

Author's response to the review of

"A novel semi-direct method to measure OH reactivity by chemical ionisation mass spectrometry (CIMS)" by Jennifer B.A. Muller et al., Atmos. Meas. Tech. Discuss., doi: 10.5194/amt-2018-99

The authors greatly appreciate the comments, suggestions and follow-on questions provided by all three anonymous referees. All points made by the referees are addressed in the following sections.

Referee #1

Page 1, line 13: Please consider re-phrasing 'between below 1 and 40', perhaps to 'from less than 1 to 40'.

Response: Re-phrased as suggested.

Page 1, line 27: 'termed also' to 'also termed'.

Response: Changed.

Page 3, line 17: 'produced O(1D)' to 'O(1D) produced' (also subscript in CF₂ above).

Response: Changed and subscript in "CaF₂" corrected.

Page 6, Section 3: Is there any potential for photolysis of carbonyl compounds? What would the impact be?

Response: We assume the referee refers to measurements in ambient air. Also, as no carbonyl compounds have been used for calibration, this response focusses on ambient air only.

Yes, in principle there is potential for photolysis of carbonyl compounds within the UV zone. Using atmospherically common aldehydes (formaldehyde, acetaldehyde, propionaldehyde) as an example, the impact would be that the photolysis can lead to some products (here H) which have a lower OH reactivity than the aldehyde itself. However, some products have larger rate constants (e.g. HCO + OH). Reaction rate constants of OH with the products can be different by a few orders of magnitude than those with aldehydes, see Table below, rate constants for k(298K) from NIST Chemical Kinetics Database, IUPAC and JPL Recommendations.

Response-Table 1: Reaction Rate constants OH + aldehydes and OH + aldehyde photolysis products (only major product channels considered here).

Units: $\text{cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$	Formaldehyde HCHO	Acetaldehyde CH_3CHO	Propionaldehyde $\text{C}_2\text{H}_5\text{CHO}$
Reaction with carbonyl	$k_{\text{OH}+\text{HCHO}} = 9.38 \times 10^{-12}$	$k_{\text{OH}+\text{CH}_3\text{CHO}} = 1.5 \times 10^{-11}$	$k_{\text{OH}+\text{C}_2\text{H}_5\text{CHO}} = 2 \times 10^{-11}$
Reaction with photolysis product 1	$k_{\text{OH}+\text{H}} = 9.9 \times 10^{-17}$ (products $\text{H}_2 + \text{O}$)	$k_{\text{OH}+\text{CH}_3} = 8 \times 10^{-11}$	$k_{\text{OH}+\text{C}_2\text{H}_5} = 4 \times 10^{-11}$ (products $\text{C}_2\text{H}_4 + \text{H}_2\text{O}$)
Reaction with photolysis product 2	$k_{\text{OH}+\text{HCO}} = 1.83 \times 10^{-10}$	$k_{\text{OH}+\text{HCO}} = 1.83 \times 10^{-10}$	$k_{\text{OH}+\text{HCO}} = 1.83 \times 10^{-10}$

Although fast, the reaction of OH with these products of photolysis will be less important than their reaction with O_2 . The reaction with oxygen to produce OH, HO_2 or RO_2 radicals is often almost equally fast: the reaction $\text{H} + \text{O}_2 \rightarrow \text{OH} + \text{O}$ is fast with $k(298\text{K}) \sim 3.5 \times 10^{-11} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$ and the reaction $\text{H} + \text{O}_2 + \text{M} \rightarrow \text{HO}_2 + \text{M}$ similarly so at $k(298\text{K}) \sim 1.2 \times 10^{-12} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$ for $[\text{M}_{\text{MOHP}}] = 2.3 \times 10^{19} \text{ molecules cm}^{-3}$. For $\text{HCO} + \text{O}_2 \rightarrow \text{CO} + \text{HO}_2$, $k(298\text{K})$ is $\sim 5.1 \times 10^{-12} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$. For $\text{CH}_3 + \text{O}_2 + \text{M} \rightarrow \text{CH}_3\text{O}_2 + \text{M}$, $k(298\text{K})$ is $\sim 8 \times 10^{-13} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$. For $\text{C}_2\text{H}_5 + \text{O}_2 \rightarrow \text{C}_2\text{H}_4 + \text{HO}_2$, $k(298\text{K})$ is $\sim 3.8 \times 10^{-15} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$.

If dissociation by photolysis was to significantly reduce the aldehyde concentration, this could lead to an underestimation of measured OH reactivity. However back-of-the-envelope calculations show that only a fraction of a percent of carbonyl compounds photolyses in the CIMS UV zone at $\lambda = 185 \text{ nm}$ (Response-Table 2 below). This is a negligible amount and therefore can be ignored as a source of uncertainty for the OH reactivity measurements.

Response-Table 2: Back-of-the-envelope calculations of aldehyde loss by photolysis in CIMS UV zone. Assumptions and system conditions also listed.

	Formaldehyde HCHO	Acetaldehyde CH_3CHO	Propionaldehyde $\text{C}_2\text{H}_5\text{CHO}$
†Absorption cross section σ_λ at $\lambda \sim 185 \text{ nm}$ [$\text{cm}^2 \text{ molecule}^{-1}$]	1.15×10^{-18}	3×10^{-20}	1×10^{-17}
Quantum yield q_λ assumed (upper limit) [$\text{molecules photon}^{-1}$]	1	1	1
Photon flux I [$\text{photons cm}^{-2} \text{ s}^{-1}$]	4×10^{12}	4×10^{12}	4×10^{12}
Photolysis rate constant $k = q_\lambda \sigma_\lambda I$ [s^{-1}]	4.6×10^{-6}	1.2×10^{-7}	4×10^{-5}
Typical mixing ratio at MOHp [ppb]	2	1.4	0.4
Concentration at MOHp [molecules cm^{-3}]	4.6×10^{10}	3.2×10^{10}	9.2×10^9
Residence time in UV zone [s]	0.0034	0.0034	0.0034
% of carbonyl photolysed	1.6×10^{-4}	4×10^{-8}	1.4×10^{-5}
Change in OH reactivity	7×10^{-5}	2×10^{-8}	3×10^{-6}

† Mainz UV-VIS spectral atlas http://satellite.mpic.de/spectral_atlas ; Keller-Rudek, H., Moortgat, G. K., Sander, R., and Sörensen, R.: The MPI-Mainz UV/VIS spectral atlas of gaseous molecules of atmospheric interest, *Earth Syst. Sci. Data*, 5, 365–373, (2013), DOI: 10.5194/essd-5-365-2013

A sentence to address this comment, and the comment of referee #3 regarding OVOC photolysis (see later), has been added on page 6, introductory paragraph Section 3:

“Effects from photolysis of organic OH reactants such as e.g. aldehydes and alcohols in the CIMS UV zone have been estimated to be negligible and are not discussed further in this section.”

Page 8, line 12: Remove ‘such’ in ‘such e.g. OH. . .’.

Response: Removed.

Page 9, line 26: Change to ‘a range of VOCs and calculated OH reactivity’.

Response: Changed.

Page 9, line 29: Can you comment on how long ‘extensive flushing’ is required for?

Response: ‘Extensive flushing’ is admittedly a vague description. In our case, both flushing of the lines with 100 ml/min for one hour, as well as flushing with a large flow (several L/min) for several minutes was sufficient to remove trace contamination. However what constitutes sufficient flushing depends on the set up and length of tubing. To clarify, the phrase ‘extensive flushing’ has been changed and the sentence now reads: “It was observed that tubing, valves etc. needed to be sufficiently flushed as to remove trace contamination and achieve a low constant level of residues before carrying out the zero OH reactivity measurements.”

Page 10: Is it possible for future experiments to purify the SO₂ used?

Response: Purification and obtaining a SO₂ gas mixture without traces of NO is something we are currently working on. First tests on commercial mixtures of SO₂ indicate that SO₂ in synthetic air contain lower level of NO contamination than SO₂ in N₂. We are continuing to monitor the trace levels of NO in all of the SO₂ mixtures we use and remain in contact with the compressed gas suppliers to understand the source of NO contamination. We are also planning to test set ups to chemically remove NO by adding ozone to the SO₂ gas stream prior to the injection into the CIMS system. The set up will aim to remove the ozone after the reaction with NO has completed. The effect of injecting the reaction product NO₂ into the CIMS has been estimated to be negligible for OH reactivity measurements. Although the reaction rate constant of NO₂ + OH is one order of magnitude greater ($k \sim 10^{-11} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$) than for SO₂ + OH ($k \sim 10^{-12} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$), the SO₂ mixing ratio (~ 10

ppm) in the sample flow is six orders of magnitudes larger than the NO₂ mixing ratio (~100 ppt). For zero OH reactivity measurements, the produced NO₂ is estimated to make up less than 0.05 s⁻¹.

Page 12, line 28: 'from reaction chain' to 'from the reaction chain' (both instances).

Response: Changed, "the" added.

Page 13, line 3: Is this the rate or the rate coefficient?

Response: This is the rate coefficient; "rate" has now been unambiguously defined and changed to "reaction rate constant"

Page 14, line 17: 'inorganic species'.

Response: Changed.

Page 15, line 20: 'systemacity in errors' to 'systematic errors'.

Response: Changed.

Page 17, line 3: 'fit parameter' to 'fit parameters'.

Response: Changed, "s" added.

Page 17, line 12: Please re-phrase 'highly performant'.

Response: Wording was changed from "The FZJ LIF instrument was shown to be highly performant throughout the campaign" to "The FZJ LIF instrument performed very well throughout the campaign"

Page 19, line 10: '. . .observed to have a clear diurnal. . . '.

Response: Changed, article "a" inserted.

Page 19, line 12: '. . .dominance of biogenic VOCs in summer is contrasted by higher concentrations.. '.

Response: Changed.

Page 19, line 31: 'a representative ambient air sample'.

Response: Changed.

(End Referee #1)

Referee #2

Line 31 on Page 3: With 13 SLM sample flow through the 0.019 m diameter chemical reactor sample tube. . .

Comment: The flow rate control in the sample tube is critical in the instrument setup since it is directly related to the scaling rate as well as wall loss rate. It is not clearly stated in the manuscript what the flow rate, how the flow is controlled and what the size of the sample tube in Fig.1 is. Is the pressure in the sample tube close to ambient pressure? All these information will be helpful to understand the reactions between two titration zones.

Response: The sample flow is around 13 SLM and the dimensions of the sample tube are: diameter of 0.019 m and length of 0.30 m. The complete length from sample tube tip to the pinhole is 0.8 m. The pressure in the sample tube is close to ambient pressure (around 900 hPa at MOHp). The sample flow of 13 SLM is not itself kept constant by a mass flow controller but is the result of the difference of several other mass flow controlled flows in the system: Addition of 84 SCCM per injector (i.e. total of 168 SCCM), addition of sheath air is maintained at 37.0 SLM, HNO₃ enriched flow is kept at 5.0 SCCM, addition of pinhole synthetic air is controlled at 1.1 SLM and the total flow that is removed from the ionisation region is maintained at 51.0 SLM. The resulting balance of flows ($51.0 - 0.168 - 37.0 - 1.1 - 0.005 = 12.727$ SLM) equals the sample flow. In order to obtain the residence time between the titration zones ($F1$ to $F2 = 0.15$ m) the volumetric flow rate has to be calculated and the mass flow rates have to be corrected for the ambient temperature and pressure.

Salient points on the sample flow tube and the flow set up has been added in the manuscript: "The CIMS sample flow tube dimensions are 0.019 m in diameter and 0.30 m in length, with a sample flow of around 13 SLM. The complete length from sample tube tip to the pinhole is 0.8 m. The distance between the front injectors is 0.15 m and between front and rear injectors is 0.054 m (Fig. 1). The pressure in the sample tube is close to ambient pressure (around 900 hPa at MOHp). The sample flow of 13 SLM is not itself kept constant by a mass flow controller but maintained by the difference of other mass flow controlled flows. The total residence time within the flow tube is circa 0.9 s which is long enough for HOx recycling to become significant inside the flow tube and the measurement artefacts from recycling thus need to be considered and accounted for."

Line 6 on Page 7: Additionally, changes in volume flow rates can also affect flow characteristics in the sample tube, and therefore OH wall loss and. . .

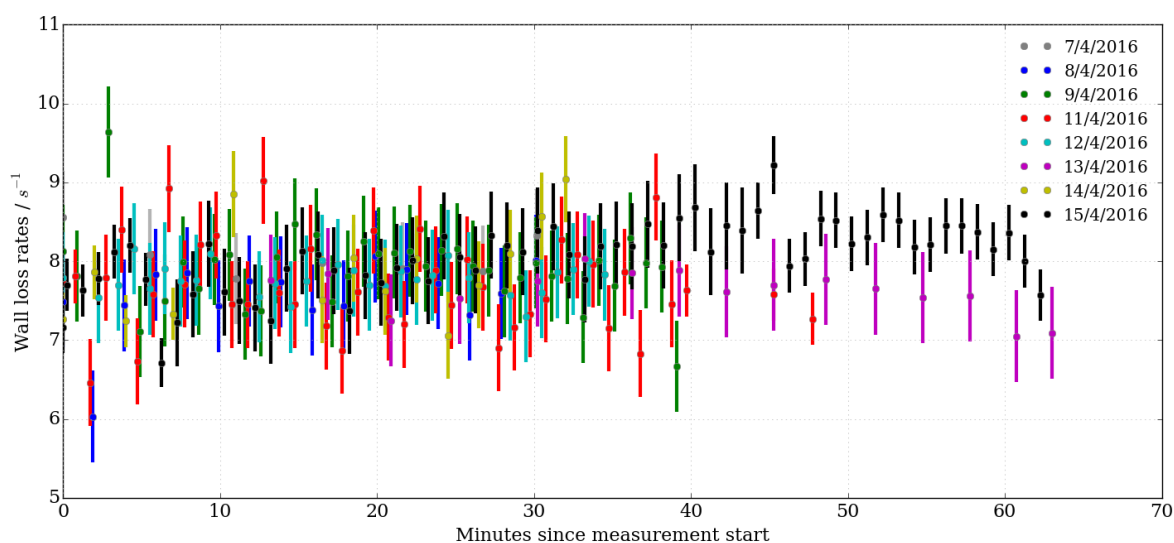

Line 23 on Page 9: However the wall loss rate can be affected as the measurement of zero reactivity is done with synthetic air . . .

Comment: The wall loss rate is a common issue of OH reactivity measurement and can be caused by various reasons. The wall loss rate can be measured by zero reactivity measurements as well as OH reactivity calibrations, which shall give similar results.

In the manuscript the causes of the wall loss rate were discussed in several parts but little data were shown. A more detailed the wall loss rate measurement results will be helpful to prove the stability and capability of the instrument.

Response: We agree that the determination of wall loss rates represent a key aspect of any OH reactivity measurement system. Wall loss rates k_w have now been included in Table 2, showing the validation of wall loss rates determined with the experimental set up using the external glass flow tube are equivalent to the measurements in an operational set up (FZJ SAPHIR chamber, Fuchs et al., 2017).

To further illustrate the quality of the wall loss measurements, zero OH reactivity was measured every day during the OH reactivity comparison campaign in April 2016 at the SAPHIR chamber. At the beginning of each day, the chamber was humidified without addition of OH reactants, i.e. zero OH reactivity in the chamber, so consequently the wall loss rates were measured for 0.5-1 hour. The time series of these measurements are shown here:

The wall loss rates are overall stable for each individual day, and also for the whole campaign period from 7-15/4/2016.

Looking at stability over longer periods of time (half a year), the CIMS wall loss rates in Table 2 give indication of a similar level of variability and uncertainty compared to the shorter term stability shown above.

The above response has been added to the Supplementary material as S3 and is referenced in Section 3.3 “Validation of CIMS OH reactivity calibration using external glass flow tube”.

Line 18 on Page 14: The effect of OH reactivity underestimation was considerably stronger for CO than for the other OH reactants, so only data from propane, ethane and isoprene experiments were used to derive a correction function. . .

Comment: In Page 19 Line 14, the authors mentioned ‘inorganic trace gases such as CO and NO₂ which contribute greatly to the total OH reactivity at MOPh’. Why was the CO experiments not used when CO is the main contributor of OH reactivity at MOPh?

Response: Considering long-term medians, CO alone makes up typically 15 - 25 % of the total measured OH reactivity. When using only CO as OH reactant for the NO response experiments, CO

mixing ratios of up to about 10 ppm have to be used. Since HO₂ is directly produced as OH reacts with CO, the non-linear recycling process of HO₂ + NO = OH is strongly amplified which is not comparable with the effect expected during ambient air measurements. Therefore the results from CO and NO calibration experiments are not directly applicable and transferrable to ambient air measurements. However for e.g. propane the NO calibration experiments can be applied to ambient measurements as propane + OH does not produce this non-linear amplification of recycling.

To clarify, the sentence was rephrased as follows: "The effect of OH reactivity underestimation was considerably stronger for CO than for the other OH reactants, because NO induced OH recycling is amplified when OH reacts with CO to additionally produce HO₂ in the CIMS system. These non-linear results from the external glass flow tube experiments with large HO₂ production are therefore not directly applicable and transferrable to ambient air measurements. Thus only data from propane, ethene and isoprene experiments were used to derive a correction function that would be representative for an ambient air matrix."

Minor comments:

Line 17 on Page 14: 'specie' should be 'species'

Response: Changed.

Line 19 on Page 14: 'ethane' should be 'ethene'

Response: Changed.

(End Referee #2)

Referee #3

1/ Limitations and uncertainties associated to this measurement technique are thoroughly investigated in section 3. This is a relatively long section and it would be beneficial for the reader to insert an additional table at the end this section to summarize all the sources of uncertainties.

Response: An overview table has been put together and as suggested included in Section 3. Reference to the table is made in the introductory paragraph on page 7. Consequently, Table 2 has become Table 3, and the overview table below is Table 2. All references to previous "Table 2" have been changed to "Table 3".

Reference to Table 2 reads: "All uncertainties, limitations and their relevance to the scaling rate, the wall loss rate and ambient measurements discussed in this section are shown in Table 2."

Table 2: Overview of uncertainties (1σ) and limitations discussed in Section 3, indicating relevance to scaling rate sr_{CIMS} determination, wall loss rate k_w determination and/or relevance for ambient measurements.

