of these CIMS reagent ions has its drawbacks, which are generally related to their selectivity and sensitivity

96 towards different atmospheric species. For example, acetic acid is difficult to measure with
97 $CH_3CO_2^-$ as the CIMS reagent ion due to interferences from the reagent ion chemistry that
98 complicates the desired ion-molecule reactions. In addition, while many organic acids can
99 be detected using I^- as a reagent ion, its sensitivity to different acids can vary by orders of
100 magnitude (Lee et al., 2014).

101 The sulfur hexafluoride (SF_6^-) anion has been used as a CIMS reagent ion to
102 measure atmospheric inorganic species such as sulfur dioxide (SO_2), nitric acid (HNO_3)
103 and peroxynitric acid (HO_2NO_2) (Slusher et al., 2001; Slusher et al., 2002; Huey et al.,
104 2004; Kim et al., 2007). SF_6^- commonly reacts with most acidic gases at the collision rate
105 by either proton or fluoride transfer reactions (Huey et al., 1995). The SF_6^- ion chemistry
106 is selective to acidic species, which can simplify the mass spectral analysis of organic acids.
107 However, SF_6^- is reactive to both ozone (O_3) and water vapor, which can lead to interfering
108 reactions that limit its applicability to many species in certain environments (Huey et al.,
109 2004). For these reasons, this work is focused on assessing the ability of SF_6^- to measure a
110 series of organic acids in ambient air. The major advantage that SF_6^- has over I^- and
111 $CH_3CO_2^-$ is that it allows for the detection of acetic acid and SO_2. CF_3O^- has a similar
112 chemistry to SF_6^- but it also has issues due to hydrolysis and the ion precursor is not
113 commercially available. We present ambient measurements of gas-phase organic acids
114 conducted in a mixed forest-agricultural area in Georgia in early fall of 2016 to evaluate
115 the performance of a SF_6^- CIMS technique. Gas-phase organic acid measurements are
116 compared to gas-phase water-soluble organic carbon ($WSOC_g$) measurements performed
117 during the field study to estimate the fraction of $WSOC_g$ that is comprised of organic acids
118 at this rural site. Laboratory experiments are conducted to measure the sensitivity of SF_6^-
119 with a series of organic acids of atmospheric relevance.

120 **2. Methods**

121 **2.1. Field site**

122 Real-time ambient measurements of gas-phase organic acids were obtained using a
123 chemical ionization mass spectrometer from 3 Sept to 12 Oct 2016 at the SouthEastern
124 Aerosol Research and Characterization (SEARCH) site located in Yorkville, Georgia. A

detailed description of the field site has been provided by Hansen et al. (2003). Briefly, the Yorkville field site (33.931 N, 85.046 W) was located ~55 km northwest of Atlanta (the closest urban center), and was on a broad ridge in a large pasture where there were occasionally grazing cattle. The field site was surrounded by forest and agricultural land. There were no major roads near the field site and nearby traffic emissions were negligible. The closest power plant was Plant Bowen, which was located ~25 km north of the field site. The sampling period was characterized by moderate temperatures (24.0 °C average, 32.6 °C max, 9.5 °C min) and high relative humidities (68.9 % RH average, 100 % RH max, 21.6 % RH min). The study-averaged diurnal trends of relative humidity, temperature and solar radiance are shown in Fig. S1. Data reported are displayed in EDT. Volumetric gas concentrations reported are at ambient temperature and relative humidity.

2.2. SF_6^- CIMS

2.2.1. CIMS instrument and air sampling inlet

The CIMS instrument was housed in a temperature-controlled trailer during the field study. The inlet configuration and CIMS instrument used in this study is shown in Fig. 1. Since HNO_3 and organic acids may condense on surfaces, an inlet configuration with a minimal wall interaction was used. This inlet configuration was previously described by Huey et al. (2004) and Nowak et al. (2006); hence, only a brief description will be provided here. The inlet was a 7.6 cm ID aluminum pipe that extended ~40 cm into the ambient air through a hole in the trailer's wall. This positioned the inlet ~2 m above the ground. A donut-shaped ring was attached to the ambient sampling port of the pipe to reduce the influence of crosswinds on the pipe's flow dynamics. This ring was wrapped with a fine wire mesh to prevent insects from being drawn through the pipe. A flow of ~2800 L min^{-1} was maintained in the pipe using a regenerative blower (AMETEK Windjammer 116637-03). Part of this flow (7 L min^{-1}) was sampled through a custom-made three-way PFA Teflon valve, which connected the pipe's center to the CIMS sampling orifice. The valve was maintained at a temperature of 40 °C in an insulated aluminum oven and could be switched automatically between ambient and background modes. In ambient mode, ambient air was passed through a 25 cm long, 0.65 cm ID Teflon

Deleted: temperature controlled

tube into the CIMS. In background mode, ambient air was first drawn through an activated charcoal scrubber before being delivered into the CIMS. A small flow of ambient air (~0.05 L min^{-1}) was continuously passed through the scrubber to keep it at equilibrium with ambient humidity levels. Most of the sampled air flow (6.7 L min^{-1}) was exhausted using a small diaphragm pump. The rest of the sampled air flow (0.3 L min^{-1}) was introduced into the CIMS instrument through an automatic variable orifice, which was used to maintain a constant sample air mass flow.

The CIMS instrument was comprised of a series of differentially pumped regions: a flow tube, a collisional dissociation chamber, an octopole ion guide, a quadrupole mass filter and an ion detector. These sections were evacuated by a scroll pump (Edward nXDS 20i), a drag pump (Adixen MDP 5011) and two turbo pumps (Varian Turbo-V301), respectively. Ambient air was drawn continuously into the flow tube. A flow of 3.7 standard liter per minute (slpm) of N_2 containing a few ppm of SF_6 (Scott-Marrin Inc.) was passed through a ^{210}Po ion source into the flow tube. SF_6^- anions, which were produced via associative electron attachment in the ^{210}Po ion source, reacted with the sampled ambient air in the flow tube to generate analyte ions. Arnold and Viggiano (2001) showed that the formation of $F^-•(HF)_n$ cluster ions from the reaction of SF_6^- and water vapor is enhanced at high flow tube pressures. Since these $F^-•(HF)_n$ cluster ions could interfere with mass spectral analysis, the flow tube was maintained at a low pressure (~13 mbar, 0.5 % uncertainty) in this study to reduce both the water vapor concentration and reaction time in the flow tube, thus minimizing interferences from SF_6^- reaction with water vapor. The analyte ions exited the flow tube and were accelerated through the collisional dissociation chamber (CDC), which was maintained at ~0.8 mbar (10 % uncertainty). The molecular collisions in the CDC served to dissociate weakly bound cluster ions into their core ions to simplify mass spectral analysis. Flow tube and CDC pressures were controlled by the automatic variable orifice. For this study, the CDC was operated at a relatively high electric field (~113 V cm^{-1}) to efficiently dissociate cluster ions. The resulting ions were then passed into the octopole ion guide (maintained at ~6 x 10^{-3} mbar), which collimated the ions and transferred them into the quadrupole mass spectrometer (maintained at ~10^{-5} mbar) for mass selection and detection. It should also be noted that we always used gloves when working on the CIMS during this study to limit contamination of lactic acid

emissions from human skin. In addition, we kept people away from the front of the SF_6^--CIMS sampling inlet to minimize lactic acid interferences as well.

Ions monitored during the field study included mass-to-charge ratio (m/z) 45, 59, 65, 73, 75, 79, 82, 87, 89, 101, 102, 103, 108, 117, 131 and 148. The assignment of these ions will be discussed in section 3. The dwell time for each m/z ion was set to 0.5 s and measurements of these ions were obtained every ~13 s, which resulted in a ~4 % (= 0.5/13 x 100 %) duty cycle for each ion monitored. The data presented in this paper was averaged to 1-hour intervals unless stated otherwise.

2.2.2. Background and calibration measurements during field study

Background measurements were performed every 25 min during the field study. During each background measurement, the sampled air flow was passed through an activated charcoal scrubber prior to delivery into the CIMS. The scrubber removed > 99 % of the targeted species in ambient air. Calibration measurements were performed every 5 h during the field study through standard additions of $^{34}SO_2$ and either formic or acetic acid to the sampled air flow. Each background and calibration measurement period lasted ~4 and ~3.5 min, respectively, which not only gave the scrubber (during background measurements) and flow tube ample time to equilibrate when the three-way PFA Teflon valve was switched between ambient and background modes, but also allowed us to obtain good averaging statistics during background and calibration measurements. A 1.12 ppm $^{34}SO_2$ gas standard was used as the source of the sulfur standard addition. 1.85 ppb of $^{34}SO_2$ was added to sampled air flow during calibration measurements. The formic and acetic acid calibration sources were permeation tubes (VICI Metronics) with emission rates of 91 and 110 ng min^{-1}, respectively. The emission rates were measured by scrubbing the output of the permeation tube in deionized water via a gas impinger immersed in water, which was then analyzed for formate and acetate using ion chromatography (Thermo Fisher Scientific). Eight samples of each acid were analyzed over the course of the field study and the standard deviations of the permeation rates were ≤ 6 %. 6.75 ppb of formic acid and 5.87 ppb of acetic acid was added to sampled air flow during calibration measurements. The CIMS instrument sensitivity measured by the $F_2{}^{34}SO_2^-$ ion signal (m/z 104) was similarly applied to all the other measured species (except for formic and acetic acids)

using relative sensitivities determined in laboratory studies. The $F_2{}^{34}SO_2^-$ calibrant ion signals were also used to calibrate ambient $F_2{}^{32}SO_2^-$ ion signals and determine ambient SO_2 concentrations as discussed in section 3.2.5.

