

We thank the reviewer for the comments. Reviewer comments are provided in bold and our responses are given in plain text. We are also submitting a track changes version of the manuscript and supplement.

Reviewer 2:

Overview: This paper is nicely written and presented, and shows really good systematic testing of the prototype AMOD sampler/analysers. This is a really exciting area! However the major drawbacks of the paper are that the authors only present a small fraction of the data collected (e.g. was only potassium, iron and black carbon analysed? Why is all the analytical data not reported or repositied elsewhere and cited?). Data is only presented in graphs and no attempt at detailed statistics on the data collected is shown. The authors refer repeatedly to their companion paper, but the comparison of the variability of data collocated with reference stations vs the citizen science sites would add significant context to the paper. A really robust, self critical assessment of the successes and failures of the pilot study would make this a stronger paper.

All of the pilot data is being archived online in the open-source CSU digital repository (mountainscholar.org, a link will be added to the final paper). However, since these data are measured at people's houses, we truncated the latitude and longitude values to protect their personal identities and organized the files using a unique alphanumeric identifier.

The XRF analysis gives values for Mg, Al, Si, S, K, Ca, Ti, Cr, Fe, Ni, Cu, Zn, Ga, As, Se, Cd, In, Sn, Te, I, and Pb. However, our mass concentrations were relatively low (Figure 2) and many of these elements were not detected on any of our filters. Our lab gained the capability for this elemental analysis during the campaign; thus only filters collected later in the campaign were analyzed for elements (and as the reviewer mentions later, this analysis increases the cost of our project). We have added more information on our collected data to the paper.

“Elemental composition analysis was done using X-ray fluorescence (XRF) spectroscopy (Kellogg and Winberry, 1999); this analysis can give values for magnesium, aluminum, silicon, sulfur, potassium, calcium, titanium, chromium, iron, nickel, copper, zinc, gallium, arsenic, selenium, cadmium, indium, tin, tellurium, iodine, and lead. Only a subset of filters (those collected later in the campaign) were analyzed for composition.”

We did include a section in the paper on the lessons learned during the campaign, but it is difficult to include a really robust assessment of the successes and failures of the campaign because we were learning, testing, and adjusting as we went. This was the pilot for a much larger network that we hope to deploy, and we wanted to learn as much as possible about our methods and procedures. We tested different trainings with our participants and used different methods to recruit participants. We tried different camera tripods. We made device changes and upgrades. For example, we added Plantower PMS5003 instruments into the devices part way through to have

more PM data. We had to switch our microbalance, and we started doing chemical composition analysis to potentially provide more information on sources. And finally, we decided to completely redesign the AMOD based on the results of the campaign.

Major comments:

1) All chemical composition data and travel blank data should be presented

Chemical composition was only done on a subset of filters (our lab gained this capability midway through the campaign). We have added a figures to the supplement showing the filter elemental composition. The XRF (as stated earlier) gives results for more elements, but we only plotted the elements with a mass above 0/limit of detection. The table is being added to the digital repository.

Figure S5. The calculated mass concentration of each elemental species determined by XRF for each filter.

We have also added to the text in our methods sample:

“The average mass added to the filters that were used for sampling was $42 \pm 19 \mu\text{g}$. The average difference in pre- and postweight mass for blank filters was $5 \pm 4 \mu\text{g}$. Filter mass had to be greater than the corresponding blank mass and greater than $10 \mu\text{g}$ to be included in our analysis. Average $\text{PM}_{2.5}$ concentrations were calculated using the added mass and the amount of sampled air.” Note that these values were calculated using filters weighed on the new microbalance.

2) All reference data should be cited – which monitoring network are they in and where is the data deposited?

We have added the websites where data can be downloaded for the EPA site (<https://www.epa.gov/aqs>, monitoring site 08-069-0009), AERONET sites (data available here: <https://aeronet.gsfc.nasa.gov/>), and both MODIS satellite datasets (Collection 6.1, Level 2 AOD data available here for Aqua: https://ladsweb.modaps.eosdis.nasa.gov/archive/allData/61/MYD04_L2/ and here for Terra: https://ladsweb.modaps.eosdis.nasa.gov/archive/allData/61/MOD04_L2/) to the text.