Section #	Source of uncertainty	Relevant for sr_{CIMS} determination	Relevant for k_w determination	Relevant for ambient measurements
3.1	Changes in ambient pressure and temperature			Uncertainty around mean $\pm 0.17 \text{ s}^{-1}$ Maximum systematic deviation $\pm 0.4 \text{ s}^{-1}$
3.2.1	Measurement of OH by CIMS			$[\text{OH}]_{\text{T1}}$ median variability 1.5 % $[\text{OH}]_{\text{T2}}$ median variability 2.7 % $\ln([\text{OH}]_{\text{T1}}/[\text{OH}]_{\text{T2}})$ typical uncertainty 7.1 %
3.2.2	OH reactant concentration in calibration gas mixture	Uncertainty in 1 % CO gas mixture = 2 % in OH reactivity Uncertainty in 0.2 % propane gas mixture = 5 % in OH reactivity		
3.2.3	OH reactant contamination in calibration gas mixture	Not detectable here, see text.		
3.2.4	OH reactant contamination in carrier gas (here synthetic air)		$0.02 \pm 0.02 \text{ s}^{-1}$ Contamination level can vary, see text.	
3.2.5	NO contamination in all gas mixtures	For $0\text{--}40 \text{ s}^{-1}$, sr_{CIMS} overestimation 5 % For $20\text{--}40 \text{ s}^{-1}$, sr_{CIMS} overestimation 9 % For $0\text{--}20 \text{ s}^{-1}$, sr_{CIMS} overestimation 1 %		NO up to 380 ppt in sample flow from SO_2 gas mixture
3.2.6	OH kinetic rate constants	Uncertainty in sr_{CIMS} for CO 11 % Uncertainty in sr_{CIMS} for propane 5 %		
3.3	Calibration using external glass flow tube	Jülich mean $9.1 \pm 0.4 \text{ s}^{-1}$ MOHp mean $9.7 \pm 0.5 \text{ s}^{-1}$	Jülich mean $8.6 \pm 0.5 \text{ s}^{-1}$ MOHp mean $9.4 \pm 0.8 \text{ s}^{-1}$	
3.4	Upper measurement limit	40 s^{-1}		40 s^{-1}
3.5	Ambient NO leading to instrument internal HOx recycling	NO up to 15 ppb, non-linear function, see text		NO up to 4 ppb, underestimation $0.8 \text{ s}^{-1}/\text{ppb}$

2/ Was the photolysis of ambient OVOCs by the mercury lamp radiation investigated? The amount of radicals produced from OVOC photolysis will not likely be significant compared to the HOx production from water photolysis but could this lead to a significant change in KOH?

Response:

In addition to the response given to the comment raised by Referee #1 about the photolysis of carbonyl compounds, photolysis of methanol (CH₃OH) and ethanol (C₂H₅OH) are considered here as additional atmospherically common OVOC species. Approach for estimation same as above (response to Referee #1).

Response-Table 3. Reaction rate constants for OH with alcohols (OVOC) and with alcohol photolysis products. Only major product channels considered.

Units: cm³ molecules⁻¹ s⁻¹	Methanol CH₃OH	Ethanol C₂H₅OH
Reaction with alcohol	$k_{OH+CH_3OH} = 9 \times 10^{-13}$	$k_{OH+C_2H_5OH} = 3.2 \times 10^{-12}$
Reaction with photolysis product 1	$k_{OH+H} = 9.9 \times 10^{-17}$ (products H ₂ + O)	$k_{OH+H_2} = 6.7 \times 10^{-15}$
Reaction with photolysis product 2	$k_{OH+CH_3O} = 3 \times 10^{-11}$	$k_{OH+CH_3CHO} = 1.5 \times 10^{-11}$
Reaction with photolysis product 3	$k_{OH+H_2} = 6.7 \times 10^{-15}$	
Reaction with photolysis product 4	$k_{OH+CH_2O} = 4.38 \times 10^{-12}$	

In the case where H (or H₂) is a product of photolysis, H will actually react faster with oxygen to produce OH or HO₂ radicals: the reaction $H + O_2 \rightarrow OH + O$ is fast with $k(298K) \sim 3.5 \times 10^{-11} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$ and the reaction $H + O_2 + M \rightarrow HO_2 + M$ is similarly fast at $k(298K) \sim 1.2 \times 10^{-12} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$ for $[M_{MOHP}] = 2.3 \times 10^{19} \text{ molecules cm}^{-3}$.

Also products CH₃O and CH₂O will react with O₂ at fast rates (order of 10⁻¹⁵ and 10⁻¹² cm³ molecules⁻¹ s⁻¹, NIST).

The photolysis of alcohols leads to products that have greater reaction rate constants with OH than the alcohols themselves (Response-Table 3), so the potential exists for an overestimation of OH reactivity, if the process of photolysis is important enough.

Response-Table 4. Back-of-the-envelope calculations of alcohol loss by photolysis in CIMS UV zone. Assumptions and system conditions also listed.

	Methanol CH₃OH	Ethanol C₂H₅OH

† Mainz UV-VIS spectral atlas http://satellite.mpic.de/spectral_atlas ; Keller-Rudek, H., Moortgat, G. K., Sander, R., and Sørensen, R.: The MPI-Mainz UV/VIS spectral atlas of gaseous molecules of atmospheric interest, *Earth Syst. Sci. Data*, 5, 365–373, (2013), DOI: 10.5194/essd-5-365-2013

Response-Table 4 shows that, as for the aldehydes, the photolysis of common OVOC, such as alcohols, in the CIMS UV zone is not sufficient enough to create detectable changes in OH reactivity during ambient air sampling.

A sentence to address this comment, and the comment of referee #1 regarding carbonyl compound photolysis (see above), has been added on page 6, introductory paragraph Section 3:

“Effects from photolysis of organic OH reactants such as e.g. aldehydes and alcohols in the CIMS UV zone have been estimated to be negligible and are not discussed further in this section.”

Minor comments:

P3 L11: “The CIMS system is frequently calibrated. . .”. Please indicate how often calibrations are performed.

Response: OH concentration calibrations are performed every 20 minutes. This has now been included in the text: “The CIMS system is calibrated every 20 minutes to obtain absolute OH concentrations ...” Although calibration frequency has changed since, the method of calibration has remained the same and has been fully described in Berresheim et al. (2000) to which the reader is referred in the text. The following has now also been clarified in the text (page 4, last paragraph of Section 2.1): “It is worth noting that the absolute OH concentrations are not critical for the OH reactivity measurement as the ratio between titration zone 1 and 2 is used (see Section 2.2), i.e. it is a relative measure and the stability of conditions between the two zones is relevant instead. Amongst other things, the development of the CIMS OH reactivity measurement arose out of the synergy of utilising the already existing frequent OH calibration measurement”.

P3 L14: How is the generated OH concentration determined during calibration experiments?

Response: As mentioned above the absolute OH concentration is not critical for the OH reactivity measurement, therefore we did not include the full description on how the OH concentration is determined during calibration experiments, but rather refer the reader to the previous in-depth report by Berresheim et al.(2000).

P4 L17-18: “. . .leading to the quantification of the contribution from recycling and other artifacts. . .”. The term “recycling” may not be the most appropriate here since it does not include OH radicals

produced from HO₂+NO in the CIMS inlet in the presence of SO₂ and propane. I would not use this term.

Response: Point taken. The term “recycling” has been removed here and the sentence now reads: “This involves adding both SO₂ and propane at the front injector, leading to the quantification of the contribution from ambient sulfuric acid and artefacts producing sulfuric acid.”

P5 L16: How was the reaction time inferred? Please clarify whether this is calculated or measured?

Response: This reaction time value is calculated based on the geometry of the CIMS sample tube and the sample flow rate. This has now been clarified in the text: “... the distance between the two titration zones is equivalent to a calculated reaction time of about 0.1 s.”

P5 L24: Please report values for the generated air flow rate and the CIMS sampling flow rate. The CIMS sampling flow rate of 2280 mL/min is reported P11 but this is too late.

Response: The flow rates through the ambient air inlet, the CIMS sample tube and the OH reactivity calibration glass tube are now specified in this Section 2.3: “Since the inlet air flow rate (Fig. 1) of 2280 L/min is too large to be generated for OH reactivity calibration, an external glass flow tube is placed on top of the sample tube during OH reactivity calibration, schematically shown in Fig. 2. The setup is such that the excess of the OH reactivity calibration flow of 50 SLM can overflow and the normal CIMS sample flow rate is maintained at 13 SLM.”

A later sentence referring to the external glass flow tube was shortened and adapted as follows: “The OH reactant is delivered in a humidified synthetic air matrix, which is made of Milli-Q ultrapure water, ...”

P8 L20: The authors should explain (or remind the reader) why the OH reactivity value is integrated over 10 min but the time resolution is twice longer (20 min). We would expect a time resolution of 10 min.

*Response: The sentence has been modified and extended to reiterate that OH reactivity is *one* of several measurements made sequentially by the CIMS instrument: “Titration zone measurements in zone 2 immediately follow those in zone 1 so that the measured OH reactivity is effectively an average over a ten minute period. However during routine operation the OH reactivity time resolution is actually 20 minutes because the complete operational CIMS measurement sequence includes other separate measurements such as sulfuric acid and peroxyradical concentration measurements.”*

P10 L12-13: How did the authors come up with NO contamination levels of 140 ppt and 20 ppt in the SO₂ and zero air mixtures, respectively? Was it measured? Or are these conservative upper limits? Something else?

Response: The NO contamination level of 20 ppt in zero air is based on measurements using a chemiluminescence (CLD) analyser. The measurements showed concentrations of up to a few ppt in zero air, so based on the detection limit of the CLD analyser the value of 20 ppt was used. This constitutes a conservative, yet realistic upper limit.

Levels of up to a few hundred ppt NO from the SO₂ gas mixtures were confirmed by direct measurements using CLD analysers (as detailed in the same section in the manuscript). However the NO contamination level of 140 ppt in the SO₂ mixture is derived from FACSIMILE modelling during the OH reactivity comparison campaign at the Jülich chamber SAPHIR in April 2016 (Fuchs et al., 2017) and constitutes a realistic level of contamination. Here, an effect of OH reactivity suppression (at OH reactivity > 20 s⁻¹) was observed during the CO experiments. This effect had not previously observed and by elimination of causes was identified to be the result of the presence of NO in the SO₂ gas mixture. Unfortunately direct measurement of NO was not possible at that point anymore since the SO₂ gas from this mixture had been expended for routine measurements at MOHp. The CIMS measurement data from the SAPHIR CO chamber experiments were compared to FACSIMILE modelling results for a range of NO contamination levels and so the NO mixing ratio of 140 ppt was determined by best fit comparison.

To provide some additional information on the choice of NO contamination levels, the following sentence has been added in Section 3.2.5: “The 140 ppt NO is based on contamination found in the SO₂ titration gas mixture during the OH reactivity comparison campaign (Fuchs et al., 2017) and the 20 ppt NO is based on the detection limit of the chemiluminescence analyser for NO concentration measurements at MOHp. The levels of concentration were also confirmed by direct NO measurements of the gas mixtures.”

P11 L5: Please double-check the uncertainty values stated for the scaling rate. How were they calculated? The 1 σ determination using the IUPAC rate constant for OH+propane seems very small. The IUPAC compilation indicates that logk for OH+propane is ± 0.08 at 298K, which I think translates into a 1 σ uncertainty of approximately 10%. How can the uncertainty on the scaling rate be lower than the uncertainty on the rate constant?

Response: We double-checked the calculation, and indeed the underlying IUPAC uncertainty estimates were erroneous. They have been corrected for both OH + propane and OH + CO reactions. IUPAC provides estimates of expanded uncertainties at 95 % confidence level, and on page 5, as well as in the supplementary material (S2), 1 σ uncertainties (~simple uncertainty at 68 % confidence level) are quoted. The uncertainty in the scaling rate for propane has now been changed from 2 % to 5 %, and for CO has now changed from 15 % to 11 %.

The conclusions in Section 3.2.6 and the supplementary material S2 are not affected by this correction.

P11 section 3.3: This section compares scaling rate values derived from flow tube calibrations to values inferred from atmospheric chamber experiments. This provides a nice validation of the flow

tube calibration method. The authors should also discuss the comparison of k_w values derived from these different experiments? Were the k_w values consistent within uncertainty?

Response: The calculated k_w values have been added to Table 2 and the comparison of k_w is discussed in an additional paragraph at the end of Section 3.3 as follows:

“Comparing the wall loss rates from the 6th and 7th of April 2016 (i.e. external flow tube vs chamber), the k_w values agree within one standard deviation, indicating the validity of the calibration approach using the external flow tube. However, as for the scaling rate, not all individual experiments at the SAPHIR chamber produced k_w values that agree within one standard deviation, and the maximum difference in mean k_w values is 1.2 s^{-1} . Similarly, the individual k_w measurements made at MOHp over the course of 6 months do not all agree within one standard deviation (Table 2), but the mean statistics of the SAPHIR chamber campaign and the MOHp long-term wall loss rate do agree within 1σ .”

P12 L14-15: How is the upper limit for OH reactivity measurements quantified? Is the calculation based on a 3σ detection limit of OH in zone 2?

Response: The upper limit is indeed based on the limit of detection of OH in zone 2. The quoted LOD of $5 \times 10^5 \text{ molecules cm}^{-3}$ for OH in Table 1 was confirmed by Berresheim et al. (2000) and is larger than the 2σ scatter of signal rate measurements, thus constitutes a conservative value. Therefore the quoted LOD has been used to determine the upper measurement limit for OH reactivity. In the modelled case where no NO is present in the system, the LOD for OH in zone 2 is reached around 40 s^{-1} , as evident in Figure 7b. As mentioned in the manuscript, the exact value of the upper limit of OH reactivity by this criterion (zone 2, [OH] LOD) will be variable as “the upper measurement limit is (...) dependent on the initially produced $[\text{OH}]_{\text{UV}}$ concentration”. Therefore it is important to note that the quantification here (i.e. 40 s^{-1}) is not an immutable number, and is based on model results with typical conditions ($[\text{H}_2\text{O}]$, T , p etc.) at MOHp. It is also approximately confirmed by calibration experiments with propane as OH reactant where CIMS OH reactivity shows underestimation above ca. 40 s^{-1} .

To clarify, the first sentence of Section 3.4 has been extended to quote the LOD criterion used: “The upper measurement limit for the described CIMS system is largely determined by the detectable OH concentration in titration zone 2 (i.e. the 2σ [OH] LOD of $5 \times 10^5 \text{ molecules cm}^{-3}$, 5 min integration time, Table 1).”

P12 L26: Sup. mat. S1 is cited for more details about the tagged mechanism. However there is no information about the tagging feature in S1.

Response: The reactions where the recycled OH is tagged have been added to supplementary material S1:

“The following reactions are added to those in Table S1 when tagging for recycled OH (OHrec) is used and H_2SO_4 production pathways are separated:

P14 Eqs. 7-10: How was this complex empirical function determined? Can physical meanings be associated to some of the terms?

Response: As Figure 8 illustrates, the response to the presence of NO in the system is non-linear for both increasing NO concentrations and OH reactivity, so non-linear functions were explored. As stated in the text, the empirical function was found by looking at the CIMS response for one given NO concentration one at a time: "By exploring CIMS OH reactivity measurements for each NO concentration (Fig. 9a), it was found that the correction could be empirically well described by an exponential equation of the form(...)". The fit parameters were determined by a Python (SciPy) curve fitting routine (i.e. finding a mathematical best fit solution) using all data (all NO concentrations and OH reactivity) and no attempt was made to create terms or parameters representative of physical processes. This is also already stated in the manuscript: "The fit parameters do not directly represent any physical or chemical processes or our understanding of the HOx recycling chemistry."

A different approach to describe the CIMS response was attempted by way of finding a solution to a simplified differential equation that described the expected chemical recycling reactions, radical production and loss processes (not shown or discussed in the manuscript). In that approach some approximate assumptions had to be made for which experimental data were lacking (such as e.g. HO₂ wall loss) and which could not be refined without further extensive experimental tests. As a consequence, the predictive capability of the more deterministic approach did not exceed that of the empirical eight-parameter exponential function. Finding a correction function with physically meaningful variables as input is current work in progress.

P16 L22: A scatter of 10-20% is reported. Under which conditions was it observed (nature of trace gases, OH reactivity level, etc.). How many σ is it?

Response: The full results from the OH reactivity comparison campaign at the SAPHIR chamber are described in detail in Fuchs et al. (2017); here a brief summary was added in the manuscript: "The scatter was greatest for the experiment of isoprene, MVK and MACR and the "urban mix" experiment with o-xylene, toluene, 1-pentene and was largest for OH reactivity above 15 s⁻¹. Since one standard deviation is at the order of 7 %, the reported scatter of up to 20 % is less than 3 σ of the measurements."

P17 L7-9: Please be quantitative. How accurate is "high accuracy" and "lower accuracy"?

Response: Mean deviation from reference OH reactivity has been included and the sentence now reads:

"The comparison including OH reactivity up to 40 s⁻¹ has shown that CIMS measurements were of high accuracy for certain chemical conditions (experiments with CO, pentane, monoterpenes, sesquiterpenes) where CIMS measurements and the OH reactivity reference agreed within uncertainty (mean deviation less than 13 %). For other conditions (isoprene, MVK, MACR mixture and urban mixture of o-xylene, toluene, 1-pentene) lower accuracy was observed, with a mean deviation to the reference of 27 %."

Table 1: How many σ did the authors used to calculate the limits of detection? What are the precisions on Δt and k_w values?

Response: The limit of detection for OH concentration was determined by Berresheim et al. (2000) who wrote "From the 2 σ scatter of signal count rate measurements at nighttime, the corresponding detection limits for 5 min signal integration were calculated to be 2 x 10⁵ molecules cm⁻³ for OH (...). However, for the present time we conservatively estimate the OH detection limit to be 5 x 10⁵ molecules cm⁻³". This conservative estimate has been found to be robust and stable and thus has been quoted here.

The limit of detection for KOH is a 1 σ value.

The precision on Δt is ± 5 %.

The precision on k_w is $\pm 8 \%$.

All values/references have now been included in Table 1.

Table 1: MOHp CIMS kOH measurement and system properties.

CIMS system property	value and measure
[OH] limit of detection	^a 5×10^5 molecules cm^{-3}
kOH limit of detection	^b 0.5 s^{-1}
kOH upper measurement limit	40 s^{-1}
typical [OH] ₀ and [HO ₂] ₀ produced in UV zone	10^8 molecules cm^{-3}
kOH temporal resolution	$60 - 300 \text{ s}$
typical reaction time $\Delta t = (t_2 - t_1)$	^b $0.1 \text{ s} \pm 5 \%$
typical OH wall loss rate k_w	^b $10 \text{ s}^{-1} \pm 8 \%$
kOH measurement accuracy	^b 1 s^{-1} ($k_{OH} < 30 \text{ s}^{-1}$) ^b 2 s^{-1} ($k_{OH} 30-40 \text{ s}^{-1}$)
kOH measurement precision	^b 0.14 s^{-1}
known interference	nitric oxide (NO)

^a based on $> 2 \sigma$ signal count rates, Berresheim et al. (2000).

^b 1σ

Fig. 14: It would be useful to add a time series for NO since it can disturb the measurements. Could the measurement underestimation due to the presence of NO also be quantified and shown as another time series?