2.2.3. Laboratory calibration

To estimate the levels of sensitivities for a series of acids of atmospheric relevance, HNO_3, oxalic, butyric, glycolic, propionic and valeric acid standard addition calibrations were performed in post-field laboratory work. Many of these acids have previously been measured in rural and urban environments (Kawamura et al., 1985; Veres et al., 2011; Brophy and Farmer, 2015). The response of the CIMS acid signals were measured relative to the sensitivity of $^{34}SO_2$ in these calibration measurements. The HNO_3 calibration source was a permeation tube (KIN-TEK) with a permeation rate of 39 ng min^{-1}, which was measured using UV optical absorption (Neuman et al., 2003). Solid or liquid samples of oxalic (Sigma Aldrich, ≥ 99 %), butyric (Sigma Aldrich, ≥ 99 %), glycolic (Sigma Aldrich, 99 %), propionic (Sigma Aldrich, ≥ 99.5 %) and valeric (Sigma Aldrich, ≥ 99 %) acids were used in calibration measurements. The acid sample was placed in a glass impinger, which was immersed in an ice bath to provide a constant vapor pressure. A flow of 6 to 10 mL min^{-1} of N_2 was passed over the organic acid in the glass impinger. This organic acid air stream was then diluted with varying flows of N_2 (1 to 5 L min^{-1}) to achieve different mixing ratios of the organic acid. Mixing ratios were calculated from either the acid's emission rate from the impinger or the acid's vapor pressure. The emission rate of gas-phase oxalic acid from the impinger was measured by scrubbing the output in deionized water using the same method for calibrating the formic and acetic acid permeation tubes, followed by ion chromatography analysis for oxalate. Three samples were analyzed and the emission rate was determined to be 14 ng min^{-1} with a standard deviation of < 5 %. The vapor pressures of butyric and propionic acids at 0 ˚C were measured using a capacitance manometer (MKS Instruments). The vapor pressures of glycolic and valeric acids at 0 ˚C were estimated using their literature vapor pressures at 25 ˚C and enthalpies of vaporization (Daubert and Danner, 1989; Lide, 1995; Acree and Chickos, 2010).

Attempts to generate a calibration plot for pyruvic acid using its liquid sample (Sigma Aldrich, 98 %) and the setup described above were unsuccessful as this acid was

found to interact very strongly with surfaces. Glyoxylic acid calibrations were not performed due to the presence of impurities in the glyoxylic acid monohydrate solution used (Sigma Aldrich, 98 %), which resulted in the appearance of ions not attributed to glyoxylic acid. We attempted to generate calibration plots for malonic (Sigma Aldrich, ≥ 99.5 %), succinic (Sigma Aldrich, 99 %) and glutaric (Sigma Aldrich, 99 %) acids by passing N_2 over their solid samples at room temperature. However, it was not possible to generate large enough gas phase concentrations for calibration since these organic acids have very low vapor pressures. The vapor pressures of malonic, succinic and glutaric acids are 5.73 x 10^{-4}, 1.13 x 10^{-4} and 4.21 x 10^{-4} kPa at 298 K, respectively (Booth et al., 2010), which are at least 2 orders of magnitude lower than the organic acids that we calibrated. Although heating up the malonic, succinic and glutaric acid samples will likely generate sufficient vapors for calibration, this method of generating calibrant gases will lead to large measurement uncertainties due to vapors condensing out and adhering onto surfaces at room temperature prior to introduction into the CIMS.

2.2.4. Detection limits and measurement uncertainties

The detection limits of the organic acids were estimated as 3 times the standard deviation values (3σ) of the ion signals measured during background mode. Although each background measurement period lasted ~4 min, ion signals of the different organic acids took up to 1.5 min to stabilize during the switch between ambient, calibration and background measurements during the field study. Thus, ion signals measured during the first 1.5 min were not included in the calculation of the average and standard deviation of ion signals measured during background mode. Table 1 summarizes the average detection limits of calibrated organic acids for 2.5 min averaging periods which corresponds to the length of a background measurement with a 4 % duty cycle for each m/z. The mean difference between successive background measurements ranged from 1 to 40 ppt for the different organic acids. Future work will focus on reducing the instrument background, and therefore improving the detection limits of these organic acids.

The uncertainties (1σ) in our ambient measurements of formic, acetic and oxalic acid concentrations originated from CIMS and ion chromatography calibration measurements. The ion chromatography measurement uncertainty was estimated to be 10

Deleted: the

Deleted: IC

Deleted: IC

%. For formic and acetic acids, which were calibrated during the field study using permeation tubes, their CIMS measurement uncertainties were estimated to be 6 and 7 %, respectively, based on one standard deviation of the acids' calibrant ion signals. For oxalic acid, which was calibrated in post-field laboratory work, the CIMS measurement uncertainty was estimated to be 9 % based on one standard deviation of the $^{34}SO_2$ sensitivity (3 %), the acid's calibrant ion signals (7 %) and linear fit of the calibration curve (5 %). Hence, the uncertainties in our ambient measurements of formic, acetic and oxalic acid concentrations were estimated to be 12, 12 and 14 %, respectively.

For nitric acid, which was calibrated in post-field laboratory work using a permeation tube and UV optical absorption, the uncertainty in its ambient concentrations was estimated to be 13 % based on uncertainties in UV absorption measurements (10 %) and one standard deviation of the acid's UV absorption signals (3 %), $^{34}SO_2$ sensitivity (3 %) and acid's calibrant ion signals (8 %). For propionic acid, which was calibrated in post-field laboratory work using vapor pressures measured by a capacitance manometer, the uncertainty in its ambient concentrations was estimated to be 14 % based on the vapor pressure measurement uncertainty (10 %) and one standard deviation of the $^{34}SO_2$ sensitivity (3 %), the acid's calibrant ion signals (8 %) and linear fits of the acid's calibration curves (3 %). Ambient concentrations and the corresponding uncertainties of glycolic, valeric and butyric acids were not quantified.

2.3. $WSOC_g$ measurements

$WSOC_g$ was measured with a MIST chamber coupled to a total organic carbon (TOC) analyzer (Sievers 900 series, GE Analytical Instruments). Ambient air first passed through a Teflon filter (45 mm diameter, 2.0 μm pore size, Pall Life Sciences) to remove particles in the air stream. This filter was changed every 3 to 4 days. The particle-free air was then pulled into a glass Mist Chamber filled with ultrapure deionized water at a flow rate of 20 L min^{-1}. The MIST chamber scrubbed soluble gases with Henry's law constants greater than 10^3 M atm^{-1} into deionized water (Spaulding et al., 2002). The resulting liquid samples from the MIST chamber were analyzed by the TOC analyzer. The TOC analyzer converted the organic carbon in the liquid samples to carbon dioxide using UV light and chemical oxidation. The carbon dioxide formed was then measured by conductivity. The

Deleted: '

Deleted: '

Deleted: For glycolic and valeric acids which were calibrated in post-field laboratory work using vapor pressures estimated from literature vapor pressures at 25 °C and enthalpies of vaporization, the uncertainties in their ambient concentrations were likely significantly larger compared to the other measured organic acids due to uncertainties in their estimated vapor pressures. We estimate the uncertainties in ambient concentrations of glycolic and valeric acids to be 22 % based on an assumed vapor pressure uncertainty of 20 % and one standard deviation of the $^{34}SO_2$ sensitivity (3 %), the acids' calibrant ion signals (8 %) and linear fits of the acids' calibration curves (2 %).

amount of organic carbon in the liquid samples is proportional to the measured increase in conductivity of the dissolved carbon dioxide. Each $WSOC_g$ measurement lasted 4 min. Background $WSOC_g$ measurements were performed for 45 min every 12 h by stopping the sample air flow and rinsing the sampling lines with deionized water. The TOC analyzer was calibrated using different concentrations of sucrose (as specified by the instrument manual) before and after the field study. The limit of detection was 0.4 μgC m^{-3}. The measurement uncertainty was estimated to be 10 % based on uncertainties in the sample air flow, liquid flow and TOC analyzer uncertainty. The MIST chamber and upstream particle filter were located in an air-conditioned building so were generally below ambient temperature. Hence, evaporation of collected particles (which will lead to positive artifacts in $WSOC_g$ measurements) are not expected to be significant.