3) Masses measured on the filters with statistics including when PM mass <LOD should be presented

Rather than including a large table, we have put a csv file with the table with all the filter data into the digital repository. The difference in mass between pre- and postweights had to be greater than the difference in mass on the corresponding blank filter and had to be greater than 10 µg. Link to the digital repository will be added to the final paper.

4) A diagram summarising the different time frames for the different measurements (24 hours, 48 hours, 3 days. . .) would aid the reader to understand (more my limitation than the authors, but a picture speaks a thousand words)

We are not entirely sure what the reviewer is suggesting, but we have made the following diagram in an attempt to address this suggestion. It has been added to the supplement as Fig S1, and we have added to the text in the Methods section: “A diagram of measurements taken during a sampling event is given in Fig. S1.”

Figure S1. Diagram of sampling event measurements. A sampling event lasts 48 hours and 15 minutes. Filter Measurements are continuous (pumps run continuously, filters collect mass during entire sampling event), providing an integrated measurement of PM_{2.5}. For AOD, the first value is from a single measurement at the start time, and the two subsequent are selected from a 30-minute window centered on the 24-hour and 28-hour mark after the start time of the sampling event. For devices with a Plantower PMS5003, measurements are taken every 30 seconds during the sampling event, providing a time-resolved measurement of PM_{2.5}.

5) In the discussion section, the variability due to day of week are posited as reasons for changes in PM levels – which given that there are air quality networks in the area the authors could have looked at the local variation for those periods with the reference sensors rather than qualitatively discuss it.

We have added the following figure to the supplement:

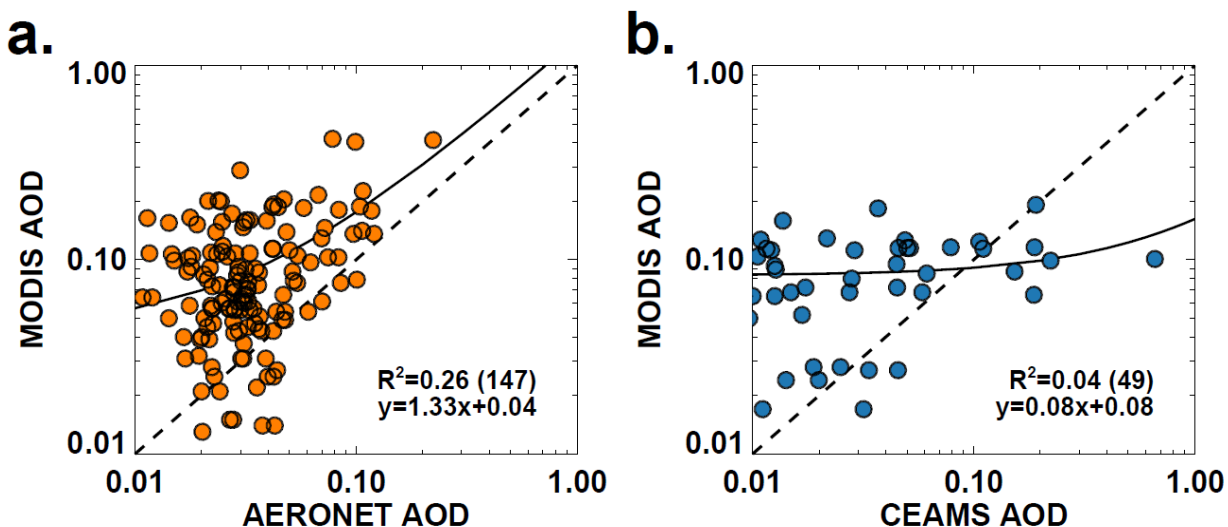

This figure shows the distribution of daily average PM_{2.5} concentrations for each day of the week measured at two sites in northern Colorado (Fort Collins and Greeley) for October through December of 2017. It shows that Fridays generally have the highest average concentrations and weekends have lower concentrations, though this might not be statistically significant due to the limited number of weeks (~13).

We have added to the text in section 3.1: “This is corroborated by comparing the distribution of daily average concentrations by weekday for monitor sites in northern Colorado. At these sites, concentrations are generally highest on Fridays and lower on weekends during the measurement period (Fig. S4).”