Response: Figure 14 has been adapted and another panel added. Since NO mixing ratios and the measurement underestimation are related to each other by a factor (0.7) they are referenced accordingly on the two y-axes of the panel. The left hand axis shows the measurement underestimation in s^{-1} and the right hand axis shows the NO mixing ratio (ppb) at MOHp. The figure legend has been extended to include the added information.

“Figure 14: Observations at MOHp for the year 2015. (a) OH Reactivity measurements by CIMS, with 3 hour and daily means in blue and orange respectively. Filtered for recorded instrumental and laboratory interferences and seven outliers not coinciding with short term CO and NO₂ concentration peaks. 15541 valid measurement points. (b) Measured NO mixing ratios (right y-scale) and estimated CIMS OH reactivity measurement underestimation as a result of NO presence in ambient air (left y-scale).”

Technical corrections

P1 L27: “. . .termed also total OH loss rate. . .” should read “. . .also termed total OH loss rate. . .”

Response: Changed.

P4 L20-23: This sentence should be rephrased. It’s not clear what is meant by “. . . is the final OH concentration without UV light subtracted from the final OH concentration with the UV lamp on.”

Response: Some clarification is provided as to which individual OH measurements make up the OH reactivity measurement, and the sentence has been rephrased and extended:

“For the OH reactivity measurement in ambient air, OH concentrations are measured in titration zone 1 and 2 (Fig. 1), i.e. $[OH]_{T1}$ and $[OH]_{T2}$. In each titration zone, OH is both measured when the UV lamp is on and OH is produced in front of the inlet via R1 and R2, i.e. the same as during OH concentration calibration ($[OH]_{UV}$) as well as when the UV lamp is off, i.e. the same as during a normal OH concentration measurement, i.e. $[OH]_{ambient}$. The OH measurement used for OH reactivity is then the difference between the two measurements: $[OH]_{T,1,2} = [OH]_{UV,1,2} - [OH]_{ambient,1,2}$. This way any

contribution from ambient OH on the OH reactivity measurement, typically at the order of a few percent, is removed.”

P4 Eq. 1: Missing negative sign in the exponential factor. k_w should also be added in this equation for consistency with Eqs. 2-4

Response: Corrected. Equation 1 is now:” $[OH](t) = [OH]_0 \times e^{-(k_{OH} + k_w) \times t}$ with $k_{OH} = \sum k_{X_i+OH} \times [X_i]$ and X_i for the OH reactants and k_w as the measurement system’s wall loss rate. “

P4 L32: Delete the word “lawful”

Response: Deleted.

P6 L7: “. . . within the flow tube from point of the inlet to . . .” should read “. . . within the flow tube from the inlet tip to . . .”

Response: Changed.

P6 L18-19: “The scaling rate, i.e. the times of SO₂/propane injection. . .”. Shouldn’t it read “The scaling rate, the inverse of the reaction time between T1 and T2. . .”

Response: The referee is of course correct that the scaling rate is the inverse of the reaction time between T1 and T2. In the model the SO₂ and propane injections are triggered at the time steps required to achieve this specific reaction time between T1 and T2. This has now been clarified and the sentence modified to read: “The scaling rate and OH wall loss rate are prescribed based on experimental laboratory values. The scaling rate, as the inverse of the reaction time between T1 and T2, determines the SO₂ and propane injection in the model as the injections are triggered at the required times steps to achieve the prescribed reaction time.”

P7 L3-6: “volume flow” should read “volumetric flow rate”. Several instances.

Response: Changed for the instances found in this Section 3.1.

P7 L12: “Additionally” should read “Additional”

Response: Changed.

P9 L26: “synthetic air has been measured for a range of VOC and OH reactivity calculated” should read “synthetic air has been screened for a range of VOC and OH reactivity calculated from a quantification of these contaminants”

Response: Changed as suggested.

P13 L18: Replace “annulled” by “cancelled”

Response: Changed.

P19 L24: “Calculations and propagation of uncertainties was performed. . .” should read “Calculations and propagation of uncertainties were performed. . .”

Response: Corrected.

P19 L27: Double-check the 5% value reported for $\ln([OH]_{T1}/[OH]_{T2})$. It’s 7.1% in section 3.2.1.

Response: The value of 7.1 % is the correct one and the value on page 19 was rectified. For the illustrative example uncertainties were adjusted accordingly using the correct uncertainty value of 7.1 % for $\ln([OH]_{T1}/[OH]_{T2})$. This resulted in minor changes of the values but does not affect the conclusion. Consequently, the NO concentration above the total measurement error is increased has been up-corrected to 370 ppt, i.e. the value changed from 330 to 370 ppt in the text:

“In this example the positive systematic error from the NO interference (defined in Section 3.5 as $0.8 \text{ s}^{-1} / \text{ppb NO}$) would only be increasing the total measurement error for NO concentrations above 370 ppt.”

P19 L31-32. Some units are missing.

Response: Unit for scaling rate (s^{-1}) included. The term $\ln([OH]_{T1}/[OH]_{T2})$ has not got any units as it is the ratio between two concentration measurements.

Abstract. An operational chemical ionisation mass spectrometer (CIMS) for hydroxyl radical (OH) and sulfuric acid (H_2SO_4) concentration measurements was adapted to include observations of OH reactivity, which is the inverse of OH lifetime, for long-term monitoring at the Global Atmosphere Watch (GAW) site Hohenpeissenberg (MOHp), Germany. OH measurement using CIMS is achieved by reacting OH with SO_2 , leading to the production of H_2SO_4 which is then detected. The adaptation for OH reactivity consists of the implementation of a second SO_2 injection, at a fixed point further down flow in the sample tube to detect the OH decay caused by reactions with OH reactants present in the sample.

The method can measure OH reactivity from less than 1 to 40 s^{-1} with the upper limit due to the fixed positioning of the second SO_2 injection. To determine OH reactivity from OH concentration measurements, the reaction time between the two titration zones and OH wall losses in the sample tube need to be determined accurately through OH reactivity calibration. Potential measurement artefacts as a result of HOx recycling in the presence of NO have to be considered. Therefore NO contamination from gases used in instrument operation must be minimised and ambient NO must be measured concurrently to determine the measurement error.

This CIMS system is shown here to perform very well for OH reactivity below 15 s^{-1} and NO concentrations below 4 ppb, both values that are rarely exceeded at the MOHp site. Thus when deployed in suitable chemical environments, this method can provide valuable continuous long-term measurements of OH reactivity. The characterisation utilises results from chamber, laboratory and modelling studies and includes the discussion and quantification of sources of uncertainties.

1 Introduction

Trace gas removal in the troposphere is largely controlled by the hydroxyl radical (OH). In a time when the chemical composition of the atmosphere is significantly and rapidly changing (Monks et al., 2009) we need to better understand what processes determine the oxidative self-cleaning capacity of the atmosphere as well as monitor how this oxidation efficiency is evolving over longer timescales. The estimation and measurement of OH reactivity, also termed total OH loss rate (s^{-1}), contributes to elucidating oxidant budgets and thus our understanding of atmospheric photochemical cycling and oxidation capacity (e.g. Stone et al., 2012; Rohrer et al., 2014; Yang et al., 2016). As envisioned in a recent “roadmap for OH

reactivity”, continuous OH reactivity measurements at long-term monitoring stations should become permanent additions to the standard observation portfolio in time (Williams and Brune, 2015). The purpose of this paper is to both present a new measurement method for OH reactivity and demonstrate the suitability of this approach for long-term measurements at the Global Atmosphere Watch (GAW) monitoring station Hohenpeissenberg (WMO, 2006) and other similar stations.

5 OH reactivity can be measured using a range of different approaches. Established techniques have recently been summarised by e.g. Hansen et al. (2015), Yang et al. (2016) and Fuchs et al. (2017). In principle OH reactivity can either be measured by directly probing the pseudo first order OH decay curve occurring in the presence of OH reactants or by observing the relative change in OH reactivity of a chosen OH reactant not present in the atmosphere. In the direct approach, OH is detected by Laser Induced Fluorescence (LIF) (Kovacs and Brune, 2001) or Chemical Ionisation Mass Spectrometry (CIMS) (McGrath,
10 2010). The more indirect method is called Comparative Reactivity Method (CRM) and here Proton-Transfer-Reaction Mass Spectrometry (PTR-MS) (Sinha et al., 2008) or a Gas Chromatographic Photo-Ionisation Detector (GC-PID) (Nölscher et al., 2012) is used for detection of the commonly chosen OH reactant pyrrole. For the direct method measuring the decay of OH concentration, a flow tube set up forms an integral part of the measurement system. Either the flow tube is used with a laser-photolysis pump and probe approach (Sadanaga et al., 2004) or it is used with a moveable injector (Kovacs and Brune, 2001;
15 Ingham et al., 2009; Hansen et al., 2015). The combination of a moveable injector inside a flow tube combined with OH detection by CIMS is described by McGrath (2010) and the method described here uses a CIMS for OH detection, but with a novel approach of measuring the OH decay.

The development and design of the method to measure OH reactivity with CIMS as described here arose out of an existing and ongoing long-term measurement setup for OH and H₂SO₄ at the Meteorological Observatory Hohenpeissenberg (MOHp) in Germany (Berresheim et al., 2000; Rohrer and Berresheim, 2006). The measurement of OH reactivity was added
20 to the continuous OH and H₂SO₄ measurement routine in 2009. The method was conceived with the following requirements, which were all achieved: maintaining OH and H₂SO₄ observational continuity, maintaining stability and appropriate time resolution for all measurements, a design optimised for expected OH reactivity up to about 20 s⁻¹ with high level of automation and infrequent need for manual calibration. No moving parts, as would be the case of a moveable injector, had to
25 be installed, producing a suitable robustness for long-term operation.

In this paper, we first describe the measurement principles of OH reactivity by CIMS as well as the model set up used to investigate instrument internal chemical processes in Section 2. Section 3 deals with the characterisation of OH reactivity measurements, including the quantification of errors from OH reactivity calibration and instrument internal HO_x recycling in the presence of NO. Approaches for minimizing uncertainties and correcting systematic errors are suggested. The quality of
30 OH reactivity measurements are examined in Section 4, where CIMS measurements are compared to those from a LIF measurement system during a chamber study (Fuchs et al., 2017). Continuous OH reactivity measurements of ambient air at the MOHp during the year 2015 are also presented in Section 4, before concluding remarks in final Section 5.

2 Measurement principles using CIMS

2.1 OH measurement

The method for measuring OH reactivity using CIMS builds on OH concentration measurements that have been described extensively elsewhere (in principle e.g. Eisele and Tanner, 1991; Tanner et al. 1997; and specifically for this CIMS instrument and set up in Berresheim et al., 2000; Schlosser et al., 2009).

Briefly, OH radicals are converted to sulfuric acid molecules (H_2SO_4) by addition of SO_2 . H_2SO_4 is then ionised by charge transfer utilising negative chemical ionisation with NO_3^- reactant ions. The NO_3^- reactant ions are produced by flowing synthetic air enriched with HNO_3 over a radioactive alpha emitter (^{241}Am) before entering the ionisation region as sheath flow at atmospheric pressure. Both NO_3^- reactant and HSO_4^- product ions are then monitored by quadrupole mass spectrometry to determine concentrations (Fig. 1).

The CIMS system is calibrated every 20 minutes to obtain absolute OH concentrations and to monitor changes to the calibration factor which is indicative of stability in instrument sensitivity. For this, a special calibration unit forms an integral part of the measurement set up (Tanner et al., 1997) and is described in detail in Berresheim et al. (2000). Ambient water vapour is photolysed at 185 nm produced by a UV Pen-Ray lamp to produce a known OH concentration in front of the sample tube, with about 5 ms travel time before SO_2 is injected. The Hg lamp also produces a 253 nm emission line which is suppressed by an interference filter (CaF_2 , 185 nm, Laseroptik) to avoid OH production by O_3 photolysis and the reaction of the $\text{O}(^1\text{D})$ produced with water vapour (Fig. 1). The photolysis of water vapour produces an equal amount of OH and H radicals (R1), the latter reacting rapidly with O_2 to produce the hydroperoxy radical HO_2 (R2).

OH is then measured indirectly through the conversion of OH to H_2SO_4 which occurs in the flow tube chemical reactor in front of the ionisation region. The OH titration proceeds via reactions (R3-R5) within approximately 20 ms, after the addition of SO_2 to the sample tube flow via front injectors F1 or F2 achieving a SO_2 concentration of about 10 ppm in the sample tube chemical reactor (Fig. 1).

The CIMS sample flow tube dimensions are 0.019 m in diameter and 0.30 m in length, with a sample flow of around 13 SLM. The complete length from sample tube tip to the pinhole is 0.8 m. The distance between the front injectors is 0.15 m

and between front and rear injectors is 0.054 m (Fig. 1). The pressure in the sample tube is close to ambient pressure (around 900 hPa at MOHp). The sample flow of 13 SLM is not itself kept constant by a mass flow controller but maintained by the difference of other mass flow controlled flows. The total residence time within the flow tube is circa 0.9 s which is long enough for HOx recycling to become significant inside the flow tube and the measurement artefacts from recycling thus need to be considered and accounted for. When nitric oxide (NO) is present, HOx recycling and thus OH production within the sample tube can occur via reactions (R6-R8):

Other important recycling reactions, such as HO₂-radical reactions including those with halogens (e.g. Cl) as well as the reaction of HO₂ and O₃, are considered negligible here because of the continental measurement location and time frames relevant for the CIMS system. In order to minimise the effect of NO induced HOx recycling, excess propane (C₃H₈) is added via the rear injectors (R1/R2 in Fig. 1) after the OH titration with SO₂ has completed. Propane concentration in the sample is then about 315 ppm, leading to OH loss by reaction with propane 20 times faster than with SO₂, and about 97 % OH is consumed by propane.

An additional measurement cycle is performed to quantify the residual recycled OH, ambient H₂SO₄ and any other species such as stabilised Criegee intermediates (e.g. Mauldin et al., 2012; Novelli et al., 2014) that react with SO₂ to form a H₂SO₄ measurement artefact. After the titration measurement (or “signal” mode, i.e. SO₂ injection at front and propane injection at rear), a “background” measurement is made. This involves adding both SO₂ and propane at the front injector, leading to the quantification of the contribution from ambient sulfuric acid and artefacts producing sulfuric acid. The final OH concentration is thus the difference between signal and background measurements.

For the OH reactivity measurement in ambient air, OH concentrations are measured in titration zone 1 and 2 (Fig. 1), i.e. [OH]_{T1} and [OH]_{T2}. In each titration zone, OH is both measured when the UV lamp is on and OH is produced in front of the inlet via R1 and R2, i.e. the same as during OH concentration calibration ([OH]_{UV}) as well as when the UV lamp is off, i.e. the same as during a normal OH concentration measurement, i.e. [OH]_{ambient}. The OH measurement used for OH reactivity is then the difference between the two measurements: [OH]_{T,1,2} = [OH]_{UV,1,2} – [OH]_{ambient,1,2}. This way any contribution from ambient OH on the OH reactivity measurement, typically at the order of a few percent, is removed. It is worth noting that the absolute OH concentrations are not critical for the OH reactivity measurement as the ratio between titration zone 1 and 2 is used (see Section 2.2), i.e. it is a relative measure and the stability of conditions between the two zones is relevant instead. Amongst other things, the development of the CIMS OH reactivity measurement arose out of the synergy of utilising the already existing frequent OH calibration and ambient OH measurements.

2.2 OH reactivity (kOH) measurement

The total loss rate of OH (kOH), or OH reactivity, is defined as the inverse of OH lifetime and described by the pseudo first order decay of OH in the presence of OH reactants (Kovacs and Brune, 2001):

$$[OH](t) = [OH]_0 \times e^{-(kOH + k_w) \times t} \quad (1)$$

with $kOH = \sum k_{Xi+OH} \times [X_i]$ and X_i for the OH reactants and k_w as the measurement system's wall loss rate.

Whilst some measurement techniques effectively capture the full OH decay curve (Sadanaga et al., 2004), the CIMS technique is based on the logarithmic relation of any two points of OH concentration at time t_1 and time t_2 (i.e. $[OH]_{t1}$ and $[OH]_{t2}$) on the decay curve, from which OH reactivity can be calculated if the (reaction) time $\Delta t = (t_2 - t_1)$ between the two points and the CIMS system specific OH wall loss rate k_w are known.

$$\frac{-d[OH]}{dt} = (kOH + k_w) \times [OH] \quad (2)$$

$$[OH]_{t2} = [OH]_{t1} \times e^{-(kOH + k_w) \times \Delta t} \quad (3)$$

$$kOH = \left\{ \ln \left(\frac{[OH]_{t1}}{[OH]_{t2}} \right) \right\} \times sr_{CIMS} - k_w \quad (4)$$

with sr_{CIMS} being the scaling rate $sr_{CIMS} = \frac{1}{(t_2 - t_1)}$ in s^{-1} . The total loss rate as measured by CIMS includes the OH loss by chemical reactions (kOH) as well as OH loss onto flow tube walls (k_w). The wall loss rate can be quantified using Eq. (4) when no OH reactants are delivered to CIMS via zero air, i.e. a zero measurement. The scaling rate sr_{CIMS} is determined under synthetic conditions when a known amount of OH reactivity is delivered to the instrument (Section 2.3.)

To achieve the measurements of two OH concentrations on the OH decay curve, two consecutive measurements in two separate titration zones in the CIMS flow tube are implemented (Fig. 1). The distance between the titrations zones have been optimised for the physical and operational set up at the MOHp and a typical low kOH regime. The CIMS has a vertically oriented inlet with a sample tube that is 0.63 m long to draw sample air through the observation platform floor into the laboratory where the instrument is installed at the ceiling. The injectors for the second titration zone were permanently installed 0.15 m downflow of the first zone which is at the tip of the sample tube. Considering the fixed sample mass flow rate, the distance between the two titration zones is equivalent to a calculated reaction time of about 0.1 s. Typical CIMS OH reactivity measurement properties and system parameters are summarised in Table 1.

2.3 OH reactivity calibration to determine scaling rate sr_{CIMS} and wall loss rate k_w

The scaling rate sr_{CIMS} and wall loss rate k_w are parameters that need to be determined experimentally by regular OH reactivity calibration. Since the inlet air flow rate (Fig. 1) of 2280 L/min is too large to be generated for OH reactivity

calibration, an external glass flow tube is placed on top of the sample tube during OH reactivity calibration, schematically shown in Fig. 2. The setup is such that the excess of the OH reactivity calibration flow of 50 SLM can overflow and the normal CIMS sample flow rate is maintained at 13 SLM. OH reactivity ranging from 0 – 20 s⁻¹ is produced using propane as OH reactant from either home-made mixture of 0.18 % propane in N₂ (purity 99.999 %), or commercially available 0.2 % propane (purity 99.999 %) in N₂ (purity 99.9999 %) (Riessner-Gase, Lichtenfels, Germany). The OH reactant is delivered in a humidified synthetic air matrix, which is made of Milli-Q ultrapure water, with a conductivity of 0.055 μS cm⁻¹ at 25 °C and up to 2 ppb Total Organic Carbon, and synthetic air (20 % O₂, 80 % N₂) with a purity of 99.5 % for O₂ and 99.999 % for N₂. The lower section of the glass tube that is illuminated by the UV light is made of Suprasil quartz to allow transmission of the 185 nm UV wavelengths and hence OH production in front of the inlet tip.