2.4. Supporting gas measurements

Supporting gas measurements were provided by a suite of instruments operated by the SEARCH network. A non-dispersive infrared spectrometer (Thermo Fisher Scientific) provided hourly CO measurements. A UV absorption analyzer (Thermo Fisher Scientific) provided hourly O_3 measurements. A gas chromatography-flame ionization detector (GC-FID, Agilent Technologies) provided hourly VOC measurements.

3. Results and discussion

3.1. General SF_6^- CIMS field performance

3.1.1. SF_6^- ion chemistry with organic acids

CIMS measurements of atmospheric constituents use ion-molecule reactions to selectively ionize compounds of interest in the complex matrix of ambient air and produce characteristic ions. The reactions of SF_6^- with the organic acids (HX) proceed through reactions 1a to 1c, and gave similar products to those reported previously for SF_6^- reactions with inorganic acids (Huey et al., 1995): SF_5^-, X^- and X^-•HF where X^- is the conjugate base of the organic acid (reactions 1a-c).

$$SF_6^- + HX \rightarrow X^-\bullet HF + SF_5 \quad (1a)$$

$SF_6^- + HX \rightarrow X^- + HF + SF_5$ (1b)

$SF_6^- + HX \rightarrow SF_5^- + HF + X$ (1c)

The effective branching ratios of the SF_5^-, X^- and X^-•HF product ions can be impacted by the field strength of the CDC. The SF_5^- ion (m/z 127, reaction 1c) is a common reaction product of the reactions of SF_6^- with many species and is probably thermodynamically driven by the formation of HF (Huey et al., 1995). Unfortunately, the production of SF_5^- does not allow for the selective detection of any atmospheric species. In addition, the larger the branching ratio of the SF_5^- channel, the lower the CIMS sensitivity is to an individual acid since the effective rate constants for the X^- and X^-•HF channels are lower.

The reaction of SF_6^- with formic acid and oxalic acid also produced SF_4^- ions (m/z 108). These reactions are probably thermodynamically driven by the formation of CO_2 and HF:

$SF_6^- + HC(O)OH \rightarrow SF_4^- + CO_2 + 2HF$ (2)

$SF_6^- + HO(O)CC(O)OH \rightarrow SF_4^- + 2CO_2 + 2HF$ (3)

We used the X^- and/or X^-•HF ions to determine ambient organic acid concentrations since these ions are characteristic of the individual acids. For all the organic acids, the X^-•HF ion signal is substantially lower than that of the X^- ion for the conditions in this study. However, this is probably largely due to the relatively high collision energy used in the CDC, which led to efficient dissociation of the fluoride adducts to form X^- ions. Consequently, only the proton transfer channel (1b) is used to quantify most of the organic acids in the field study. The exceptions are formic and acetic acid as discussed in section 3.2.1 and 3.2.2

Table 1 shows a summary of the sensitivities of X^- and X^-•HF ions of some common atmospheric organic acids. The average sensitivities of the $HCOO^-$ (m/z 45) and $HCOO^-$•HF (m/z 65) ions of formic acid were 1.29 ± 0.22 and 0.29 ± 0.05 Hz ppt^{-1}, respectively, while the average sensitivities of the CH_3COO^- (m/z 59) and CH_3COO^-•HF (m/z 79) ions of acetic acid were 1.46 ± 0.29 and 0.30 ± 0.06 Hz ppt^{-1}, respectively. A weak ^{210}Po ion source (< 1 mCi) was used by SF_6^--CIMS instrument during the field study, hence these

sensitivities will be substantially higher if a stronger radioactive source is used. Post-field laboratory work suggest that the sensitivities may increase by as much as a factor of 5 for a new commercial 20 mCi ^{210}Po ion source. Nevertheless, these sensitivities are compared to formic and acetic acid sensitivities measured by a high-resolution time-of-flight chemical ionization mass spectrometer (Aerodyne Research Inc.) that utilized I^- reagent ions during the field study. Although the formic acid sensitivity measured by I^--CIMS (1.33 ± 0.28 Hz ppt^{-1}) was comparable to that measured by SF_6^--CIMS, the acetic acid sensitivity measured by I^--CIMS (< 0.1 Hz ppt^{-1}) was substantially lower than that measured by SF_6^--CIMS. Previous studies have similarly reported low acetic acid sensitivity measured by I^--CIMS (Aljawhary et al., 2013; Lee et al., 2014).

3.1.2. Characterization of interferences

SF_6^- is very sensitive to many trace atmospheric species but its reactions with water vapor and O_3 when sampling ambient air can lead to issues both with selectivity and stability. For example, SF_6^- reacts nonlinearly with water vapor to form a series of $F^-•(HF)_n$ cluster ions (Huey et al., 1995; Arnold and Viggiano, 2001). SF_6^- also reacts efficiently with O_3 to form O_3^-, which is rapidly converted to CO_3^- in ambient air (Slusher et al., 2001). These reactions can deplete SF_6^- as well as form a variety of potentially interfering ions from secondary reactions (e.g., $F^-•(HF)_n$ and CO_3^- ions) that depend on more abundant atmospheric species. For these reasons, efforts were made to minimize interferences by limiting reaction times and the flow sampled into the CIMS. This was accomplished by sampling only 0.3 L min^{-1} of air through the variable orifice into the flow tube and maintaining the flow tube at a low pressure (~13 mbar). The 0.3 L min^{-1} sampled air flow is diluted by 3.7 slpm of N_2/SF_6 flow in the flow tube. The ratio of the sampled air flow to the N_2/SF_6 flow introduced into the flow tube is approximately 1:13. While the high N_2/SF_6 flow (3.7 slpm) passed through the radioactive source into the flow tube increased the SF_6^- reagent ion signal, the high dilution of the sampled air flow in the flow tube reduced the CIMS instrument sensitivity by decreasing the number density of the analytes.

Figure 2 shows a mass spectrum of ambient air. Interference peaks at m/z 39 (F^-•(HF) and CO_3^-, respectively) can be attributed to the presence of water and O_3, respectively. The reagent ion $^{32}SF_6^-$ is present at m/z 146. The $^{32}SF_6^-$ reagent ion signal was

saturated, and this caused the sharp drop in the m/z 146 signal as shown in Fig. 2. Since the $^{32}SF_6^-$ reagent ion signal was saturated for the entire field study, we monitored the ion signal of its isotope $^{34}SF_6^-$ to determine if the reaction of SF_6^- with ambient water vapor (5.92×10^{-6} to 2.19×10^{-5} g cm^{-3}) and O_3 (2.1 to 82.4 ppb) depleted SF_6^- reagent ions. Figure S2a shows the time series of the $^{34}SF_6^-$ ion signal and ambient water vapor concentration for the entire field study. Despite fluctuations in ambient water vapor and O_3 concentrations, the $^{34}SF_6^-$ ion signal was relatively constant for the entire field study with a standard deviation of < 3%. This indicates that the reaction of SF_6^- with ambient water vapor and O_3 did not significantly deplete the $^{32}SF_6^-$ reagent ions during the field study.

The $F_2{}^{34}SO_2^-$ ion signal was used to monitor the CIMS SO_2 sensitivity during the field study. Figure S2b shows the time series of the $F_2{}^{34}SO_2^-/{}^{34}SF_6^-$ ion signal ratio obtained in calibration measurements. There is a ~50 % increase in the $F_2{}^{34}SO_2^-/{}^{34}SF_6^-$ ion signal ratio on 28 Sept 2016, indicating an increase in the CIMS instrument sensitivity. The increase in CIMS instrument sensitivity is due to the decrease in ambient water vapor concentrations on 28 Sept 2016 (Fig. S2a). Previous laboratory and field studies showed that this was due to the hydrolysis of $F_2{}^{34}SO_2^-$, which led to the loss of this ion and diminished sensitivity at higher levels of ambient water vapor (Arnold and Viggiano, 2001; Slusher et al., 2001). However, the SO_2 sensitivity at $F_2{}^{34}SO_2^-$ only varied within a factor of two for the entire field study with a clear relationship to water vapor (Fig. S2c). The SO_2 sensitivity did not show any obvious dependence on ambient O_3 concentrations (Fig. S2d).

Deleted: noticeable

The formic ($HCOO^-$ at m/z 45 and $HCOO^-$•HF at m/z 65) and acetic (CH_3COO^- •HF at m/z 79) acid ions did not show any obvious dependence on ambient water vapor and O_3 concentrations during calibration measurements (Fig. S3). Therefore, we do not expect the sensitivities of the X^- and X^-•HF ions of the studied organic acids to depend on ambient water vapor and O_3 concentrations. We accounted for water vapor dependence of the $F_2{}^{34}SO_2^-$ ion signal using the linear relationship between the $F_2{}^{34}SO_2^-$ ion sensitivity and ambient water vapor concentration (Fig. S2c) in our post-field calibrations, where the response of the CIMS acid signals were measured relative to the of the $^{34}SO_2$ sensitivity.

3.1.3. Background and calibration measurements

Figure S4 shows an example of the CIMS instrument response during the switch between background, calibration and ambient measurements of formic and acetic acids during the field study. The 13 s time resolution data was used to determine the CIMS instrument time response. Formic (m/z 45, 65 and 108) and acetic (m/z 79) acid ion signals took ~1.5 min to reach a steady state after switches between ambient, calibration and background measurements (Figs. S4a and S4c).