To obtain the scaling rate, CIMS OH measurements in titration zone 1 (T1) and titration zone 2 (T2), i.e. $\ln([\text{OH}]_{\text{T1}}/[\text{OH}]_{\text{T2}})$, are regressed against the known OH reactivity (Fig. 3). The regression slope itself constitutes the reaction time Δt in seconds. The scaling rate sr_{CIMS} is the inverse of the reaction time in seconds. The wall loss rate k_w is the product of the scaling rate and the value of $\ln([\text{OH}]_{\text{T1}}/[\text{OH}]_{\text{T2}})$ measured during the addition of zero OH reactivity, i.e. synthetic air only.

2.4 Facsimile model representation of OH reactivity measurement by CIMS

To investigate and simulate OH reactivity measurements by the CIMS instrument in different operating and chemical conditions, radical and trace gas concentrations in the CIMS sample flow tube have been modelled. For this, a zero dimensional (0D) model has been used where the time evolution of ~1 second represents the development of trace gas concentrations within the flow tube from the inlet tip to the entry point of the vacuum system of the mass spectrometer downstream. The numerical simulations were executed using the FACSIMILE program (Chance et al., 1977), including several sulfur oxidation steps occurring during the conversion of OH to H₂SO₄ in the chemical mechanism scheme (see Supplementary Material S1).

A typical modelling simulation involves initialisation with a given OH and HO₂ concentration representing their production in the UV zone in front of the flow tube. When modelling runs are to represent typical CIMS operating conditions, the absolute OH and HO₂ concentration produced in the UV zone, i.e. OH_{UV} and HO_{2UV}, is not critical, however the ratio between OH_{UV} / HO_{2UV} can significantly affect the subsequent chemical cycling. For simulations representing typical operational conditions, a ratio of OH_{UV} / HO_{2UV} = 1 is used, based on (R1) and (R2). All other relevant trace gases (e.g. propane for OH reactivity and NO to investigate HO_x recycling effects) are also initialised. Then a sequence of 4 runs is done where the titration (= signal) and background modes (see Section 2.1 and Fig. 4) in the two titration zones are modelled to reproduce the individual OH signals that make up a modelled CIMS OH reactivity value. The scaling rate and OH wall loss rate are prescribed based on experimental laboratory values. The scaling rate, as the inverse of the reaction time between T1 and T2, determines the SO₂ and propane injection in the model as the injections are triggered at the required times steps to achieve the prescribed reaction time. The injections were achieved in the modelling run by simply setting the concentration to the given level at the specific time step, ignoring any mixing time that might actually occur in the flow tube.

For analysis the time series of the radical and trace gas species were inspected over 1 s, $[\text{OH}]_{\text{T1}}$ and $[\text{OH}]_{\text{T2}}$ calculated from endpoint H_2SO_4 concentrations and modelled CIMS OH reactivity values determined. Where simulations were run to investigate H_2SO_4 production pathways with and without significant HOx recycling, all pathways that produced H_2SO_4 through recycled OH were tagged, allowing the separation of instrument internally produced OH and OH produced in the UV zone, i.e. initial or external OH.

3 Sources of uncertainty in CIMS OH reactivity measurements

In order to obtain OH reactivity values from the measured OH concentrations, Eq. (4) is evaluated and therefore uncertainties in the scaling rate sr_{CIMS} and wall loss rate k_{w} contribute to the uncertainty in OH reactivity. Here, the sources of uncertainties for each parameter are considered. All uncertainties, limitations and their relevance to the scaling rate, the wall loss rate and ambient measurements discussed in this section are shown in Table 2. Effects from photolysis of organic OH reactants such as e.g. aldehydes and alcohols in the CIMS UV zone have been estimated to be negligible and are not discussed further in this section.

3.1 Ambient pressure and temperature dependent reaction time

A fixed mass flow in the sample tube is maintained by a constant mass flow difference induced in the ionisation region (Berresheim et al., 2000) which means that with changing ambient temperature and pressure, the volumetric flow rate through the sample tube varies. This variability in volumetric flow rate affects the residence time in the tube, and therefore the OH reaction time with OH reactants through changing the residence time between CIMS titration zone 1 and 2. Additionally, changes in volumetric flow rates can also affect flow characteristics in the sample tube, and therefore OH wall loss and mixing of injected SO_2 . This constitutes a source of error which needs to be taken into account, especially so for long-term measurements where temperature and pressure have periodic behavior over a range of timescales.

Figure 5 shows the changes in reaction time calculated for F1 to F2 (Fig. 1) purely based on the observed temperature and pressure changes, and therefore volumetric flow rates in the sample tube, at the Meteorological Observatory Hohenpeissenberg for the year 2015. A clear annual cycle is evident with smaller scaling rate sr_{CIMS} (= longer reaction times) in the winter months and larger scaling rates sr_{CIMS} (= shorter reaction times) in the summer. Additional variability at shorter timescales is superimposed at daily and several day long cycles as a result of boundary layer dynamics, surface energy exchange and frontal weather systems. If the scaling rate was assumed to be a fixed value, as in the example of Fig. 5 a flow-based mean sr_{CIMS} of 6.0 s^{-1} for 2015, the associated uncertainty of $\pm 0.17 \text{ s}^{-1}$ (1 sigma) and a maximum deviation at the order of $\pm 0.4 \text{ s}^{-1}$ would result in a non-negligible, seasonally systematic error when dealing with long-term data.

In order to account for this variability in CIMS OH reactivity reaction time, the long-term measurements at MOHp are calculated using a normalised scaling rate and concurrent temperature and pressure observations (Eq. 5 and 6). The scaling

rate determined by laboratory experiment is referenced to the long-term climatological mean pressure and temperature at MOHp ($T_{\text{reference}} = 7\text{ }^{\circ}\text{C}$, $p_{\text{reference}} = 904\text{ hPa}$).

$$N_{TP} = \left(\frac{T_{\text{reference}}}{T_{\text{observed}}} \right) \times \left(\frac{p_{\text{observed}}}{p_{\text{reference}}} \right) \quad (5)$$

$$5 \quad kOH_{\text{corr}} = N_{TP} \times \left\{ \ln \left(\frac{[OH]_{t1}}{[OH]_{t2}} \right) \right\} \times sr_{\text{CIMS}} - k_w \quad (6)$$

3.2 Experimental determination of scaling rate sr_{CIMS} and wall loss rate k_w

The uncertainties of the scaling rate sr_{CIMS} and wall loss rate k_w are dependent on the accuracy and precision of the calibration points (Fig. 3). The calibration of CIMS OH reactivity is on the one hand fundamentally based on knowing the absolute OH reactant concentration and its OH reactivity based on published kinetic rate constants. On the other hand, the uncertainty in the CIMS measured term $\ln([OH]_{T1}/[OH]_{T2})$ is e.g. dependent on CIMS instrument, UV-source and mass flow controller performances and quality of gas mixtures such as SO_2 mixture for OH titration.

3.2.1 Uncertainty in $\ln([OH]_{T1}/[OH]_{T2})$

There are several factors that can produce an error in the OH (i.e. H_2SO_4) concentration detection by CIMS during the OH reactivity measurements. These include conditions that change between the measurements in titration zone 1 and 2, such as e.g. $[\text{H}_2\text{O}]$, UV lamp intensity, wind speed and direction (i.e. crosswinds in front of the sample tube), all affecting $[OH]_{\text{UV}}$ production, as well as short term instrumental variability. Variability in ambient OH is expected to have a negligible effect because $[OH]_{\text{UV}}$ is larger by two orders of magnitude compared to typical variability in ambient OH. All these uncertainties are not dealt with here independently but are estimated by the standard deviation of consecutive or repeated measurement points.

During the OH reactivity calibration experiments the measurement repeatability in $\ln([OH]_{T1}/[OH]_{T2})$ is considered in the linear regression determining the scaling rate (Fig. 3), and thus it also constitutes a factor in the uncertainty of the scaling rate itself. The repeatability in $\ln([OH]_{T1}/[OH]_{T2})$ is defined as the standard deviation of all replicate measurements at a given OH reactant concentration. Under synthetic conditions (e.g. OH reactivity calibration), the median variability for $[OH]_{T1}$ was found to be 1.5 % and variability for $[OH]_{T2}$ was 80 % larger with a median of 2.7 % . However in absolute terms, the variability is larger for $[OH]_{T1}$ as it is on average larger than $[OH]_{T2}$ by a factor of four.

During the routine operation of ambient sampling at MOHp, five consecutive measurements are made in each titration zone, each taking 30 seconds, and each titration zone is sampled with and without the UV lamp on, i.e. sampling of each titration zone is five minutes long. The variability in the consecutive measurements as expressed by the standard deviation provides the basis for the uncertainty in the averaged values ($[OH]_{T1}$, $[OH]_{T2}$) that is used for the calculation of OH reactivity. Titration zone measurements in zone 2 immediately follow those in zone 1 so that the measured OH reactivity is effectively an average over a ten minute period. However during routine operation the OH reactivity time resolution is actually 20

minutes because the complete operational CIMS measurement sequence includes other separate measurements such as sulfuric acid and peroxyradical concentration measurements. As an example for typical values at MOHp, looking at six months' worth of ambient OH reactivity measurements, both $[\text{OH}]_{\text{T1}}$ (mean = $118.9 \pm 5.8 \times 10^6$ molecules cm^{-3}) and $[\text{OH}]_{\text{T2}}$ (mean = $33.2 \pm 1.7 \times 10^6$ molecules cm^{-3}) have a mean error of 5 % (4.9 and 5.1 % respectively). The propagated error in the mean in the term $\ln([\text{OH}]_{\text{T1}}/[\text{OH}]_{\text{T2}})$ is 7.1 %.

3.2.2 OH reactant concentration in OH reactivity calibration gas mixture

Depending on the experimental set up for the OH reactivity calibration, OH reactant concentrations are either measured or calculated. In the case of parameters established during the chamber based OH reactivity comparison campaign (Fuchs et al., 2017) OH reactant concentrations were directly measured. In case of the standard OH reactivity calibrations at MOHp the OH reactant concentrations are calculated based on mass flow, concentration of the OH reactant gas mixture and dilution in the carrier gas. The accuracy of the OH reactant concentration in the gas mixture is considered here for a home-made mixture of 0.18 % propane, a commercial 0.218 % propane mixture and a commercial 1 % CO mixture.

Both propane OH reactivity calibration mixtures were analysed for their propane content by the MOHp GC-FID system used for long-term measurements of VOC (Plass-Dülmer et al., 2002). To allow analysis with this system, the samples were diluted by a factor of 10^6 . Propane concentrations were observed $12 \% \pm 6 \%$ higher than declared on the label for the home-made and commercial mixture respectively, but agree within two standard deviations of the combined measurement error. A 12 % increase in mean concentration corresponds to an increase of 12 % of the scaling rate, and the 1 standard deviation measurement uncertainty (i.e. concentration of $\pm 0.011 \%$ propane in mixture) is equivalent to about ± 5 ms uncertainty in the reaction time. The measured propane concentrations were used to calculate OH reactivity with the concentration measurement uncertainty translating to an OH reactivity uncertainty of 5 %.

The commercial CO 1 % mixture (purity 99.5 % CO in 99.9999 % N_2) has a specified 2 % measurement uncertainty, which means the relative error in calculated OH reactivity from this uncertainty is 2 %.

3.2.3 OH reactant contamination in calibration gas mixture

Whilst there is an uncertainty in the concentration of the chosen OH reactant, there is a potential additional error as a result from other OH reactants traces, i.e. contaminant OH reactants, in the calibration gas mixture. If the OH reactant contamination, other than NO, is large and unaccounted for, the scaling rate can be underestimated because the calculated OH reactivity is underestimated. In case of NO contamination HOx recycling inside the CIMS instrument can produce an underestimation of the $\ln([\text{OH}]_{\text{T1}}/[\text{OH}]_{\text{T2}})$ term and thus produce an overestimation of the scaling rate. For the case of the 0.18 % and 0.218 % propane mixture, no OH reactant contamination was found when a dilution of the mixture was analysed for 40 VOC species (Plass-Dülmer et al., 2002; Hoerger et al., 2015). This sampling approach required a dilution by a factor of 10^6 which precludes a sensible estimation of an upper limit of OH reactivity from contaminant species. The measurements do not reveal substantial contamination, yet extra OH reactivity from contaminant traces cannot be ruled out.

3.2.4 OH reactant contamination in synthetic air (carrier gas)

CIMS calibrations of OH reactivity are done using synthetic or zero air as carrier gas. Uncertainty due to OH reactants traces in synthetic air do not affect the derivation of the scaling rate, i.e. the slope of the regression (Fig. 3) because a constant flow of synthetic air is used in experiments and any additional OH reactivity from carrier gas contamination provides a fixed OH reactivity across the whole range of calibration OH reactivity. However the wall loss rate can be affected as the measurement of zero reactivity is done with synthetic air, in which case contaminant OH reactants can lead to an overestimation of the wall loss rate. To obtain an estimate of typical OH reactant contamination and consequently error in the wall loss rate synthetic air has been screened for a range of VOC and OH reactivity calculated from a quantification of these contaminants. This standard synthetic air (Riessner-Gase, Lichtenfels, Germany) is composed of 20 % oxygen (purity 99.5 % O₂) and 80 % nitrogen (purity 99.999 % N₂).

The synthetic air was analysed for 40 VOC species (Plass-Dülmer et al., 2002; Hoerger et al., 2015) leading to a calculated OH reactivity of $0.02 \pm 0.02 \text{ s}^{-1}$. It was observed that tubing, valves etc. needed to be sufficiently flushed as to remove trace contamination and achieve a low constant level of residues before carrying out the zero OH reactivity measurements.

For the long-term OH reactivity measurements, not all synthetic air compressed gas cylinders used for zero measurements and OH calibrations were analysed for its contamination by VOC and inorganic OH reactants. Based on CIMS measurements, the variability in the zero for the same gas cylinder, i.e. reproducibility of zero, is better than 6 %. However it has also been observed that differences between synthetic air cylinders can vary greatly in its contaminant levels. Differences in the CIMS zero measurement for different synthetic air cylinders have been observed to vary up to 42 %, indicating OH reactivity by contaminant OH reactants can make up to about 5 s^{-1} , making such cylinders unsuitable for OH reactivity calibration or other experiments.

To address the potential source of error coming from using different synthetic air gas cylinders for the regular consecutive OH reactivity calibrations and zero measurements required for the long-term measurements, a reference synthetic air cylinder has been designated recently which is used for cross-referencing and quality control of synthetic air used in experiments.

3.2.5 NO contamination in all gas mixtures

It is important to consider the contamination of nitric oxide (NO) in all gas mixtures used for CIMS measurements due to its critical role in HO_x recycling within the CIMS sample flow tube. NO can introduce significant measurement artefacts and therefore its presence in the gas mixtures used for OH reactivity calibration and routine measurements needs to be considered.

For this the Facsimile model has been used to investigate the effect of NO contamination on the determination of the scaling rate during OH reactivity calibration. Then a modelled scenario of no NO presence in the system is compared with a scenario of a realistic contamination in the experimental set up. The following realistic nominal values have been used in the NO

contamination case: 140 ppt NO from the SO₂ titration gas mixture and 20 ppt NO from the synthetic air carrier gas. The 140 ppt NO is based on contamination found in the SO₂ titration gas mixture during the OH reactivity comparison campaign (Fuchs et al., 2017) and the 20 ppt NO is based on the detection limit of the chemiluminescence analyser for NO concentration measurements at MOHp. The levels of concentration were also confirmed by direct NO measurements of the

gas mixtures. Contamination of NO in the propane calibration gas mixture is considered to be negligible as a result of the high purity of the gas mixture and the applied dilution, leading to sub ppt NO concentrations in the sample flow.

The effect of NO on instrument internal HO_x recycling is non-linear and dependent on both the level of NO present and the magnitude of OH reactivity, which is discussed in detail in Section 3.4. In the case of the OH reactivity calibration, when considering OH reactivity of 0-40 s⁻¹, the modelled NO contamination case overestimates the scaling rate by 5 %. For OH reactivity 20-40 s⁻¹, overestimation increases to 9 %. When considering the range from 0-20 s⁻¹ for the OH calibration regression (Fig. 3), which is typically seen in ambient air at MOHp, the effect of NO contamination on the scaling rate is less significant: the overestimation of sr_{CIMS} is 1 %. This shows that the determination of sr_{CIMS} in cases of NO contamination of the order of tens to hundreds of ppt NO is more accurate when small OH reactivity is considered (0-20 s⁻¹). Thus, paying particular attention to NO contamination and minimising its effect on the scaling rate determination forms part of best practice for this OH reactivity measurement method. This is also relevant in terms of long-term stability of OH reactivity measurements as the NO contamination in the 2 % SO₂ gas mixtures can vary. Concentrations of NO in the CIMS sample flow from different SO₂ cylinders have been found to range from the order of tens of ppt to up to 380 ppt NO. The 2 % SO₂ gas cylinder normally needs to be replaced every 3-6 months and the current standard operating procedure includes the measurement of NO in each SO₂ mixture to track potential sources of error from NO contamination.

3.2.6. OH kinetic rate constants

Recommended rate constants from both IUPAC (Atkinson et al., 2006) and JPL assessments (Burkholder et al., 2015) are provided with uncertainty factors, which are considered here. Discrepancies coming from the difference between recommendations are assessed for cases CO and C₃H₈ as OH reactants and described in detail in Supplementary Material S2. The uncertainty in the scaling rate from the IUPAC kinetic rate constant uncertainty (1 sigma) is for 11 % for CO and 5 % for propane, which highlights that difference in uncertainties of rate constants can be one point of consideration when choosing an OH reactant for CIMS OH reactivity measurement calibration. This issue will also be relevant for any other method that requires absolute OH reactivity values for calibration. Here, the uncertainty in the rate constant is included in the uncertainty estimation of calibration parameters such as the scaling rate sr_{CIMS}.

3.3 Validation of CIMS OH reactivity calibration using external glass flow tube

The CIMS OH reactivity calibration method using an external glass flow tube was developed and designed around the need of ease of use, minimising disturbance and downtime for the continuous operational CIMS measurements (OH, H₂SO₄) as well as remaining as close as possible to the normal measurement conditions with respect to e.g. turbulence at tip of the inlet

and flow characteristics in the sample flow tube. The validity of the OH reactivity calibration method as used at the MOHp was confirmed when the CIMS instrument took part in the first comprehensive OH reactivity instrument comparison campaign at the atmospheric SAPHIR chamber at the Forschungszentrum Jülich (FZJ), Germany, in April 2016 (Fuchs et al., 2017). At the beginning of the comparison campaign an OH reactivity calibration using the external flow tube and propane as OH reactant was carried out (Table 3). During the campaign the CIMS operating conditions were the same as at MOHp, i.e. the total air inlet flow (Fig. 1) and hence sampling rate from the chamber was 2280 L/min. This high flow rate meant that the chamber was operated in a flush mode and the concentrations of any injected OH reactants diminished rapidly within a few hours as a result of continuous dilution with synthetic air (Fuchs et al., 2017). It was possible to utilise four chamber experiments for the validation because the chamber roof was closed (excluding photochemistry in the chamber) and no NO or other reactive trace gases such as ozone was present in the chamber. CO was used as OH reactant in two experiments and pentane and a mixture of monoterpenes were each used once. For CO the determination of OH reactivity was done using the CO concentration measurements in the chamber. For pentane and monoterpenes, OH reactivity measurements from the LIF instrument from the Forschungszentrum Jülich (FZJ) are used for the determination of the CIMS scaling rate due to the low time resolution of the VOC measurements. The FZJ LIF OH reactivity measurements have been shown to be highly accurate and precise (Fuchs et al., 2017) thus providing reliable absolute OH reactivity values for this validation.

The temperature and pressure normalised scaling rates for the 6th (external flow tube) and 7th April 2016 (chamber, Table 3) agree with each other within one standard deviation. This agreement thus confirms that the OH reactivity calibration approach with the external flow tube (Fig. 2) is a valid and applicable method. Comparing all sr_{CIMS} values obtained during the chamber campaign in April 2016, it is evident that there is some variability which cannot be explained by the quoted uncertainty and the maximum difference in the mean is 0.9 s^{-1} . Similar differences have been observed for calibrations carried out at MOHp over a period of 6 months, all using the same calibration gas mixture, showing a maximum difference in the mean sr_{CIMS} values of 1.1 s^{-1} . These differences observed during both the chamber campaign as well as MOHp calibrations point toward a significant source of uncertainty which has not been understood yet. In terms of the mean values for Jülich chamber campaign and MOHp, the normalised sr_{CIMS} agree within one standard deviation uncertainty, indicating the long-term stability and robustness of CIMS measurement system.

Comparing the wall loss rates from the 6th and 7th of April 2016 (i.e. external flow tube vs chamber), the k_w values agree within one standard deviation, indicating the validity of the calibration approach using the external flow tube. However, same as for the scaling rate, not all individual experiments at the SAPHIR chamber produced k_w values that agree within one standard deviation (see also Supplementary Material S3), and the maximum difference in mean k_w values is 1.2 s^{-1} . Similarly, the individual k_w measurements made at MOHp over the course of 6 months do not all agree within one standard deviation (Table 3), but the mean statistics of the SAPHIR chamber campaign and the MOHp long-term wall loss rate do agree within 1σ .

3.4. Upper OH reactivity measurement limit

The upper measurement limit for the described CIMS system is largely determined by the detectable OH concentration in titration zone 2 (i.e. 2σ [OH] LOD of 5×10^5 molecules cm^{-3} , 5 min integration time, Table 1). As the second set of injectors is at a fixed position in the CIMS sample tube, the reaction time is therefore only variable by the flow rate. Increasing the sample flow rate would decrease the transit and reaction time between titration zone 1 and 2, leading to an increase in the upper measurement limit as detectable OH concentration could be measured at higher OH reactivity. However for a fixed (mass) flow rate as used in this system, the upper measurement limit is therefore dependent on the initially produced $[\text{OH}]_{\text{UV}}$ concentration (R1). With the current instrument setup (Table 1), the upper detection limit is about 40 s^{-1} . At this high end of OH reactivity HOx recycling in the presence of NO can introduce an additional uncertainty and determining the effective upper measurement limit under those conditions is discussed below.

To investigate CIMS OH reactivity influencing factors, the Facsimile model has been run for CO as OH reactant, contrasting effects on CIMS OH reactivity with and without an impurity of NO. An impurity of NO can be present in the commercial SO_2 gas mixtures and its effect on measurements and uncertainties is herewith assessed. For the model runs a mixing ratio of 140 ppt NO in the sample flow is used and was added into the model run at the same time as the SO_2 injection for OH titration. OH reactivity up to about 60 s^{-1} has been modelled and model set up parameters (temperature, pressure, water vapour concentration, initial $[\text{OH}]_{\text{UV}}$ and $[\text{HO}_2]_{\text{UV}}$, CIMS scaling rate and wall loss rate) have been based on typical observed conditions. The reasons why CO was chosen here is that it is a simple compound that is used for OH reactivity calibrations in general (Wood and Cohen, 2006), the reaction of $\text{CO} + \text{OH}$ leads to the direct production of HO_2 , and NO induced HOx recycling in the absence of any RO_2 presents the simplest case of HOx recycling.

The model was run with the OH recycling tagged version of the chemical mechanism (see Supplementary Material S1) whereby the total H_2SO_4 signal can be separated into the contributions coming from OH_{UV} ($\text{H}_2\text{SO}_4_{\text{OH}}$), from recycled OH ($\text{H}_2\text{SO}_4_{\text{OHrec}}$) and from the reaction chain $\text{HO}_2 + \text{SO}_2$ ($\text{H}_2\text{SO}_4_{\text{HO}_2}$) and from the reaction chain $\text{RO}_2 + \text{SO}_2$ ($\text{H}_2\text{SO}_4_{\text{RO}_2}$). Absolute H_2SO_4 concentrations for each pathway, relative contributions to total H_2SO_4 signals and differential or final H_2SO_4 signals (i.e. titration mode measurement (signal) minus background mode measurement (bkg), Fig. 4) have been analysed (Fig. 6 and 7).

Figure 6 shows the modelled H_2SO_4 concentrations for both titration zones and for the runs with and without NO impurity. It is evident that recycled OH contributes to the final H_2SO_4 concentration even in the case without NO (black dashed lines Fig. 6); however it is negligible because at the order of 10^3 molecules cm^{-3} it is several orders of magnitude smaller than the final H_2SO_4 . This HOx recycling happens via SOx chemistry only, and is not very efficient as the reaction $\text{SO}_2 + \text{HO}_2$ is slow with an upper limit reaction rate constant of 1.0×10^{-18} molecules $\text{cm}^{-3} \text{ s}^{-1}$ (Atkinson et al., 2004).

Whilst all the recycled OH in the no impurity NO case comes from the SOx chemistry itself, HOx recycling in the presence of NO can proceed faster. Although $[\text{SO}_2] > [\text{NO}]$ by about five orders of magnitude, the OH recycling reaction $\text{HO}_2 + \text{NO}$ is

about seven orders of magnitude faster than the reaction $\text{HO}_2 + \text{SO}_2$. Therefore trace levels of NO do have to be taken into account for CIMS OH reactivity measurements.

In the case of the NO impurity, the H_2SO_4 from the recycled OH is increased by two orders of magnitudes (blue dashed lines Fig. 6). For titration zone 1, this remains a negligible proportion of the final H_2SO_4 concentration, but for titration zone 2 this is no longer the case. For OH reactivity larger than 30 s^{-1} , remaining OH_{UV} concentration that is to be measured is of the same order as the recycled OH. The contribution from the recycled OH leads to a deviation from the exponential first order decay (Fig. 6b, blue solid line), and thus to an overestimation of the H_2SO_4 concentration, implying less OH loss than expected for a given OH reactivity, and consequently CIMS OH reactivity above ca. 30 s^{-1} is underestimated. At an OH reactivity of 40 s^{-1} this underestimation is 5 s^{-1} in the modelled NO impurity case.

The CIMS measurement cycle with signal and background modes is designed to cancel out contributions to artefact H_2SO_4 signals. However in the case of HOx recycling within the titration zone, this is not the case because recycled OH in the background mode is smaller than that in the signal mode (Fig. 7a). This is true for both titration zones, but of relevant magnitude in zone 2 only. This means that the signal from the recycled OH in the titration is not cancelled by the background measurement, remaining an artefact contribution to the final H_2SO_4 concentration that is used for calculating OH reactivity (Fig. 7b).

The relevance of the recycled OH in titration zone 2 becomes obvious inspecting Fig. 7c which reveals that in the case of NO presence, at increasing OH reactivity ($> 40 \text{ s}^{-1}$) when remaining OH_{UV} becomes smaller (solid blue line), the relative importance of recycled OH increases (dashed blue line), ultimately dominating the total H_2SO_4 concentration, rendering the CIMS OH reactivity measurement invalid for those conditions. The non-linear effect on final H_2SO_4 from HOx recycling compared to the NO-free case is also illustrated in Fig. 7d, showing that when NO is present, the concentrations increase non-linearly with increasing OH reactivity, and significantly more so in the background mode than in the signal mode.

In conclusion, HOx recycling in the presence of trace level NO (here as example 140 ppt is used in the model) is relevant at high OH reactivity and therefore needs to be considered when choosing the range of OH reactivity for calibration (Section 2.3). To minimise this potential systematic error during the OH reactivity calibration, scaling rates have been determined for OH reactivity ranging from 0-20 s^{-1} . Using CO for OH reactivity of 20 s^{-1} with 140 ppt NO, the modelled underestimation is 0.5 s^{-1} , i.e. 2.5 %.

An additional consideration for the upper measurement limit (without NO) is that the to-be-measured OH concentration (Fig. 7b, solid black line) becomes a small residual between two larger numbers in signal and background mode at increasingly high OH reactivity. The measurement precision (51 %, Berresheim et al., 2000) thus can also impose a constraint on the upper measurement limit.

3.5 HOx recycling in the presence of ambient air NO

An integral part of OH detection by CIMS is the chemical conversion of OH to H_2SO_4 inside the flow tube. Under certain conditions within the flow tube, HOx recycling ($\text{HO}_2 + \text{NO} \rightarrow \text{NO}_2 + \text{OH}$ (R6)) can become significant enough between the

two titration zones and produce artefact signals of H₂SO₄ which are evident for measurements especially in the second titration zone. The HO₂ in the flow tube can come from ambient air and also be instrument internally produced through production in the UV zone (R1, R2) and be a product of the titration sequence (R3, R4).

HO_x recycling in the presence of nitric oxide (NO) originating from ambient air or impurities in CIMS operational gas mixtures can lead to an apparent underestimation of OH reactivity (Section 3.4). At the MOHp, the site for which the CIMS instrument has been optimised, NO levels rarely exceed 4 ppb (99th percentile is 3.7 ppb) and the 95th percentile is 1 ppb NO. However in principle ambient NO concentrations can reach up to tens of ppb close to sources such as e.g. tailpipe emissions. Therefore, the interference of NO on CIMS OH reactivity measurements has been characterised through a series of laboratory experiments for mixing ratios up to 20 ppb NO. The experimental set up is schematically shown in Fig. 2 and replicates the OH reactivity calibration experiments with the addition of set concentrations of NO. The interference experiments were carried out for different OH reactants, representing different groups of reactants, i.e. carbon monoxide CO (inorganic species), propane C₃H₈ (alkane), ethene C₂H₄ (alkene of mostly anthropogenic origin) and isoprene C₅H₈ (alkene of biogenic source). The effect of OH reactivity underestimation was considerably stronger for CO than for the other OH reactants, because NO induced OH recycling is amplified when OH reacts with CO to additionally produce HO₂ in the CIMS system. These non-linear results from the external glass flow tube experiments with large HO₂ production are therefore not directly applicable and transferrable to ambient air measurements. Thus only data from propane, ethene and isoprene experiments were used to derive a correction function that would be representative for an ambient air matrix. Measurements above 15 ppb NO were also excluded from the correction function analysis, as measurements had low reproducibility, the reasons for which are unclear.

As also expected from Facsimile model runs of OH recycling in the CIMS sample tube, the experimental results as seen in Fig. 8 show clearly that the underestimation of CIMS OH reactivity is non-linearly dependent on both NO concentration and OH reactivity. By exploring CIMS OH reactivity measurements for each NO concentration (Fig. 9a), it was found that the correction could be empirically well described by an exponential equation of the form

$$OH\ reactivity = a \times e^{(-b \times k_{OH}measured)} + c \quad (7)$$

where factors a, b and c are functions of NO concentration in ppb (Fig 9b-d). Factors a and b are exponential functions

$$a = aa \times e^{(-ba \times [NO])} + ca \quad (8)$$

$$b = ab \times e^{(-bb \times [NO])} + cb \quad (9)$$

Factor c is a linear function, described by

$$c = ac \times [NO] + bc \quad (10)$$

To find the eight fit parameter aa, ba, ca, ab, bb, cb, ac and bc, a Python SciPy curve fitting procedure was applied to the experimental data (Jones et al., 2015). Marginally better fit results ($R^2 = 0.98$) were achieved when input values were

averaged for the three different OH reactants (propane, ethene and isoprene) (Fig. 8) compared to individual experiments (e.g. $R^2 = 0.95$ for ethene only). Whilst the overall agreement of the fitted, i.e. corrected, CIMS OH reactivity shows little bias with OH reactivity with a slope of 0.98 (Fig. 10a), when looking at the residuals (Fig. 10b,c) it is apparent that there is a positive bias between 0-3 s^{-1} , and there is a negative bias between 3-10 s^{-1} . The positive bias below OH reactivity of 3 s^{-1} has
5 got a mean overestimation of the corrected OH reactivity of 1.2 s^{-1} , i.e. on average an overestimation of 95 %. The negative bias between 3-10 s^{-1} is smaller and is on average 10 % underestimation. These biases highlight one of the disadvantages of this empirical fit function, pointing to a systematic process or effect that is not captured by this function. The fit parameters do not directly represent any physical or chemical processes or our understanding of the HOx recycling chemistry. Additionally the fit function represents an approximation of the actual recycling that is dependent on the concentration of
10 HO_2 and RO_2 present in ambient air. One standard deviation in the residuals is $\pm 1.5 s^{-1}$ which represents a large relative error at very low OH reactivity. Therefore, at low OH reactivity (below $\sim 3 s^{-1}$) applying this correction function would introduce a significant additional error in the CIMS OH reactivity measurement. This was considered when the empirical NO correction function was applied to data from the OH reactivity instrument comparison campaign where OH reactivity reached the CIMS upper measurement limit and large concentrations of NO were at times present in the chamber. The
15 correction was not applied for OH reactivity below 2.5 s^{-1} (Fuchs et al., 2017), because the systematicity in error was found to be related to OH reactivity at the very low end of OH reactivity (Fig. 10c). No **systematic errors** related to NO concentration was identified.

One source of uncertainty lies in the reproducibility or robustness of the determined effect of NO on measured CIMS OH reactivity. To investigate how robust and representative the uncertainties in corrected OH reactivity values are, the
20 distribution of residuals for different sets of experiments were checked. One dataset consisted of all individual points from the above mentioned isoprene, ethene and propane experiments carried out on the same day. This dataset includes the potential uncertainties from different RO_2 for the different OH reactants. The other dataset consisted of four different NO-HOx recycling experiments over the course of a year, using propane only and therefore giving an indication of the uncertainty associated with the reproducibility of the HOx recycling interference effect.

25 A normal distribution (Gaussian) fit function was applied to the data and fitted mean and standard deviation estimated (Fig. 11). Figure 11 shows that in both sets of experiments the bias in the mean correction is small (less than 0.42 s^{-1}), however the one standard deviation in the mean error of the fit is about $\pm 2.7 s^{-1}$. This analysis shows that with the empirical eight parameter fit the uncertainty from using different OH reactants for the NO-HOx recycling experiments is of the same order (1σ about $\pm 2.7 s^{-1}$) as for the uncertainty from measurement and experimental stability, as tested by several experiments
30 over the course of a year using one OH reactant, here propane, only.

In contrast to the range of OH reactivity and NO concentration during the characterisation experiments, the continuous long-term observations at the Meteorological Observatory Hohenpeissenberg show that the typical OH reactivity is below 15 s^{-1} and NO well below 15 ppb. Instead of applying a NO-based correction function which introduces itself considerable

uncertainty to the long-term data from 2009-2017, we take the approach to include a NO concentration based error estimation in the total CIMS OH reactivity measurement uncertainty.

For OH reactivity up to 15 s^{-1} and NO up to 4 ppb, the systematic underestimation in OH reactivity can be approximated by a linear relationship (Fig. 12). Figure 12 shows the mean underestimation in OH reactivity binned for all OH reactivity and NO concentration where the error bars represent the 1 sigma variability in measured OH reactivity underestimation for the given NO bin. The underestimation for MOHp-prevalent conditions is estimated as $0.8 \text{ s}^{-1} / \text{ppb NO}$ (Fig. 12, filled circles). Extending the range of NO concentration to 15 ppb shows that this linear relationship approximately holds even for concentrations larger than 4 ppb NO. Using this error estimation approach for the long-term data at MOHp allows the determination of expected underestimation of measured OH reactivity based simply on ambient NO concentration measurements. This systematic error is then included in the total uncertainty estimation on a point by point basis. As the 95th percentile of NO mixing ratio at the MOHp is 1 ppb, the majority of data will have a positive error estimation of less than 0.8 s^{-1} .

4 Performance of CIMS in chamber and field studies

4.1 OH reactivity instrument comparison at FZ Jülich SAPHIR chamber

The CIMS instrument was part of a comprehensive OH reactivity instrument comparison campaign at the Forschungszentrum Jülich (FZJ) SAPHIR chamber in April 2016. The full findings and results from that campaign are evaluated and discussed in Fuchs et al. (2017). With respect to CIMS, one main finding was that the CIMS instrument provides high precision data with a limit of detection better than 1 s^{-1} at a time resolution of a few minutes. In chemically complex conditions, the CIMS data show a scatter of 10-20 %. The scatter was greatest for the experiment of isoprene, MVK and MACR and the “urban mix” experiment with o-xylene, toluene, 1-pentene and was largest for OH reactivity above 15 s^{-1} . Since one standard deviation is at the order of 7 %, the reported scatter of up to 20 % is less than 3σ of the measurements. The presence of up to 32 ppb NO in the SAPHIR chamber revealed limitations of the current CIMS system, and a NO-based correction function was applied to the CIMS data, applicable for OH reactivity up to 40 s^{-1} and 15 ppb NO (details see section 3.5, Eq. 7). No data above those limits were submitted to the comparison exercise described in Fuchs et al. (2017). The quality of the correction was shown to be variable, with OH reactivity being overestimated by a factor up to 1.8 for NO concentrations from 10-15 ppb. The NO eight parameter fit correction function was derived from laboratory experiments at MOHp, and fit parameters applied to the chamber dataset. The poor performance at higher NO concentrations shows that there is an issue of applicability of the function derived from experiments with a certain set of conditions (MOHp) to a dataset where conditions were different (SAPHIR chamber). For instance, a simple modelled comparison shows that the 10 % higher atmospheric pressure leads to more effective NO-HOx recycling and therefore 10 % greater underestimation of the measured CIMS OH reactivity (prior to correction) would be expected at FZJ / 1000 hPa. This difference and potential error

have not been considered in the correction of CIMS OH reactivity in Fuchs et al. (2017). In future measurement campaigns away from the MOHp, the benefit of performing NO interference experiments during the campaign shall be considered.