The CIMS time response to a compound is governed primarily by the compound's propensity to adhere to surfaces. The decays in the formic and acetic acid ion signals and times required for them to reach steady state after the removal of calibration gases during the switch from standard addition calibration to ambient sampling were used to determine the CIMS response time. The signal decays were fitted using double exponential functions. For formic acid, the m/z 45, 65 and 108 ion signals decayed to $1/e^2$ in 37 ± 2, 33 ± 2 and 32 ± 2 s, respectively (Fig. S4b). For acetic acid, the m/z 79 ion signal decayed to $1/e^2$ in 42 ± 2 s (Fig. S4d).

Formatted: Level 1

3.2. Ambient measurements

3.2.1. Formic acid

Figure 2 shows typical mass spectra obtained under background and measurement modes during the field study. The SF_6^- reagent ion is present at m/z 146. One of the prominent species in the mass spectrum is formic acid, which is detected as $HCOO^-$ and $HCOO^-$•HF at m/z 45 and 65, respectively. Our laboratory studies demonstrated that the reaction of formic acid with SF_6^- also produced a large fraction of SF_4^- ions at m/z 108. The reaction of SF_6^- with oxalic acid also produced SF_4^- ions, but its SF_4^- product ion yield is low and gas phase oxalic acid is not present in large concentrations. In addition, SF_4^- is present in the mass spectrum obtained under background mode but the SF_4^- background ion signals are lower than those typically observed in measurement mode at the Yorkville site. As a result, we determined the ambient formic acid concentrations using the $HCOO^-$, $HCOO^-$•HF and SF_4^- ions. Figure 3a shows a scatter plot comparing the ambient formic acid concentrations measured at Yorkville using the $HCOO^-$, $HCOO^-$•HF and SF_4^- ions. Linear regression analysis reveals that the formic acid concentrations determined by the

three ions are highly correlated (R^2 = 0.99) with slopes exhibiting a near 1:1 correlation. The excellent correlation between these three ions and the agreement with laboratory data indicates that formic acid is selectively measured by this method.

The time series of formic acid, temperature and solar radiation measured at Yorkville are shown in Fig. 3b. Formic acid concentrations ranged from 40 ppt to 4 ppb during the field study, with strong and consistent diurnal trends. The day-to-day variability in formic acid concentrations are associated with changes in solar radiation and temperature. Higher formic acid concentrations are measured during warm and sunny days, similar to formic acid measurements performed in Centreville, rural Alabama during the 2013 Southern Oxidant Aerosol Study (SOAS) (Brophy and Farmer, 2015; Millet et al., 2015). Figure 3c shows the study-averaged diurnal profiles of formic acid and solar irradiance. Formic acid started to increase at 7:30, which coincided with a sharp increase in solar irradiance. Concentrations continued to increase throughout the day and peaked at 18:30, which coincided with the approximate time just before solar irradiance reached zero. Formic acid then decreased continuously throughout the night.

The immediate early-morning increase in formic acid observed in this field study is similar to that seen during the SOAS study (Millet et al., 2015). However, there are some differences in the formic acid diurnal cycles measured in this field study and the SOAS study. Formic acid peaked at 15:30 during SOAS, approximately 3 hours before solar irradiance decreased to zero. In contrast, formic acid concentrations only started to decrease at sunset (at 19:30) in this study. This suggests that there may be differences in the types and/or magnitudes of formic acid sources and sinks in this two field studies. Land cover and/or land use differences may have contributed to differences in formic acid sources and sinks at the Centreville and Yorkville field sites. The area surrounding the Yorkville field site is covered primarily by hardwood mixed with farmland and open pastures. In contrast, the Centreville field site is surrounded by forests comprised of mixed oak-hickory and loblolly trees (Hansen et al., 2003). It is also possible that seasonal differences contributed to differences in formic acid sources and sinks in the two field studies. The SOAS campaign took place in the middle of summer (1 June to 15 July 2013) when biogenic emissions are typically higher while this field study took place in early fall

503 when biogenic emissions are lower due to cooler temperatures. For example, the average
504 concentration of isoprene (a formic acid source) in this study (1.21 ppb) is lower than that
505 in SOAS (1.92 ppb (Millet et al., 2015)). Despite these differences, our overall results are
506 similar to the formic acid measurements performed in SOAS in both magnitude and diurnal
507 variability.

508 **3.2.2. Acetic acid**

509 Acetic acid is detected with SF_6^- as CH_3COO^- and CH_3COO^-•HF at m/z 59 and 79,
510 respectively. However, these ions are subject to interferences from the reaction of SF_6^- with
511 water vapor present in the sampled ambient air. Two of these interfering ions F^-•$(HF)_2$ and
512 F^-•$(HF)_3$ occur at m/z 59 and 79, respectively. As discussed earlier, we minimized the
513 impact of these interferences by diluting the sample flow into the CIMS and running the
514 CDC at a high collision energy to dissociate the HF cluster ions. As expected from cluster
515 bond strengths, we found that larger HF cluster ions dissociated more easily than smaller
516 ones. For example, at a CDC electric field of ~113 V cm^{-1} (the configuration used in this
517 field study), virtually all of the F^-•$(HF)_3$ cluster ions dissociated while very few of the F^-
518 •(HF) cluster ions dissociated. This indicates that the m/z 79 channel for acetic acid is more
519 immune to interference from water vapor than the m/z 59 channel. This is supported by the
520 observation that the background ion signal at m/z 59 (R^2 = 0.50) is more highly correlated
521 with ambient water vapor concentrations than the background ion signal of m/z 79 (R^2 =
522 0.30). In addition, the m/z 59 ion is subjected to interference from the reaction of SF_6^- with
523 O_3 present in the sampled ambient air. SF_6^- reacts with O_3 in the presence of CO_2 to form
524 CO_3^- at m/z 60 (Slusher et al., 2001). As shown in Fig. 2, the large CO_3^- peak at m/z 60 is
525 a potential interference to the m/z 59 signal. As the background scrubber also removed O_3
526 from the ambient air, there is a large difference in the m/z 60 ion signal between the
527 measurement and background modes (~100,000 Hz). Thus, even a few percent bleed over
528 of m/z 60 to m/z 59 can lead to an over-estimation of ambient acetic acid concentrations.
529 For these reasons, we used m/z 79 (X^-•HF) to determine ambient acetic acid concentrations
530 even though this channel has a lower sensitivity than the m/z 59 channel (X^-).

Deleted: ,

531 The time series of acetic acid, temperature and solar radiation measured at
532 Yorkville are shown in Fig. 4a. Acetic acid concentrations ranged from 30 ppt to 3 ppb

during the field study. The day-to-day variability in acetic acid concentrations resembled the behavior of formic acid concentrations, with higher concentrations being measured during warm and sunny days. Figure 4b shows the study-averaged diurnal profiles of acetic acid and solar irradiance. The diurnal profile of acetic acid is similar to that of formic acid with a more pronounced evening maximum. Acetic acid started to increase at 7:30 and built up through the day, peaking at 19:30 and decreased continuously overnight. In general, acetic acid concentrations are well correlated with (R^2 = 0.67) and comparable in magnitude (~60 % on average) to formic acid. The study-averaged formic acid/acetic acid concentration ratio (1.65) is comparable to ratios from previous field studies in rural and urban environments (Talbot et al., 1988; Talbot et al., 1995; Granby et al., 1997; Khare et al., 1999; Talbot et al., 1999; Baboukas et al., 2000; Singh et al., 2000; Kuhn et al., 2002; Baasandorj et al., 2015; Millet et al., 2015).

3.2.3. Larger organic acids

In addition to formic and acetic acid, eight other ions were monitored during the field study: m/z 73, 75, 87, 89, 101, 103, 117 and 131. These ions were chosen as they had significant signals when ambient air was sampled and were not obviously formed from SF_6^- reaction with water vapor or O_3. Since the CIMS utilized in this study only had unit mass resolution, these ions are the sum of all organic acid isomers and isobaric organic acids of the same molecular weight as well as other product ions from species that might react with SF_6^-. We will refer to organic acids with m/z 75, 87, 101, 103, 117 and 131 by their ion masses. We assign the m/z 73 ion as the X^- ion of propionic acid because it does not have organic acid isomers and isobaric species at that m/z. In addition, real-time ion chromatography measurements of aerosol composition performed during the field study demonstrated the presence of particulate oxalic acid (Nah et al., 2018). For this reason, we assign the m/z 89 ion as the X^- ion of oxalic acid. As shown in Nah et al. (2018), the gas-particle ratios of the organic acids depend of their thermodynamic conditions, which are dependent on the acid's physicochemical properties, ambient temperature, particle water and pH. Since the measured gas-particle partitioning ratios of oxalic acid (calculated using the CIMS and ion chromatography measurements) are in good agreement with their corresponding thermodynamic predictions (Nah et al., 2018), this indicated that our

Deleted: malonic, succinic and glutaric

Deleted: s, respectively

assignment of the m/z 89 ion to oxalic acid is reasonable. In addition, the high sensitivity of SF_6^- to oxalic acid also helps limit interferences due to other acids. Particulate formic acid and acetic acid were also detected by ion chromatography during the field study, but were at much lower concentrations relative to the gas phase (Nah et al., 2018).

Figures 5 and S5 show the time series and diurnal profiles of oxalic and propionic acids and organic acids with ions m/z 75, 87, 101, 103, 117 and 131 measured during the field study. These organic acids displayed very similar day-to-day variability as formic and acetic acids, with higher concentrations (or ion signals) being measured on warm and sunny days. The diurnal profiles of all the measured organic acids have similar diurnal trends, with their concentrations (or ion signals) reaching a maximum between 17:30 and 19:30 and rapidly decreasing after sunset.

3.2.4. Comparison with $WSOC_g$

$WSOC_g$ measurements were performed during the field study using a MIST chamber coupled to a TOC analyzer. The study average $WSOC_g$ was 3.6 ± 2.7 μgC m^{-3}, slightly lower than that measured during the SOAS study (4.9 μgC m^{-3}) (Xu et al., 2017), and approximately four times lower than that measured in urban Atlanta, Georgia (13.7 μgC m^{-3}) (Hennigan et al., 2009). Despite being comparable in magnitude, the diurnal profiles of $WSOC_g$ measured in this study and the SOAS study are different. $WSOC_g$ measured in the SOAS study decreased at sunset, while $WSOC_g$ measured in this study decreased 2 hours after sunset. Differences in $WSOC_g$ concentrations and diurnal profiles at the three different sites may be due to differences in emission sources as a result of different measurement periods, land use and/or land cover.

To estimate the fraction of $WSOC_g$ that is comprised of organic acids, the total organic carbon contributed by formic, acetic, oxalic and propionic acids is compared to the $WSOC_g$ measurements. This comparison primarily serves as a check to determine if the peak assignments are plausible by ensuring that the estimated sum of organic carbon contributed by these four organic acids is less than or equal to the measured $WSOC_g$. Figures 6a and 6b show the time series and diurnal profiles of $WSOC_g$ and the organic carbon contributed by the four organic acids. Formic and acetic acids comprised majority

Deleted: As these organic acids have low vapor pressures, their gas-phase concentrations are expected to be lower than their particle-phase concentrations, though their gas-particle ratios will depend on thermodynamic conditions (Nah et al., 2018).

Deleted: For simplicity, we also denoted m/z 73, 75, 87 and 101 ions as X^- ions of propionic, glycolic, butyric and valeric acids, respectively, for the remainder of this paper. These organic acids have previously been measured in rural and urban environments (Kawamura et al., 1985; Veres et al., 2011; Brophy and Farmer, 2015). However, we note that these assignments are speculative. Post-field calibration measurements were used to estimate the ambient concentrations of these organic acids.

Deleted: ,

Deleted: butyric, glycolic, propionic and valeric acids

Deleted: Daytime concentrations of these organic acids ranged from a few tens of ppt to several hundred ppt. The time series of ion signals (Hz) of malonic, succinic and glutaric acids normalized to the instrument's sensitivity to $F_2^{34}SO_2$ (Hz ppb^{-1}) are shown in Fig. S3. The ion signals of these organic acids are 1 to 2 orders of magnitude smaller than the sensitivity of the $F_2^{34}SO_2^-$ ion (study-averaged sensitivity = 2928 ± 669 Hz ppb^{-1}), resulting in these ratios to be less than 1. Concentrations of these organic acids are not available since calibrations were not performed for these compounds.

of the total organic carbon contributed by the four organic acids (study averages of 41 and 54 %, respectively). The carbon mass fraction of $WSOC_g$ comprised of these four organic acids ranged from 2 to 100 %. Based on the orthogonal distance regression slope shown in Fig. 6c, the study-averaged carbon mass fraction of $WSOC_g$ comprised of the four organic acids is 22 %. The total organic carbon contributed by the four organic acids are moderately correlated with $WSOC_g$ (R^2 = 0.42). This is likely due to the presence of other water-soluble gas phase species (with different day-to-day variability from the organic acids) that contribute to the $WSOC_g$. This is supported by slight differences in the diurnal profiles of $WSOC_g$ and the organic carbon contributed by the organic acids (Fig. 6b). While the diurnal profiles of $WSOC_g$ and the organic carbon contributed by the four organic acids have similar general shapes, $WSOC_g$ peaked at 21:30, approximately 2 hours after the solar irradiance have decreased to zero. In contrast, the organic carbon contributed by the four organic acids start to decrease at sunset (at 19:30).

3.2.5. SO_2 and HNO_3 observations

In addition to evaluating the field performance of the SF_6^- CIMS technique in gas-phase organic acid measurements, another focus of this study was to investigate the possible sources of the measured organic acids. For this reason, HNO_3 and SO_2 (two common anthropogenic tracers) were also measured by SF_6^- CIMS during the field study. Correlations between the concentrations of organic acids and those of HNO_3 and SO_2 were then examined to determine if the organic acids were anthropogenic in nature (section 3.3). While their reactions with SF_6^- have multiple product channels (Huey et al., 1995), only the NO_3^-•HF (m/z 82) and $F_2SO_2^-$ (m/z 102) ions were used for quantitative purposes:

$$SF_6^- + HNO_3 \rightarrow NO_3^-\bullet HF + SF_5 \quad (4)$$

$$SF_6^- + SO_2 \rightarrow F_2SO_2^- + SF_4 \quad (5)$$

Figure S6 shows the time series of SO_2 and HNO_3 measured during the field study. As expected at a rural site, SO_2 and HNO_3 concentrations are low most of the time (study averages of 230 and 180 ppt, respectively). However, there were occasional periods when the site was impacted by anthropogenic pollution. In particular, there are spikes in both SO_2 and HNO_3 concentrations lasting between 1 to 3 hours throughout the study that

Deleted: S4

corresponded to the site being impacted by power plant or urban emissions. Outside of these anthropogenic spikes, HNO_3 showed a clear diurnal profile with a maximum at approximately 12:30, consistent with local photochemical production.

3.3. Potential sources of organic acids

Correlation analysis on organic acid concentrations can provide insights on their sources. Figure 7 shows that the concentration of formic acid is strongly correlated with those of the other measured organic acids (R^2 = 0.68 to 0.89). This suggests that these organic acids have the same or similar sources at Yorkville. The sources of organic acids can be biogenic or anthropogenic in nature. To determine if the primary sources of organic acids are of biogenic or anthropogenic origin, we first examined the correlations of organic acid concentrations with those of anthropogenic pollutants CO, SO_2, O_3 and HNO_3. CO and SO_2 are common tracers for combustion sources. The organic acid concentrations (or ion signals) are poorly correlated with CO (Fig. S7, R^2 = 0.04 to 0.15) and SO_2 (Fig. S8, R^2 = 0.01 to 0.23), indicating that primary emissions from combustion are a minor source of organic acids in Yorkville. HNO_3 and O_3 are common photochemical tracers of urban air masses. The organic acid concentrations (or ion signals) are weakly correlated with O_3 (Fig. S9, R^2 = 0.11 to 0.31) and HNO_3 (Fig. S10, R^2 = 0.33 to 0.60). In addition, there is no noticeable increase in organic acid concentrations during periods of elevated CO, SO_2, O_3 and HNO_3 concentrations when the site was impacted by pollution plumes. Formic acid/CO ratios (which have been used in some studies to determine the contribution of polluted air masses) ranged between 1.0 x 10^{-3} to 2.5 x10^{-2} ppb ppb^{-1}. The ratio peaked consistently in the mid-afternoon, which coincided with when formic acid and CO reached their maximum and minimum, respectively. In addition, there were no spikes in the formic acid/CO ratio during the study, suggesting that contributions of polluted air masses to the daily increase in formic acid are minimal. Together, these results indicate that the primary sources of organic acids in Yorkville are likely not anthropogenic in nature.

Diurnal profiles of the measured organic acids suggest that their sources are linked to higher daytime temperatures and/or photochemical processes. Figure 8 compares the concentrations (or ion signals) of organic acids against ambient temperatures measured during the study. Since there was a noticeable decrease in mean ambient temperatures

starting on 28 Sept 2016, we grouped the datasets into two time periods (3 to 27 Sept and 28 Sept to 12 Oct) to better evaluate the effect of temperature on organic acid concentrations. The average temperature in the first time period (3 to 27 Sept) is 24.8 °C (32.6 °C max, 18.1 °C min), while the average temperature in the second time period (28 Sept to 12 Oct) is 19.5 °C (28.4 °C max, 9.5 °C min). We find that organic acid concentrations are on average higher and more highly correlated with temperatures in the warmer first time period (R^2 = 0.40 to 0.61) compared to the cooler second time period (R^2 = 0.18 to 0.55). These observations can be explained by temperature-dependent emissions of organic acids and their BVOC precursors. Previous studies have shown that emissions of organic acids and their BVOC precursors depend strongly on light and temperature, with substantially lower concentrations being emitted in the dark and/or at low temperatures (Kesselmeier et al., 1997; Kesselmeier, 2001; Sindelarova et al., 2014). We find that the concentration of isoprene, which was the dominant BVOC in Yorkville, has a somewhat similar diurnal profile as the organic acids and decreased with temperature on 28 Sept 2016 (Fig. S11). In addition, the concentrations of formic and acetic acids are moderately correlated with that of isoprene (R^2 = 0.42 and 0.40, respectively) (Fig. S12).