It is worth highlighting that the fit parameters do not represent physical or chemical variables, and therefore the function does not easily lend itself to improvements or systematic interrogation when and why the correction fails. Further development on a correction function is ongoing that includes measured and estimated variables such as HO₂, RO₂ and HO₂ wall loss in the CIMS sample tube.

The comparison including OH reactivity up to 40 s⁻¹ has shown that CIMS measurements were of high accuracy for certain chemical conditions (experiments with CO, pentane, monoterpenes, sesquiterpenes) where CIMS measurements and the OH reactivity reference agreed within uncertainty (mean deviation less than 13 %). For other conditions (isoprene, MVK, MACR mixture and urban mixture of o-xylene, toluene, 1-pentene) lower accuracy was observed, with a mean deviation to the reference of 27 %. The instrument comparison has also revealed that the CIMS provides high quality OH reactivity measurements for conditions of low OH reactivity (< 15 s⁻¹) and low NO concentrations (< 4 ppb). The particular performance within those ranges, which are typically observed at MOHp, is specifically assessed here. The FZJ LIF instrument performed very well throughout the campaign, giving consistently high accuracy OH reactivity measurements (Fuchs et al., 2017). Therefore the comparisons within the range of typical conditions seen at MOHp are discussed here using the FZJ LIF as reference.

To investigate the CIMS measurement quality for conditions at the MOHp, a subset of the data from the comparison campaign was produced. All campaign data (i.e. all experiments) were selected, averaged over 2 minutes intervals, and filtered for NO concentrations below 4 ppb and FZJ LIF OH reactivity below 15 s⁻¹. For these conditions, Fig. 13a shows this subset of data evaluated in Fuchs et al. (2017). The linear regression slope of 0.94 shows that the CIMS is typically underestimating OH reactivity by 6 % compared to the LIF OH reactivity measurements. The error bars for the CIMS measurements are large (approx. ± 1.5 s⁻¹) because the total error includes the 1 standard deviation error in the fit residuals from the eight parameter NO correction (Fig. 10b). The NO correction was applied to all data as a result of NO contamination in the SO₂ titration gas mixture (Fuchs et al., 2017).

To assess the impact of not correcting for the presence of NO in the MOHp OH reactivity dataset explicitly but rather account for the systematic underestimation by a positive error, CIMS OH reactivity from the SAPHIR campaign was reevaluated and total uncertainty include the error from the presence of NO. This constitutes an independent test whether this data treatment approach for the long-term OH reactivity measurements at the MOHp is acceptable. The regression slope is 0.95, showing an underestimation compared to LIF of about 5 % (Fig. 13b). This shows that for the conditions seen at MOHp, it can be considered acceptable to not explicitly correct for presence of NO, but represent the underestimation through increased measurement uncertainty. For the comparison campaign propane was used for the scaling rate determination and it is worth noting that the difference in rate constant recommendations and rate constant uncertainties for propane (Supplementary material S2) is at the order of a few percent, and therefore the discrepancy between CIMS and LIF of 5 - 6% falls within the two sigma uncertainty of the OH + propane rate constant recommendations.

The regression in Fig. 13b shows a negative intercept of -0.63 s^{-1} in CIMS data when one fixed wall loss rate is applied for the whole campaign. If however the zero values measured at the beginning of each day in the chamber (Fuchs et al., 2017) are used to estimate a daily wall loss rate, the intercept is -0.12 s^{-1} , indicating that regular zero measurements can improve data quality. The campaign wall loss rate used in Fig. 13 was based on the zero measurement (with 3 % error) of the day before the comparison campaign, using standard synthetic air. A mere overestimation of 7 % in this zero value could cause the intercept of -0.6 s^{-1} . During repeatability tests in the laboratory at MOHp, differences between zero measurements tend to be below 7 %, but 6 % differences have been observed (Section 3.2.4). This underlines the point that high quality zero OH reactivity measurements contribute to achieving high-accuracy measurements.

4.2 Ambient OH reactivity measurements at MOHp

The Meteorological Observatory Hohenpeissenberg (MOHp) carries out continuous measurements of reactive gases, aerosols, radiation and meteorology as part of the Global Atmosphere Watch (GAW) programme (Schultz et al., 2015). Adoption of the integrative, holistic and direct measure of OH reactivity at long-term measurements sites such as those belonging to GAW holds the potential for insight into changes of oxidative capacity of the troposphere (Williams and Brune, 2015). We demonstrate here that these continuous measurements are possible.

The MOHp is situated in Southeast Germany, 40 km north of the Alps, at the top of a hill (985 m a.s.l.). The Hohenpeissenberg hill rises 300-400 m above the surrounding rural area with about 70 % mostly coniferous forest and 30 % agricultural pastures.

The main wind direction at the MOHp is South to Southwest and the advected air masses are generally clean and pollutant levels are low for these southern wind sectors (Mannschreck et al., 2004; Bartenbach et al., 2007). Air coming from the Northeast tends to have higher pollutant levels as emissions from the large city of Munich (city population of 1.5 million, ~80 km Northeast from MOHp) increase atmospheric pollutant loadings. Pollutants with longer lifetimes, such as CO, are less variable with wind direction in contrast to shorter lived species such as NO_x which show larger variability with wind direction (Mannschreck et al., 2004).

OH reactivity measurements at the MOHp started in 2009 and have been continuous since then. To our knowledge this constitutes the longest time series of OH reactivity measurements to date. The standard OH reactivity measurement interval is 20 minutes and it forms part of a sequential measurement block of H₂SO₄, OH, RO_x and OH reactivity. Here we present measurements from one year, 2015, exemplifying the continuity and stability of the long-term CIMS OH reactivity measurements at MOHp (Fig. 14). Error bars in Fig. 14 include the contribution of underestimation as a result of the presence of ambient NO, the uncertainty in the scaling rate and wall loss rate.

OH reactivity at MOHp is mostly below 15 s^{-1} (Fig. 14) which is characteristic for this kind of environment and similar magnitudes were observed in mid latitude forests and also at some suburban sites (Yang et al., 2016). No clear annual cycle is visually identifiable for 2015 and variability occurs at a range of time scales. Absence of a strong annual cycle was also modelled based on OH reactant observations at MOHp for the years 1999-2003, with typical monthly OH reactivity between

3-4 s⁻¹ (Rohrer and Berresheim, 2006). The variability in OH reactant concentrations is dependent on a range of factors, including e.g. periodic and non-periodic dynamics (Huntrieser et al., 2005; Mayer et al., 2008). As for the periodic daily cycle, reactive trace gases are significantly controlled by the rise and fall of the boundary layer top passing the measurement height. The boundary layer is generally below the station at night, meaning that the nighttime sampling then occurs in the normally more uniformly mixed residual layer. For cold and windy nighttime conditions however, this decoupling does not always occur, thus affecting the variability of pollutant concentrations (Bartenbach et al., 2007). The effect of the boundary layer building at the beginning of the day and reaching the MOHp can be observed e.g. by the peak concentrations of VOC in the morning (Bartenbach et al., 2007).

In addition to the dynamically driven effects on trace gas concentrations, short lived reactive species are strongly controlled by local emissions and chemical cycling, such as e.g. for biogenic VOC, which in sum have been observed to have a clear diurnal cycle at MOHp (Handisides et al., 2003; Bartenbach et al., 2007). In contrast, anthropogenic VOC have a less pronounced daily cycle (Handisides et al., 2003; Bartenbach et al., 2007) and dominance of biogenic VOC in summer is contrasted by higher concentrations of anthropogenic VOC, such as ethane and propane, in winter (Helmig et al., 2016). Additionally, inorganic trace gases such as CO and NO₂ which contribute greatly to the total OH reactivity at MOHp also show highest levels in winter. Shorter lived NO₂ even displays a marked weekday variation with highest concentrations midweek and lowest levels on Sundays (Gilge et al., 2010) and sharp short term peaks also do occur (Handisides et al., 2003; Acker et al., 2006). Winter shows greater short term variability in OH reactivity (Fig. 14), which is likely a result of more local pollution, especially from domestic wood burning for heating. This combined with the fact that persistent inversion layers can form in winter, contributing to enhanced mixing ratios (Gilge et al., 2010) can go some way to explain this short term variability.

As addressed in Section 3, the total measurement uncertainty in OH reactivity depends on a variety of factors that contribute to systematic and random errors. To illustrate the typical total measurement uncertainty for ambient measurements at MOHp, errors from each term in the OH reactivity calculation (Eq. 4) are examined and their contribution to the total uncertainty assessed. Calculations and propagation of uncertainties were performed using Python Uncertainties package (Lebigot, 2017) which predicts uncertainty using linear error propagation theory. The three terms are the point by point values of $\ln([\text{OH}]_{\text{T1}}/[\text{OH}]_{\text{T2}})$, the scaling rate sr_{CIMS} obtained regularly by OH reactivity calibration and the zero air value of $\ln([\text{OH}]_{\text{T1}}/[\text{OH}]_{\text{T2}})$, also determined regularly. The mean error in $\ln([\text{OH}]_{\text{T1}}/[\text{OH}]_{\text{T2}})$ is 7.1 % (Section 3.2.1) and the upper limit of reproducibility of the zero air value of $\ln([\text{OH}]_{\text{T1}}/[\text{OH}]_{\text{T2}})$ is 6 % (Section 3.2.4). As for the scaling rate sr_{CIMS} , the uncertainty in the individual values of the scaling rate for the five different experimental days in the Jülich chamber in 2016 is below 2.4 %, however the variability between days is larger. One standard deviation in the campaign mean value of sr_{CIMS} amounts to 5.3 % (Table 3). Using a representative ambient air sample with $\ln([\text{OH}]_{\text{T1}}/[\text{OH}]_{\text{T2}}) = 1.28 \pm 0.09$, zero air = 1.0 ± 0.07 , $\text{sr}_{\text{CIMS}} = 8.6 \pm 0.5 \text{ s}^{-1}$ results in an OH reactivity of $2.4 \pm 1.0 \text{ s}^{-1}$. The one standard deviation of $\pm 1.0 \text{ s}^{-1}$ is about equally determined by the error in the measured ambient air $\ln([\text{OH}]_{\text{T1}}/[\text{OH}]_{\text{T2}})$ and the scaling rate sr_{CIMS} . The uncertainty in the measured zero air value of $\ln([\text{OH}]_{\text{T1}}/[\text{OH}]_{\text{T2}})$ is not dominant here. To decrease the total measurement uncertainty

addressing uncertainties in both $\ln([\text{OH}]_{\text{T1}}/[\text{OH}]_{\text{T2}})$ and sr_{CIMS} will be effective, because the squares of the individual uncertainties are summed. In this example the positive systematic error from the NO interference (defined in Section 3.5 as $0.8 \text{ s}^{-1} / \text{ppb NO}$) would only be increasing the total measurement error for NO concentrations above 370 ppt.

It is worth noting that the example given above is meant to represent operation in typical measurement conditions and the total measurement uncertainty that can be expected with this method and instrument in its current set up. However it is clear that there are “known unknowns” that can affect the accuracy of the OH reactivity measurements. These are extensively discussed in Section 3, such as e.g. OH reactant contamination in synthetic/zero air and in the OH reactant gas used for calibration which impact the accuracy of the scaling rate and wall loss rate. In light of the continuous long-term operation of the instrument, eliminating, minimising and/or quantifying and accounting for these systematic errors forms part of the data quality control protocol that has been successively developed for these measurements. The comparison of CIMS OH reactivity measurements with the FZJ LIF measurements (Section 4.1) shows that these errors are unlikely to be large however, proving that this semi-direct method to measure OH reactivity by CIMS provides robust and accurate observations.

5 Conclusions

We presented a novel approach to measure OH reactivity successfully by a semi-direct method using a chemical ionisation mass spectrometer (CIMS) system. This approach is based on a well-established technique to measure OH and H_2SO_4 and provides an extension to the measurement portfolio at the Meteorological Observatory Hohenpeissenberg (MOHp) which also delivers continuous long-term observations of OH, H_2SO_4 and ROx by CIMS as part of the WMO Global Atmosphere Watch (GAW) programme. The development of the OH reactivity measurement came as an addition to the CIMS system measurement capability without losing existing measurements (OH, H_2SO_4) or compromising their quality.

OH is measured at the inlet tip by the conversion to H_2SO_4 using SO_2 as titrant, and an additional titration zone was added further down flow in the sample flow tube. This way one reaction time was achieved for OH reactivity measurements. The measurements require accurate determination of this reaction time as well as the OH wall losses in the flow tube.

Comparison of CIMS OH reactivity with measurements from a highly accurate and precise LIF system from the Forschungszentrum Jülich reveals that this new semi-direct CIMS method performs especially well for the conditions it was designed for, i.e. low NO concentrations and low OH reactivity. For OH reactivity below 15 s^{-1} and NO concentrations below 4 ppb, the mean underestimation of OH reactivity by CIMS was only 5 % for this comparison, which falls within the 2 sigma uncertainty of the rate constant recommendations required for the calculation of CIMS OH reactivity. Comprehensive assessment of the instrument performance for a wide range of chemical conditions can be found in Fuchs et al. (2017).

Continuous OH reactivity measurements at the MOHp started in autumn 2009 and a “snapshot” of one year of measurements from 2015 were presented here. These unique measurements demonstrate that continuous long-term observations for OH reactivity are possible, enhancing the measurement portfolio at the global GAW site Hohenpeissenberg (MOHp).

The method is described as semi-direct because OH is measured via the chemical conversion to H₂SO₄ which is then detected by CIMS and because only two points on the pseudo first order OH decay curve are measured. As a rule, the chemical conversion of OH to H₂SO₄ is an aspect of the system that needs to be considered for its potential sources of OH reactivity measurement error. A modelling study for instance showed that at high OH reactivity HOx recycling through the titration SOx chemistry can lead to small systematic underestimation of OH reactivity. In the presence of NO, this instrument internal HOx recycling is enhanced, leading to significant underestimation also at lower OH reactivity. To minimise errors from this, it is therefore important to ensure the absence of or at least minimise NO and other contaminants in gases that are used to run the instrument, as well as during the OH reactivity calibration. It is recommended that concurrent ambient measurement of NO are made and that the titration gas (SO₂) be tested for NO contamination if its absence cannot be guaranteed, as is often the case for commercially sourced mixtures for instance. To account for the unavoidable presence of NO in ambient air, it is critical to characterise the system-dependent response to the NO-HOx measurement artefact. For this CIMS system, a correction function was developed and tested in a recent OH reactivity instrument comparison campaign (Fuchs et al., 2017). The instrument comparison revealed limitations of the empirical function found to describe the systematic underestimation in OH reactivity which is both dependent on NO concentration and OH reactivity. For long-term measurements at MOHp NO concentrations and OH reactivity are low (mostly < 1 ppb NO and < 15 s⁻¹) which do not warrant a correction for operational data, but a NO-based error is included in the data treatment to reflect the increased measurement uncertainty when NO is present in ambient air above a mixing ratio of few hundred ppt.

The NO induced HOx recycling reveals a challenge to the current method, which rests on the assumption that the OH decay in the sample tube is a pseudo first order decay. This assumption does not hold when OH recycling happens between the two measurement points. To gain additional information on the OH decay curve, it would for instance be possible to add further titration zones. The current placement of the second titration zone was informed by the expected range of OH reactivity below 20 s⁻¹ at the MOHp. The fixed position of the second titration zone also imposes an upper limit to the OH reactivity that can be detected, which is around 40 s⁻¹ for this set up. The effective upper limit could be extended through increasing the flow rate through the sample tube and/or by installing titration injectors closer to the tip of the inlet.

Another approach to address the NO induced HOx recycling would be to change the production of OH and therefore effecting reduced OH recycling. For instance, it could be advantageous to produce only OH, and no HO₂, in front of the inlet, as e.g. through the use of O₃ flash photolysis by a 266 nm laser.

The method presented here shows that OH reactivity can be relatively easily measured with an existing CIMS instrument used for OH measurements. It provides accurate and continuous measurements in the specific conditions for which it was developed, i.e. low OH reactivity and low NO concentrations typical for the MOHp site. If the system is to be used in other chemical conditions or environments, it is advised to make modifications to the set up or operation, as well as characterise and correct for systematic effects such as e.g. from NO induced HOx recycling.

6 Acknowledgements

We would like to thank Felix Utschneider, Katja Michl, Erasmus Tensing, Marita Hofmann and Eva Jettmar from DWD for technical support. We also acknowledge the generous support from staff of the “Photochemistry and Radicals” and “Reactive Trace Substances” departments of the Institute of Energy and Climate Research, IEK-8: Troposphere, at the
5 Forschungszentrum Jülich, Germany. We are particularly grateful for their assistance during the OH reactivity instrument comparison campaign at the SAPHIR chamber and for the provision of the LIF OH reactivity campaign data.

Table 1: MOHp CIMS kOH measurement and system properties.

CIMS system property	value and measure
[OH] limit of detection	^a 5 x 10 ⁵ molecules cm ⁻³
kOH limit of detection	^b 0.5 s ⁻¹
kOH upper measurement limit	40 s ⁻¹
typical [OH] ₀ and [HO ₂] ₀ produced in UV zone	10 ⁸ molecules cm ⁻³
kOH temporal resolution	60 – 300 s
typical reaction time Δt = (t ₂ -t ₁)	^b 0.1 s ± 5 %
typical OH wall loss rate k _w	^b 10 s ⁻¹ ± 8 %
kOH measurement accuracy	^b 1 s ⁻¹ (kOH < 30s ⁻¹) ^b 2 s ⁻¹ (kOH 30-40 s ⁻¹)
known interference	nitric oxide (NO)

^a based on > 2 σ signal count rates, Berresheim et al. (2000).

^b 1 σ

Table 2: Overview of uncertainties (1σ) and limitations discussed in Section 3, indicating relevance to scaling rate sr_{CIMS} determination, wall loss rate k_w determination and/or relevance for ambient measurements.