Deleted: 63

Deleted: 59

Deleted: S9

Deleted: S10

Multiphase photochemical aging of ambient organic aerosols can also be a source of gas-phase organic acids (Eliason et al., 2003; Ervens et al., 2004; Molina et al., 2004; Lim et al., 2005; Park et al., 2006; Walser et al., 2007; Sorooshian et al., 2007; Vlasenko et al., 2008; Pan et al., 2009; Sorooshian et al., 2010). Organic acids may be formed in the particle phase during organic aerosol photochemical aging, with subsequent volatilization into the gas phase. Real-time ion chromatography measurements of aerosol composition demonstrated the presence of particulate formic, acetic, oxalic, malonic, succinic and glutaric acids (Nah et al., 2018). However, since the ratios of gas-phase formic and acetic acid mass concentration to the total organic aerosol mass concentration are large (study averages of 40 and 35 %, respectively) (Nah et al., 2018), it is unlikely that organic aerosol photochemical aging is a large source of formic and acetic acids. In contrast, the ratios of gas-phase oxalic, malonic, succinic and glutaric acids mass concentration to the total organic aerosol mass concentration are expected to be small, suggesting that organic aerosol photochemical aging may be an important source of these gas-phase organic acids.

In summary, the temperature dependence and diurnal profile of organic acid concentrations combined with poor correlations between organic acid concentrations and those of anthropogenic pollutants CO, SO_2, O_3 and HNO_3 strongly suggest that the primary sources of gas-phase organic acids at Yorkville are biogenic in nature. However, our data alone does not allow us to determine if the organic acids are a result of direct emissions or photochemical oxidation of other BVOC emissions and/or organic aerosols. Partitioning of these organic acids between the gas and particle phases is discussed in another paper (Nah et al., 2018).

4. Summary

SF_6^- reacted with all of the studied organic acids to produce product ions that were characteristic of the individual acids (i.e., X^- or X^-•HF). These reactions all occurred at less than the maximum collisional rate due to significant yields of SF_5^- and SF_4^-, which reduced the sensitivity of the method. For the conditions employed in this study, the sensitivities of X^- and X^-•HF ions of the organic acids ranged from 0.12 to 6.38 Hz ppt^{-1}. The detection limits of the organic acids were approximated from 3 times the standard deviation values (3σ) of the ion signals obtained during background measurements. Limits of detection ranged from 1 to 60 ppt for 2.5 min integration periods for the organic acids studied. It should be noted that the SF_6^- CIMS method is particularly sensitive to oxalic, propionic and glycolic acids, which are expected to be present at low concentrations in the atmosphere. Water vapor and O_3 can lead to interferences with this method but for the conditions employed in this study, they were largely limited to acetic acid measurements at m/z 59. However, fluctuations in ambient water vapor can also lead to changes in sensitivity for the detection of some species (e.g., SO_2). Uncertainties in organic acid concentrations originate primarily from calibration measurements and ranged from 12 to 14 %. Overall, the tractable mass spectra obtained by the SF_6^- CIMS method coupled with reasonable limits of detection and the high correlations observed between the individual organic acids demonstrated the potential of this method. Obvious next steps for the SF_6^- CIMS method are to compare it to other measurement methods for organic acids and to deploy the SF_6^- ion chemistry to a higher resolution time-of-flight mass spectrometer to reduce the potential for interferences.

The SF_6^- CIMS method was deployed for measurements of gas phase organic acids in a mixed forest-agricultural area in Yorkville, Georgia from Sept to Oct 2016. The organic acids measured in the field study were formic, acetic, propionic and oxalic acids. Ambient concentrations of these organic acids ranged from a few ppt to several ppb. All the organic acids exhibited similar strong diurnal trends. Organic acid concentrations built up throughout the day, peaked between 17:30 and 19:30 before decreasing continuously overnight. Strong correlations between organic acid concentrations indicated that these organic acids likely have the same or similar sources at Yorkville. We concluded that the organic acids were likely not due to anthropogenic emissions since they were poorly correlated with anthropogenic pollutants and their concentrations were not elevated when the site was impacted by pollution plumes. Higher organic acid concentrations were measured during warm and sunny days. Organic acid concentrations were strongly correlated with temperature during the first month of the study when ambient temperatures were high. Together, our results suggested that the primary sources of organic acids at Yorkville were biogenic in nature. Direct biogenic emissions of organic acids and/or their BVOC precursors were likely enhanced at high ambient temperatures, resulting in the observed variability of organic acid concentrations. Another potential source is the production of organic acids in the particle phase from the multiphase photochemical aging of organic aerosols followed by evaporation to the gas phase, though this source is likely not a large source of formic and acetic acids. However, given the inability of current models and photochemical mechanisms to explain formic acid observations in the Southeastern U.S. (Millet et al., 2015), it is unlikely that our observations of formic acid and larger organic acids can be explained as well. Further work (i.e., laboratory, field and modeling studies) is needed to determine how organic acids are formed in the atmosphere.

Deleted: and

Deleted: In addition, measurements tentatively assigned to oxalic, butyric, glycolic, propionic, valeric, malonic, succinic and glutaric acids were performed.

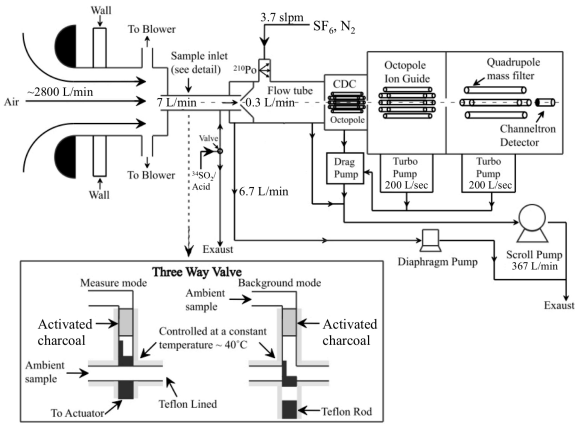

Figure 1: The CIMS instrument and inlet configuration used in the field study. The automated three-way sampling valve is shown in the inset. The figure was adapted from Liao et al. (2011).

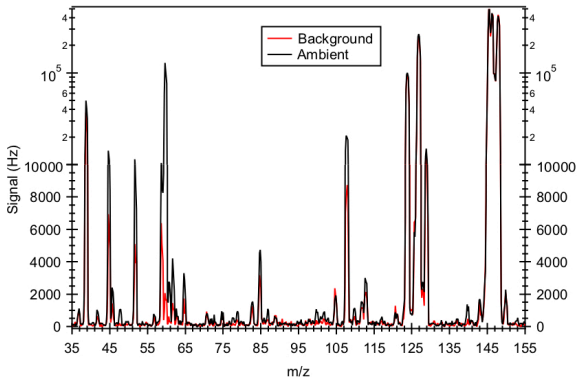

Figure 2: Mass spectrum of ambient air and background measured in Yorkville, Georgia on 8 Sept 2016 using SF_6^-. Note that the $^{32}SF_6^-$ reagent ion signal (at m/z 146) is saturated, causing the sharp drop in its signal. As a result, the ion signal of its isotope $^{34}SF_6^-$ (at m/z 150) was monitored to determine if the reaction of SF_6^- with ambient water vapor and O_3 depleted SF_6^- reagent ions.

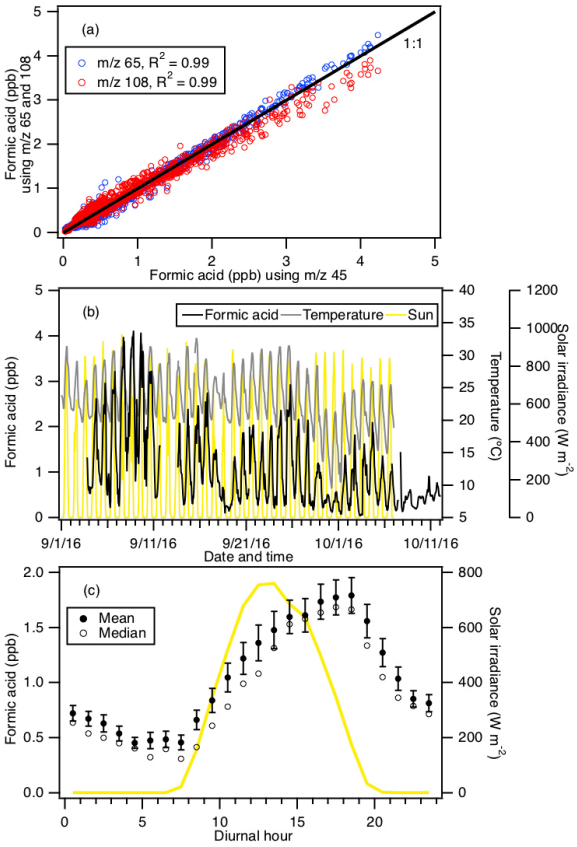

1102

1103 **Figure 3:** (a) Scatter plot comparison of ambient formic acid concentrations determined
1104 using mass peaks m/z 45, 65 and 108. The three datasets correlated well with one another
1105 (R^2 = 0.99). Linear regression of the data gave slopes of 1 (for m/z 65) and 0.95 (for m/z
1106 108), indicating that all three mass peaks can be used to determine the formic acid
1107 concentration. (b) Time series of formic acid concentration, temperature and solar
1108 irradiance. All the data are displayed as 1-hour averages. (c) Diurnal profiles of formic acid
1109 concentration (symbols) and solar irradiance (yellow line). All the concentrations represent
1110 averages in 1-hour intervals and the standard errors are plotted as error bars.