Section #	Source of uncertainty	Relevant for sr_{CIMS} determination	Relevant for k_w determination	Relevant for ambient measurements
3.1	Changes in ambient pressure and temperature			Uncertainty around mean $\pm 0.17 \text{ s}^{-1}$ Maximum systematic deviation $\pm 0.4 \text{ s}^{-1}$
3.2.1	Measurement of OH by CIMS	$[\text{OH}]_{\text{T1}}$ median variability 1.5 % $[\text{OH}]_{\text{T2}}$ median variability 2.7 %	$\ln([\text{OH}]_{\text{T1}}/[\text{OH}]_{\text{T2}})$ typical uncertainty 7.1 %	
3.2.2	OH reactant concentration in calibration gas mixture	Uncertainty in 1 % CO gas mixture = 2 % in OH reactivity Uncertainty in 0.2 % propane gas mixture = 5 % in OH reactivity		
3.2.3	OH reactant contamination in calibration gas mixture	Not detectable here, see text.		
3.2.4	OH reactant contamination in carrier gas (here synthetic air)		$0.02 \pm 0.02 \text{ s}^{-1}$ Contamination level can vary, see text.	
3.2.5	NO contamination in all gas mixtures	For $0\text{--}40 \text{ s}^{-1}$, sr_{CIMS} overestimation 5 % For $20\text{--}40 \text{ s}^{-1}$, sr_{CIMS} overestimation 9 % For $0\text{--}20 \text{ s}^{-1}$, sr_{CIMS} overestimation 1 %		NO up to 380 ppt in sample flow from SO_2 gas mixture
3.2.6	OH kinetic rate constants	Uncertainty in sr_{CIMS} for CO 11 % Uncertainty in sr_{CIMS} for propane 5 %		
3.3	Calibration using external glass flow tube	Jülich mean $9.1 \pm 0.4 \text{ s}^{-1}$ MOHp mean $9.7 \pm 0.5 \text{ s}^{-1}$	Jülich mean $8.6 \pm 0.5 \text{ s}^{-1}$ MOHp mean $9.4 \pm 0.8 \text{ s}^{-1}$	
3.4	Upper measurement limit	40 s^{-1}		40 s^{-1}
3.5	Ambient NO leading to instrument internal HOx recycling	NO up to 15 ppb, non-linear function, see text		NO up to 4 ppb, underestimation $0.8 \text{ s}^{-1}/\text{ppb}$

Table 3: Summary of scaling rate sr_{CIMS} and wall loss k_w parameters determined from OH reactivity instrument comparison campaign. All sr_{CIMS} values have been normalised using temperature and pressure to allow comparison between Jülich and MOHp datasets.

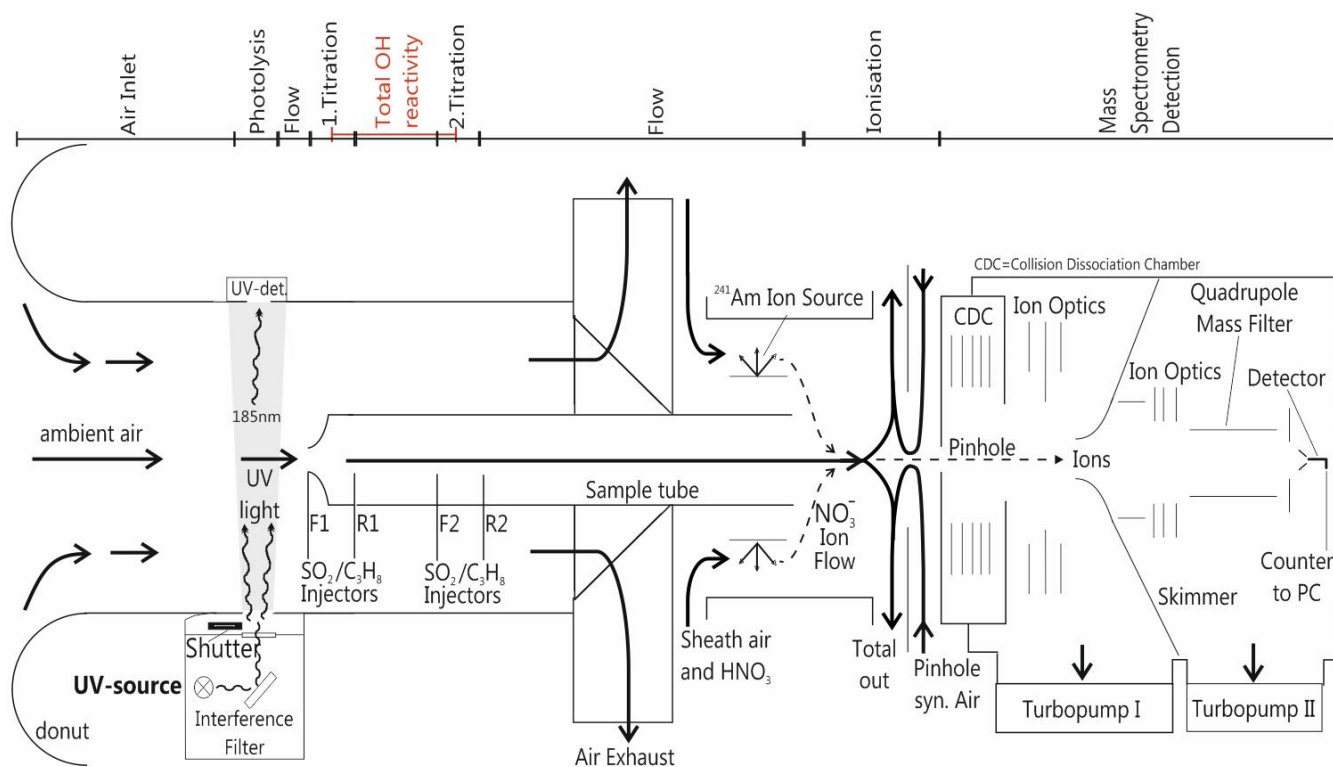

Figure 1: Schematic of CIMS system used for long-term OH, H₂SO₄ and OH reactivity measurements at the Meteorological Observatory Hohenpeissenberg, Germany. Air flows are indicated by arrows, the measurement zones are described in the upper part of the schematic.

Figure 2: Schematic of CIMS flow tube with two titration zones: P = OH and HO₂ production from H₂O photolysis. T1 zone (left hatch) = first titration zone (F1 up to R1) with H₂SO₄ from OH titration by SO₂ injection at F1. T2 zone (right hatch) = second titration zone (F2 up to R2) with H₂SO₄ from OH titration by SO₂ injection at F2. R1 and R2 = added propane to stop H₂SO₄ production from recycled OH after the first and second titration zone, respectively. KOH (grey solid) = total OH reactivity using $\ln ([OH]_{T1}/[OH]_{T2})$ indicating [OH]_{T1,T2} is reached after front (F1, F2) and before rear (R1, R2) injection.

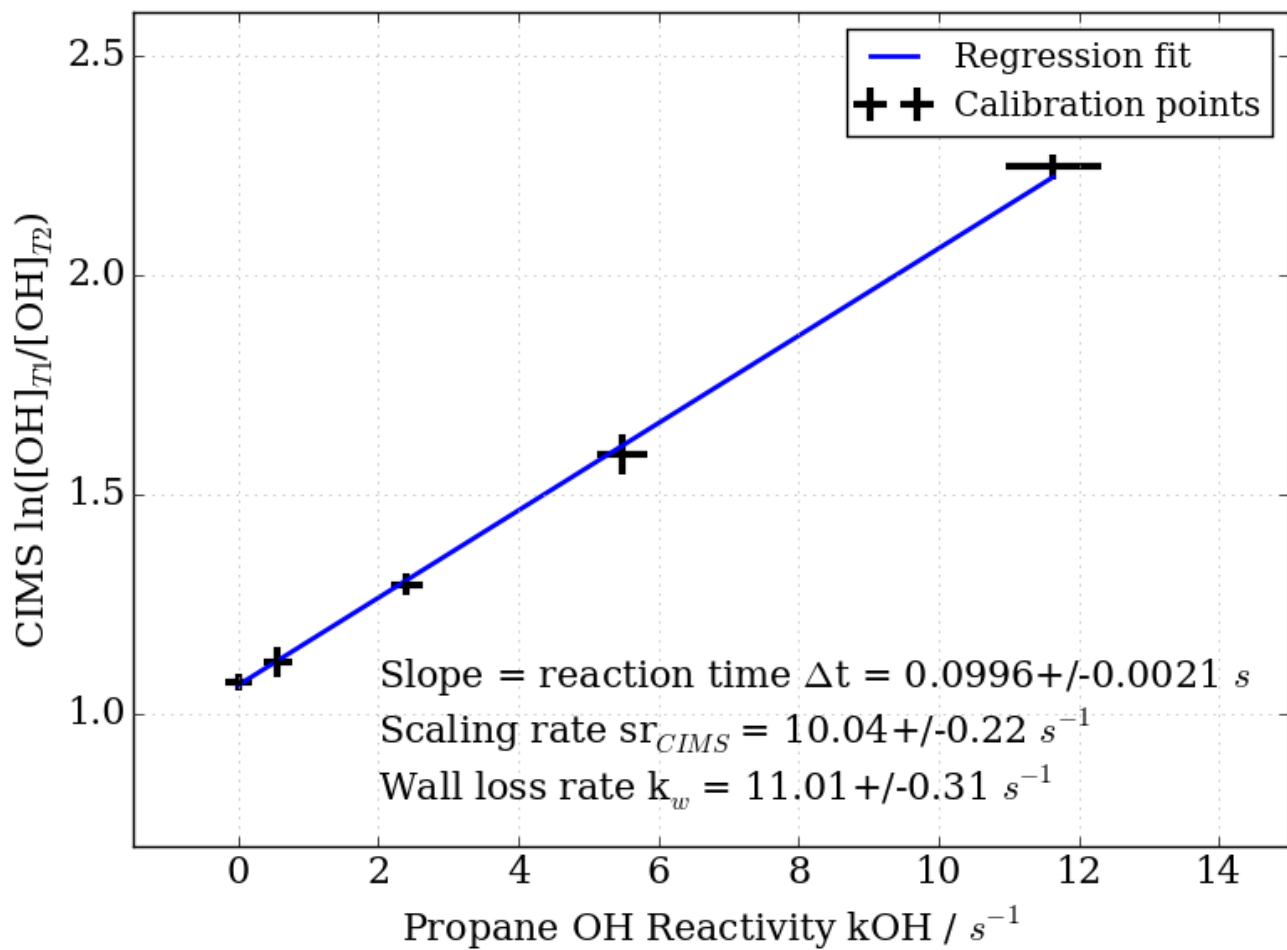

Figure 3: OH reactivity calibration curve and estimation of scaling rate by linear regression including uncertainties in both measured CIMS $\ln([OH]_{T1}/[OH]_{T2})$ and propane OH reactivity.

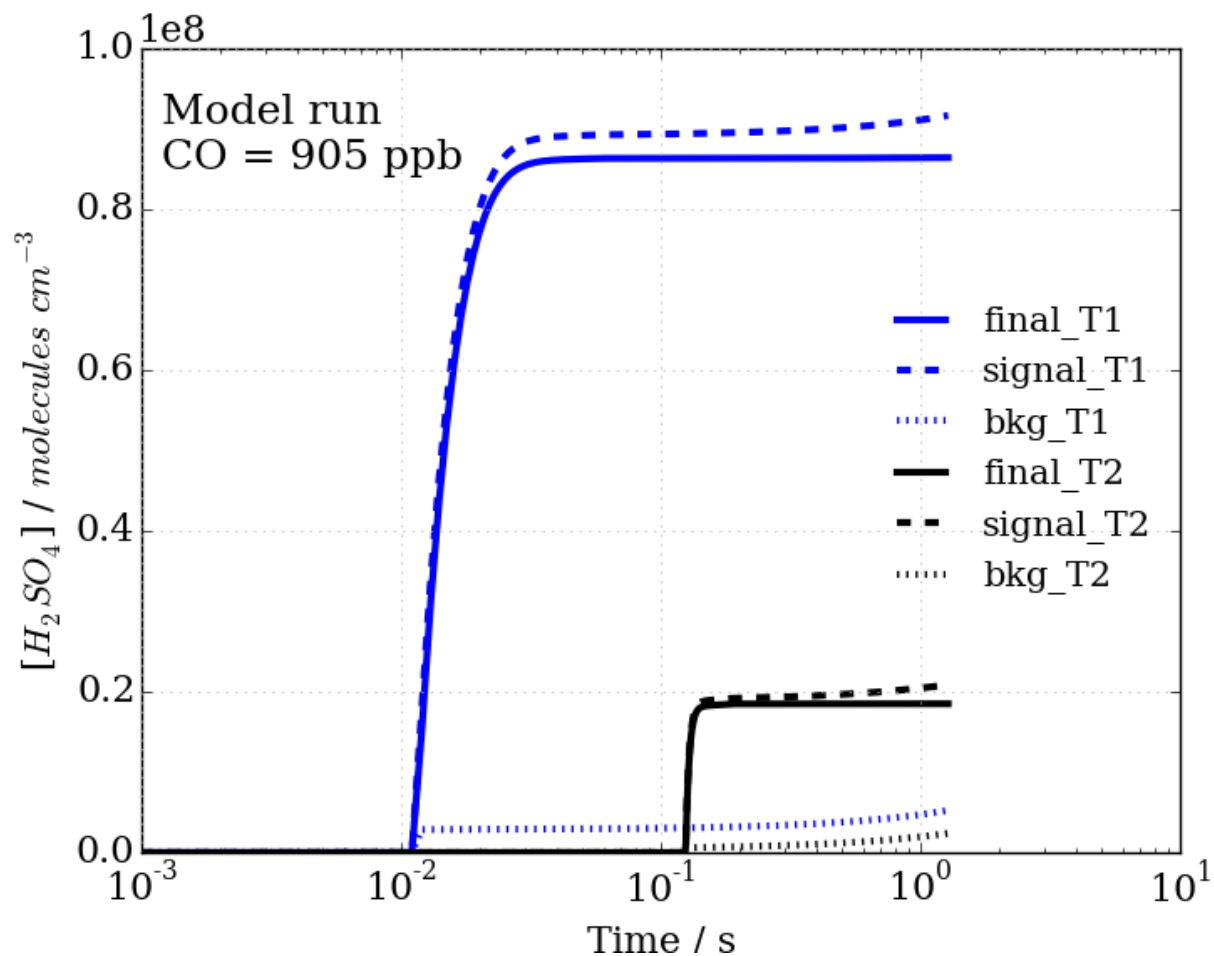

Figure 4: Sulfuric acid concentrations with time, representing progression in sample flow tube from inlet tip to ionisation region, for signal and background modes (dashed and dotted lines respectively), as well as the calculated difference, leading to final $[H_2SO_4]_{T1} = [OH]_{T1}$ and final $[H_2SO_4]_{T2} = [OH]_{T2}$ concentrations (solid lines) in titration zones 1 (T1) and 2 (T2) which are used to calculate OH reactivity.

Figure 5: Variability around mean flowspeed-based calculated scaling rate dependent on 10 min observed pressure and temperature measurements at MOHp in 2015.

Figure 6: Modelled CIMS H_2SO_4 concentrations for CO as OH reactant in titration zone 1 (a) and titration zone 2 (b) with and without NO impurity (140 ppt) present. Final concentrations describe differential between total signal and total background mode measurements. OH_rec describe the H_2SO_4 concentrations derived from recycled OH only, contributing to the total measurements.

Figure 7: Modelled CIMS H_2SO_4 concentrations and contributions from OH recycling in titration zone 2 with and without NO impurity (140 ppt) present. (a) Absolute H_2SO_4 concentrations from recycled OH only in signal and background measurement mode. (b) Total H_2SO_4 concentrations. (c) Relative contribution from OH_{UV} and OH recycled to the total (and final) H_2SO_4 concentration. (d) Non-linear increases in signal, background and final measurements in case of presence of NO impurity.

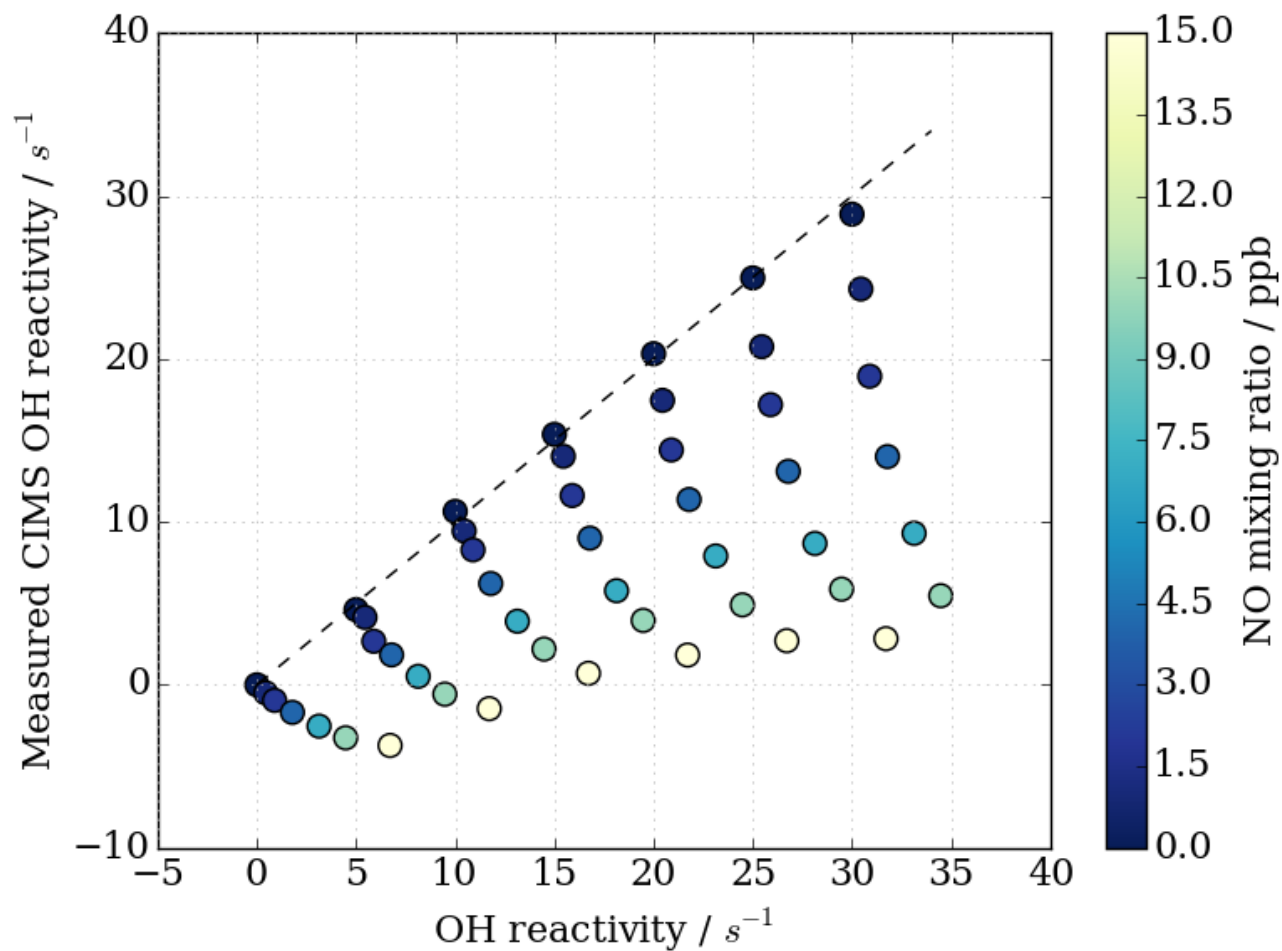

Figure 8: CIMS OH reactivity underestimation as result of NO-HOx recycling interference in external flow tube NO correction experiment. OH reactivity is the average of experiments with OH reactants propane, isoprene, ethene and NO.

Figure 9: NO HOx recycling interference on CIMS OH reactivity both dependent on OH reactivity and NO concentration (panel a). Functions of parameters (Eq. 7) are dependent on NO concentration (panels b, c, d correspond to Eq. 8, 9, 10).

Figure 10: Performance of the eight parameter correction function (Eq. 7-10), (a) goodness of fit of correction function, (b) fit residuals and (c) fit residuals normalised by OH reactivity.

Figure 11: Residuals in CIMS OH reactivity after applying NO correction function. (a) 165 individual points from isoprene, ethene and propane NO correction experiment, (b) 194 individual points from four propane NO correction experiments March 2016 – March 2017. Distribution is normalised according to number of points in each experiment.

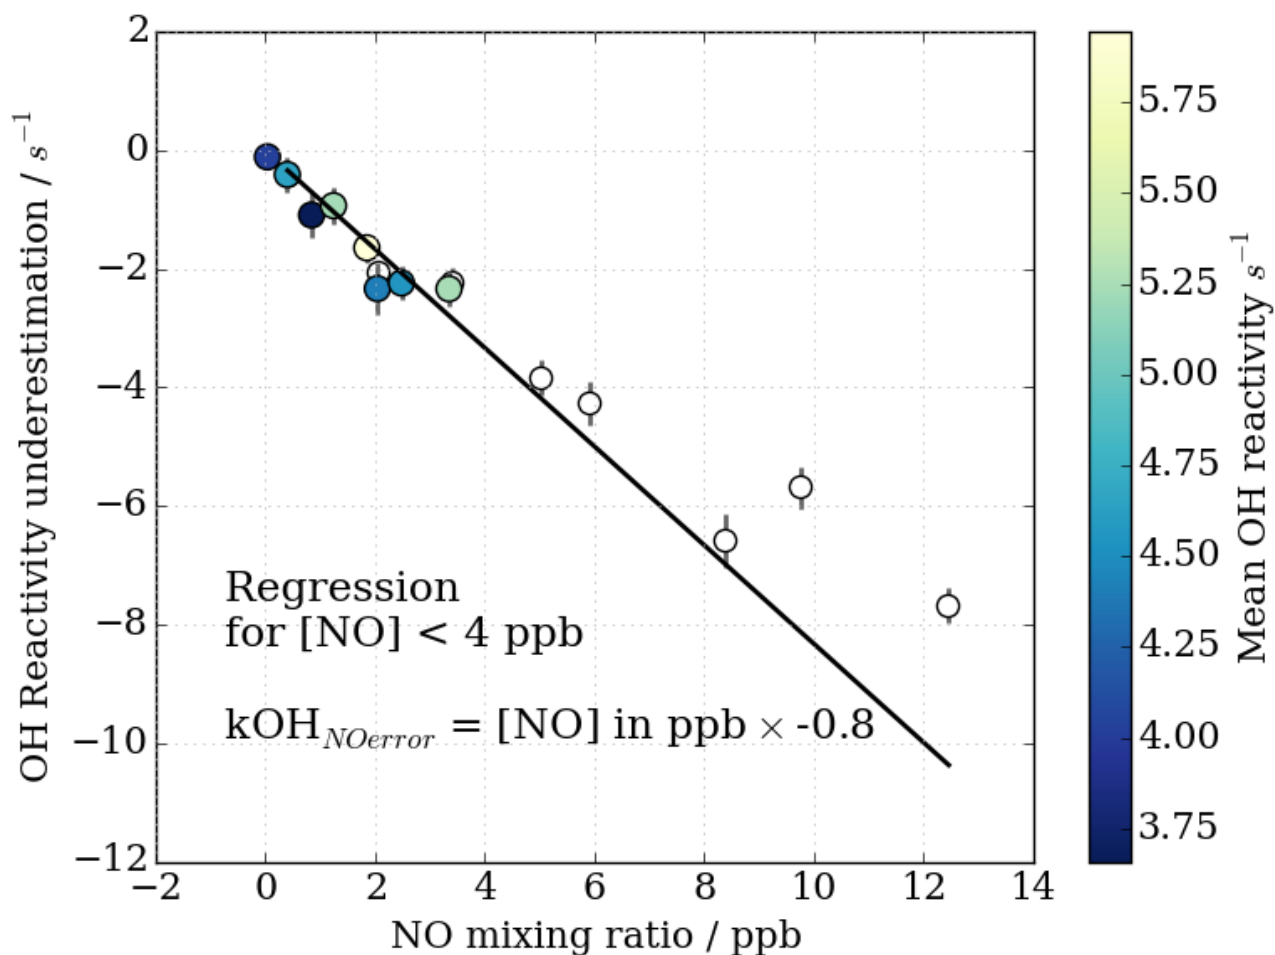

Figure 12: OH reactivity underestimation for MOHp relevant NO mixing ratio and typical OH reactivity (maximum $15 s^{-1}$). Filled circles are data used for linear regression to obtain mean underestimation of OH reactivity for NO up to 4 ppb.

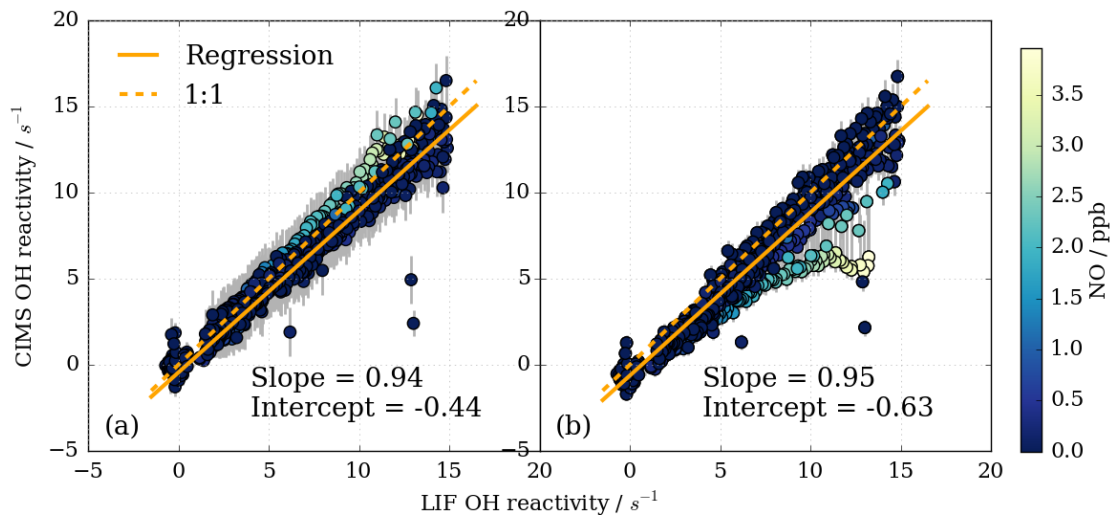

Figure 13: Subset of OH reactivity measurements from instrument comparison (Fuchs et al., 2017) for OH reactivity up to 15 s^{-1} and NO concentrations up to 4 ppb (716 data points). (a) CIMS data treatment includes eight parameter NO correction, (b) CIMS data are not corrected for NO presence, but a positive NO-dependent uncertainty is associated with the measurement (Fig. 12).

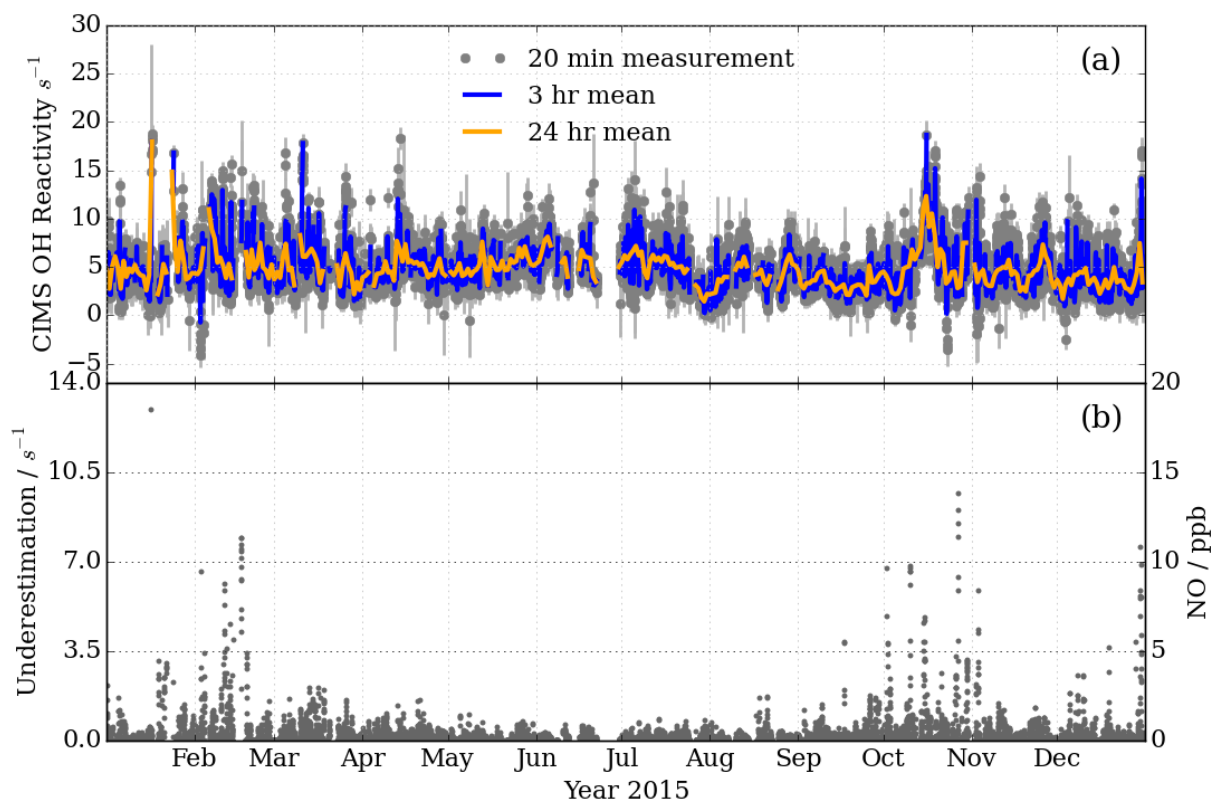

Figure 14: Observations at MOHp for the year 2015. (a) OH Reactivity measurements by CIMS, with 3 hour and daily means in blue and orange respectively. Filtered for recorded instrumental and laboratory interferences and seven outliers not coinciding with short term CO and NO₂ concentration peaks. 15541 valid measurement points. (b) Measured NO mixing ratios (right y-scale) and estimated CIMS OH reactivity measurement underestimation as a result of NO presence in ambient air (left y-scale).

S1. FACSIMILE 0D modelling of chemistry within CIMS flow tube

The following chemical mechanism has been used for the simulations described in the main paper. Only the reactions relevant to the results discussed in the main text are shown in Table S1.

Concentrations and parameters that are initialised for the flow tube experiments:

OH wall loss, HO₂ wall loss, O₂, N₂, H₂O, HO₂, NO, NO₂, CO, OH, H₂SO₄, C₃H₈

All other species are initialised zero.

RO₂ are lumped and represent RO₂ = IC₃H₇O₂ + NC₃H₇O₂

Table S1: Reactions in the flow tube relevant to HOx recycling in the CIMS flow tube

Reaction	Rate constant at T = 284 K, p = 995 hPa	Comment
OH + CO = H + CO ₂	1.1 x 10 ⁻¹³	
OH + CO = HOCO	1.3 x 10 ⁻¹³	
HOCO + O ₂ = HO ₂ + CO ₂	2.0 x 10 ⁻¹²	
OH + NO ₂ = HNO ₃	1.4 x 10 ⁻¹¹	
HO ₂ + NO = OH + NO ₂	8.1 x 10 ⁻¹²	
HO ₂ + NO ₂ = HO ₂ NO ₂	1.3 x 10 ⁻¹²	
OH + NO = HONO	8.0 x 10 ⁻¹²	
OH + HO ₂ = H ₂ O + O ₂	1.1 x 10 ⁻¹⁰	
HO ₂ + HO ₂ = H ₂ O ₂ + O ₂	1.5 x 10 ⁻¹²	
SO ₂ + OH = HSO ₃	1.0 x 10 ⁻¹²	
HSO ₃ + O ₂ = SO ₃ + HO ₂	4.4 x 10 ⁻¹³	
SO ₂ + HO ₂ = SO ₃ + OH	1.0 x 10 ⁻¹⁸	
SO ₂ + IC ₃ H ₇ O ₂ = SO ₃ + IC ₃ H ₇ O	3.5 x 10 ⁻¹⁷	*
SO ₂ + NC ₃ H ₇ O ₂ = SO ₃ + NC ₃ H ₇ O	3.5 x 10 ⁻¹⁷	*
SO ₃ + H ₂ O + H ₂ O = H ₂ SO ₄ + H ₂ O	8.4 x 10 ⁻³¹	
OH = N ₂	8.2 s ⁻¹	OH wall loss rate
HO ₂ = N ₂	0 s ⁻¹	HO ₂ wall loss rate
OH + C ₃ H ₈ = IC ₃ H ₇ O ₂	9.8 x 10 ⁻¹³	branching ratio = 0.736
OH + C ₃ H ₈ = NC ₃ H ₇ O ₂	9.8 x 10 ⁻¹³	branching ratio = 0.264
IC ₃ H ₇ O ₂ + NO = IC ₃ H ₇ O + NO ₂	9.6 x 10 ⁻¹²	branching ratio = 0.958
NC ₃ H ₇ O ₂ + NO = NC ₃ H ₇ O + NO ₂	9.9 x 10 ⁻¹²	branching ratio = 0.980
IC ₃ H ₇ O = CH ₃ COCH ₃ + HO ₂	6.7 x 10 ⁻¹⁵	k x [O ₂]
NC ₃ H ₇ O = C ₂ H ₅ CHO + HO ₂	1.1 x 10 ⁻¹⁴	k x [O ₂]
IC ₃ H ₇ O ₂ + HO ₂ = IC ₃ H ₇ OOH	2.8 x 10 ⁻¹¹	k x 0.520
IC ₃ H ₇ O ₂ + NO = IC ₃ H ₇ NO ₃	9.6 x 10 ⁻¹²	branching ratio = 0.042
IC ₃ H ₇ O ₂ = N ₂	3.2 x 10 ⁻¹⁴	k x [RO ₂]
NC ₃ H ₇ O ₂ + HO ₂ = NC ₃ H ₇ OOH	2.8 x 10 ⁻¹¹	k x 0.520
NC ₃ H ₇ O ₂ + NO = NC ₃ H ₇ NO ₃	9.9 x 10 ⁻¹²	branching ratio = 0.020
NC ₃ H ₇ O ₂ = N ₂	6.5 x 10 ⁻¹³	k x [RO ₂]

* These rate constants are estimates based on analogy reactions SO₂ + HO₂ and SO₂ + CH₃O₂. They should be considered uncertain and as an upper limit.

The following reactions are added to those in Table S1 when tagging for recycled OH (OHrec) is used and H₂SO₄ production pathways are separated:

S2. OH kinetic rate constants

Recommended rate constants from both IUPAC (Atkinson et al., 2006) and JPL assessments (Burkholder et al., 2015) are provided with uncertainty factors, which are considered here. Also discrepancies coming from the difference between recommendations are assessed for cases CO and C₃H₈ as OH reactants (Table S2). IUPAC standard temperature of 273.15 K and pressure of 10⁵ Pa are used here in the calculations of OH reactivity.

Table S2: Comparison of uncertainties in scaling rate from uncertainties and differences in kinetic rate constants for OH reactants CO and propane

OH reactant	Carbon monoxide (CO)	Propane (C ₃ H ₈)
Reaction(s)	$k = k_1 + k_2$ $k_1 : \text{OH} + \text{CO} \rightarrow \text{H} + \text{CO}_2$ $k_2 : \text{OH} + \text{CO} + \text{M} \rightarrow \text{HOCO} + \text{M}$	$k : \text{OH} + \text{C}_3\text{H}_8 \rightarrow \text{products}$
Uncertainty in sr_{CIMS} based on IUPAC rate constant uncertainty (1 sigma)	11 %	5 %
Uncertainty in sr_{CIMS} based on JPL rate constant uncertainty (1 sigma)	12 %	7 %
Difference in means between recommendations	< 4 % *	3 %

* This includes an additional IUPAC recommendation for k directly, valid for T = 200-300 K and p = 0-1 bar N₂

For CO as OH reactant, the 1 sigma uncertainty in the mean scaling rate is 11 % for IUPAC and 12 % for JPL recommendations. The difference in CIMS scaling rates from using the different recommendations is less than 4 % (Table S2), showing that the uncertainties in the rate constants themselves dominate the uncertainty in the scaling rate. Therefore the difference between recommendations is compatible within the uncertainties of the rate constant themselves.

In the case of propane as OH reactant, the 1 sigma uncertainty in the mean scaling rate is 5 % and 7 % for IUPAC and JPL recommendations respectively. The difference in mean calculated OH reactivity for the two recommendations is 3 %. The difference between recommendations is therefore at the order of the 1 sigma uncertainty of the rate constant themselves.

S3. Wall loss rate measurements during OH reactivity comparison campaign at FZJ SAPHIR chamber, April 2016

To provide an additional illustration of the quality of the wall loss measurements, rates from the OH reactivity comparison campaign at the SAPHIR chamber (Fuchs et al., 2017) are shown in Fig. S3. During the campaign in April 2016, zero OH reactivity was measured every day. At the beginning of each day, the chamber was humidified without addition of OH reactants, i.e. zero OH reactivity in the chamber, so consequently the wall loss rates could be obtained for the period of 0.5-1 hour.

Figure S3. Time series of wall loss rate k_w measurements for periods of zero OH reactivity in the SAPHIR chamber

The wall loss rates are overall stable for each individual day, and also for the whole campaign period from 7th to 15th April 2016.

Looking at stability over longer periods of time (half a year), the CIMS wall loss rates in Table 2 give indication of a similar level of variability and uncertainty compared to the shorter term stability shown above.