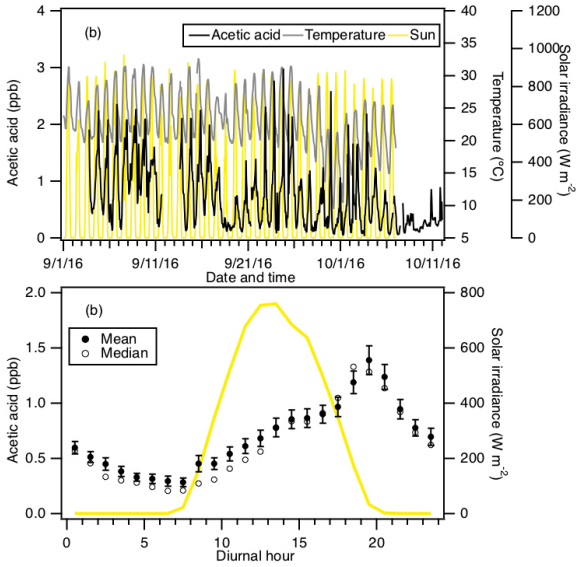

Figure 4: (a) Time series of acetic acid concentration, temperature and solar irradiance. All the data are displayed as 1-hour averages. (c) Diurnal profiles of acetic acid (symbols) and solar irradiance (yellow line). All the concentrations represent averages in 1-hour intervals and the standard errors are plotted as error bars.

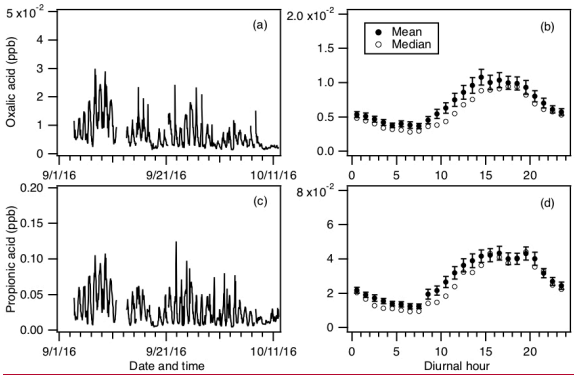

Figure 5: Time series of concentrations of (a) oxalic and (c) propionic acids measured during the field study. All the data are displayed as 1-hour averages. Their corresponding diurnal profiles are shown in (b) and (d), respectively. The diurnal profile concentrations represent averages in 1-hour intervals and the standard errors are plotted as error bars.

Deleted: (a) formic, (b) acetic, (c) oxalic, (d) butyric, (e) glycolic, (f) propionic, (g) valeric, (h) malonic, (i) succinic, and (j) glutaric acids

Deleted: The data for malonic, succinic and glutaric acids are presented as the ratio of their ion signals (Hz) to the instrument's sensitivity to $F_2{}^{34}SO_2$ (Hz ppb^{-1}) since these organic acids were not calibrated.

Table 1: Summary of organic acids of interest, their detection limits and sensitivities of their X^- and X^-•HF ions[a]

Organic Acid	Detection limit (ppt)[b]	Sensitivity (Hz ppt^{-1})	
		X^-	X^-•HF
Formic acid	30	1.29 ± 0.22	0.29 ± 0.05
Acetic acid	60	1.46 ± 0.29	0.30 ± 0.06
Oxalic acid	1	6.38 ± 0.32	0.97 ± 0.05
Butyric acid	30	0.41 ± 0.01	0.12 ± 0.004
Glycolic acid	2	5.53 ± 0.11	1.64 ± 0.03
Propionic acid	6	2.05 ± 0.02	1.26 ± 0.01
Valeric acid	10	0.76 ± 0.008	0.35 ± 0.004

[a]Only organic acids with calibration measurements are shown.

[b]Detection limits are approximated from 3 times the standard deviation values (3σ) of the ion signals measured during background mode. Shown here are the average detection limits of the organic acids for 2.5 min averaging periods which corresponds to the length of a background measurement at a 4 % duty cycle for each mass.

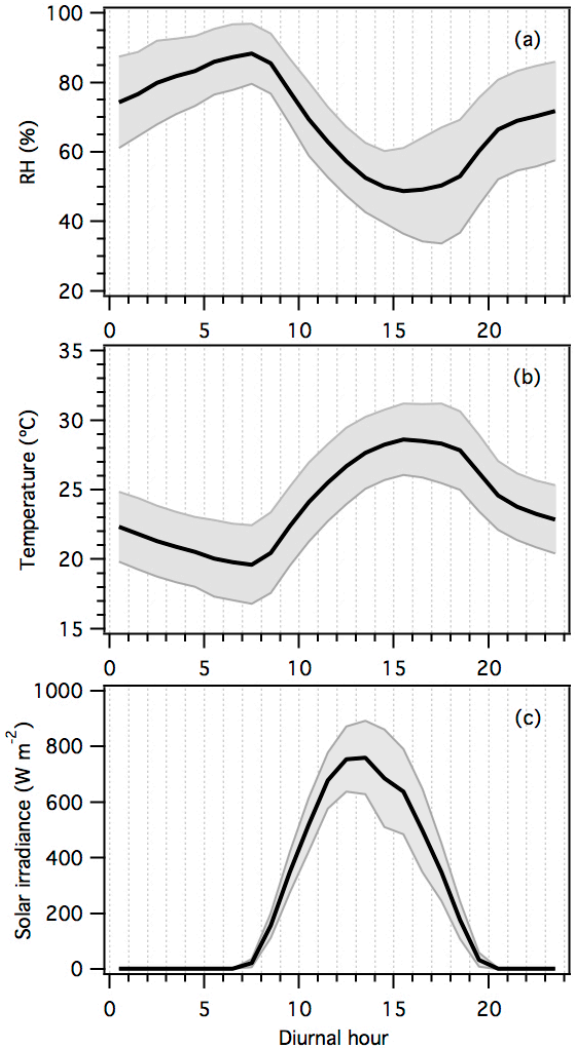

Figure S1: Diurnal trends of (a) relative humidity, (b) temperature, and (c) solar radiance. The lines within the shaded area represents the average values. The upper and lower boundaries of the shaded areas mark one standard deviation.

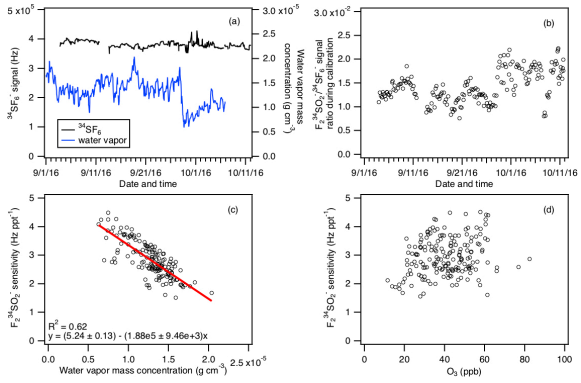

Figure S2: (a) Time series of $^{34}SF_6^-$ reagent ion signal and ambient water vapor concentration for the entire field study. The ambient water vapor mass concentrations are determined from ambient relative humidities and temperatures. (b) Time series of $F_2{}^{34}SO_2^-/{}^{34}SF_6^-$ ion signal ratio obtained during calibration measurements. Panels (c) and (d) show the $F_2{}^{34}SO_2^-$ ion sensitivity obtained from calibration measurements as a function of ambient water vapor and O_3 concentrations. Data in panels (a) to (d) are displayed as 1-hour averages.

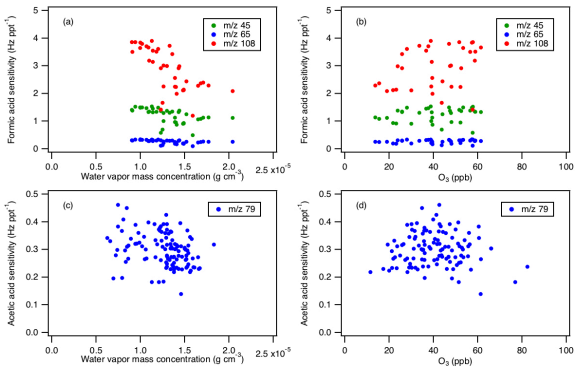

Figure S3: Panels (a) and (b) show the sensitivities of formic acid ions ($HCOO^-$ at m/z 45, $HCOO^-$•HF at m/z 65, and SF_4^- at m/z 108) obtained from calibration measurements as a function of ambient water vapor and O_3 concentrations. Panels (c) and (d) show the acetic acid sensitivity (CH_3COO^-•HF at m/z 79) obtained from calibration measurements as a function of ambient water vapor and O_3 concentrations.

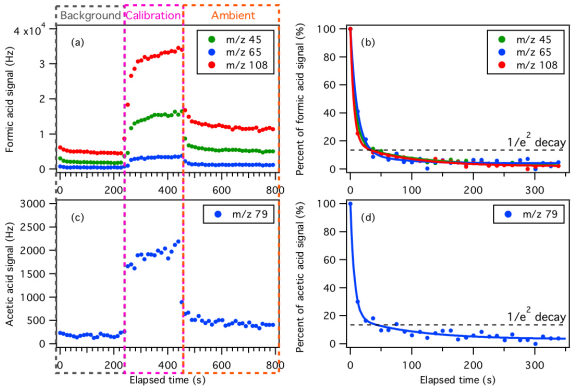

Figure S4: Example of the CIMS instrument response during switches between background, calibration and ambient measurements of (a) formic, and (c) acetic acids. Panels (b) and (d) show the percent of formic and acetic acid ion signals after the removal of a 6.75 ppb of formic acid and 5.87 ppb of acetic acid standard addition calibration as a function of time. The data shown here is 13 s time resolution data. Double exponential fits to each m/z ion are shown as colored solid lines. Black dashed lines show the times for the ions to decay to $1/e^2$.

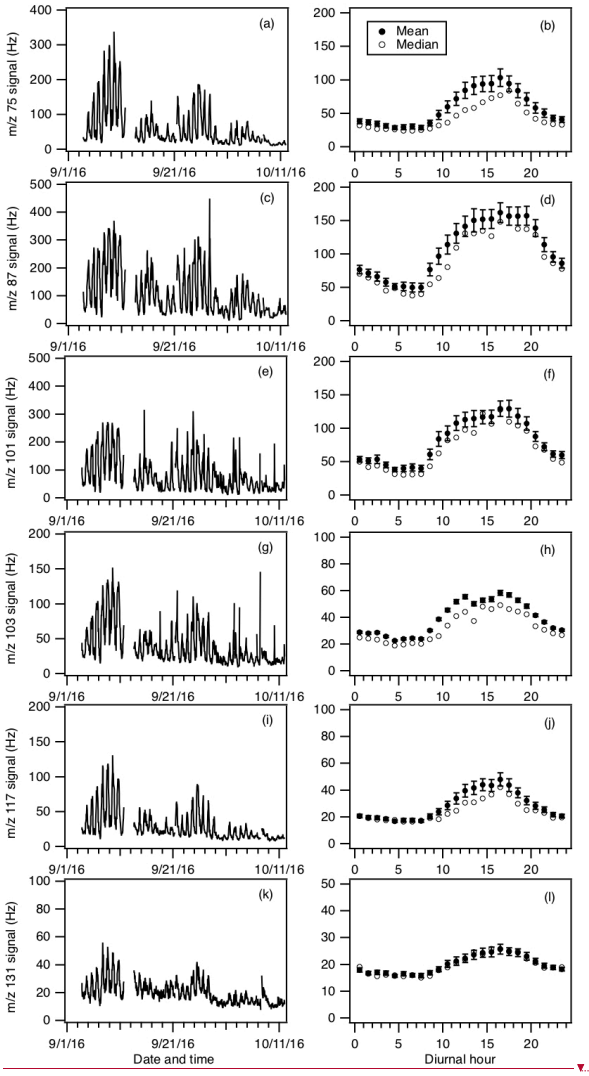

Deleted:

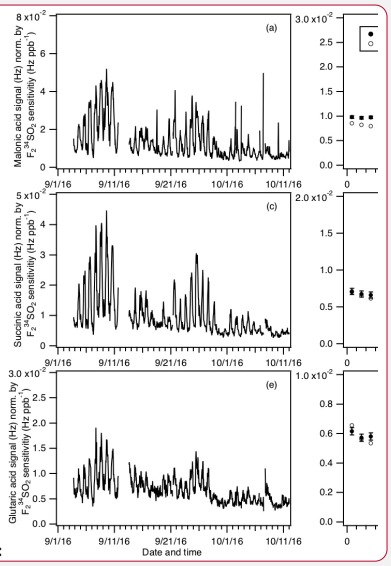

Figure S5: Time series and diurnal profiles of ion signals of organic acids with m/z 75, 87, 101, 103, 117 and 131 measured during the field study. The data are displayed as 1-hour averages. All the signals represent averages in 1-hour intervals and the standard errors are plotted as error bars.

Deleted: (a) malonic, (c) succinic, and (e) glutaric

Deleted: Their corresponding diurnal profiles are shown in (b), (d) and (f), respectively.

Deleted: These organic acids were not calibrated so all the signals are presented here as Hz normalized by the instrument's sensitivity to $F_2{}^{34}SO_2$ (Hz ppb^{-1}) which was the primary calibrant used in the field study.

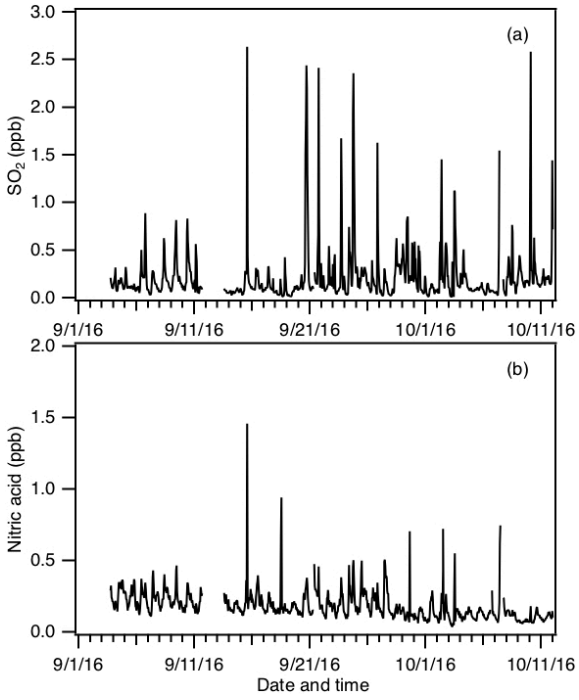

Figure S6: Time series of (a) SO_2 and (b) HNO_3 concentrations measured during the field study. All the data are displayed as 1-hour averages.

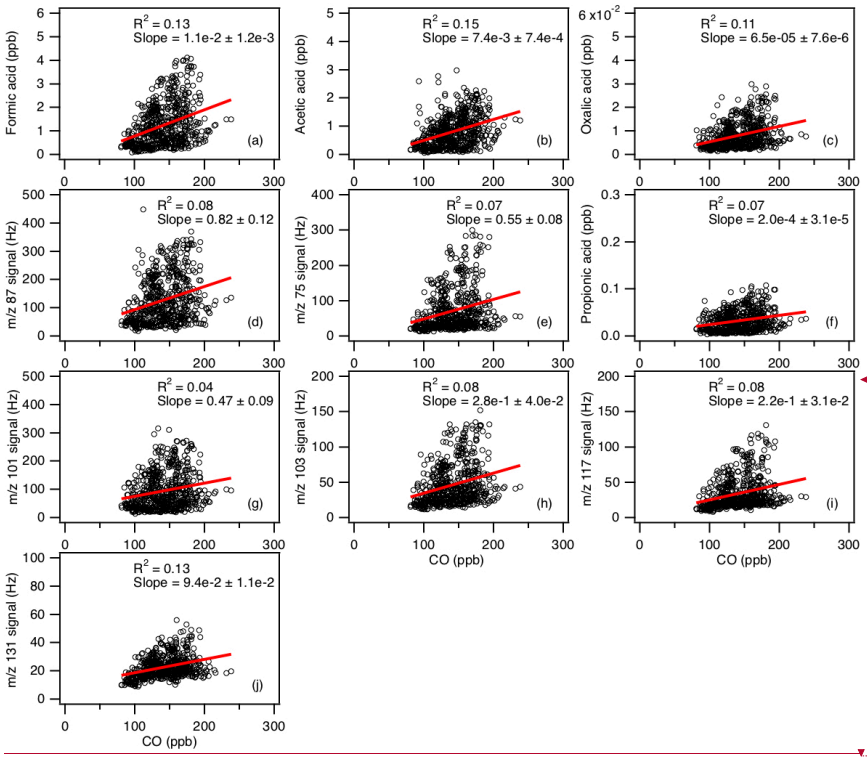

Figure S7: Scatter plots of concentrations (or ion signals) of the measured organic acids with CO concentration. All the data are displayed as 1-hour averages. Red lines shown are linear fits to the data.