6) Figure 6, it would be useful to split this into 2 plots and put the statistics fit of the data. It is quite hard to separate the blue dots from the orange to look at the distribution. Estimated x-y error bars on the plot would also help

We split this into two panels as shown in the updated plot below. We did not add the error bars because this is a log plot, so it makes the plot really messy. We chose a log plot because there were many days with really low AODs that we want to show clearly.

7) I think some work needs to be done on the interpretation. Currently, the conclusions infer that the citizen science measurements are different because they are seeing different air masses and different emissions, however that is true for all measurements in different locations. A more specific question that the authors should attempt to discuss is whether the differences are quantitative and therefore valid, and what are the QA processes to filter out data when this is the case. The authors mention discarding some data and not others, what were the rules applied and what fraction of the data were included in the final data plots?

We agree that is true that measurements in different locations experience different air masses and different emissions. However, it is often assumed that, at a certain scale, air quality in a given region is quite similar, especially with respect to the PM_{2.5} to AOD ratio. Our goal is to show that this ratio varies over shorter distances.

For the fraction of data:

If every attempted sampling event was successful, we should have had 68 filters and 204 AOD measurements. For the PM_{2.5} filter measurements, we had 65 that were returned and weighed. In our final plots, we did not include the values from the device with the missing inlet (3), the filter from the device that shutoff after falling over (1), and the values when the difference between the post-weight and pre-weight was less than 10 ug (total of 9, 2 filters were just low mass and 7 were not counted due to an issue with our microbalance [we switched to using a different microbalance for the rest of the campaign]). Thus, we ended up with 51 filters for our analysis. We have added this number to the text (“our analysis includes results from 51 filters”).

The rules for the AOD are stated in the methods:

“(1) AOD had to be greater than zero, (2) AOD had to be less than 1 (which under heavy smoke or dust might be incorrect), (3) the Ångström exponent had to be greater than 0 (which under heavy dust might be incorrect), (4) measurements taken during the 30-minute measurement window had to pass the triplet test (for three measurements taken in a one minute period, the maximum and

minimum AOD difference had to be less than 0.02 at all wavelengths following Holben et al., 1998; Smirnov et al., 2000), and (5) the air mass factor had to be less than 5 (Smirnov et al., 2000).” We also did not get three AOD measurements if a device’s battery was not fully charged before sampling and ran out. If every sampling event yielded 3 AOD values, we would have had 204. We ended up with 115. We added to the text:

“After removing measurements that did not meet our criteria, we ended up with 115 AOD values for our analysis; as we used the same filtering criteria in Wendt et al., (2019), we would assume the same quality as quantified in those validation experiments.”

8) The authors state that these are low cost instruments, however I would ask the authors to check their economics: the capital cost is relatively modest, but what are the costs for chemical analysis/filter consumables/postage/data analysis/data cleaning/communication with citizen scientists? Development costs? It is mentioned in this paper and in the companion paper that sun tracking, GPS, cloud filtering etc. are being developed which also incur costs.

As the reviewer notes, we say these are “low cost instruments”. This does not mean that the network is low cost or the project overall is low cost, but that the relative cost of the instruments is low. We acknowledge that the term “low cost monitor” is used widely, but there is not a standard price point. However, the US EPA has published a document that defines low-cost monitors as “\$100-\$2500”

(https://cfpub.epa.gov/si/si_public_record_report.cfm?Lab=NERL&dirEntryId=277996). Our use of the term “low cost” in this paper is relative to standard EPA reference monitors and AERONET, instruments that either take filter measurements or provide AOD values. Compared to an AERONET or EPA monitor, our device is very low cost. This is what we tried to stress in the introduction. Additionally, these scientific devices also have substantial costs for development, maintenance, consumables, and analysis beyond the quoted cost for the instrument. If we included those costs for the instruments, our cost comparisons would be more significant.

As to the actual dollars:

We are a research institution, and we receive grant funding for these projects. Most of the processes listed in the reviewer’s comment are done in-house by graduate students, postdocs, and research scientists. The primary author, Bonne Ford, did the data cleaning, primary data analysis (with John Volckens and Jeffrey Pierce), and the majority of the communication with citizen scientists. It is part of our research endeavors to automate our data cleaning and some of our data analysis to reduce this burden in the future. Eric Wendt, primary author on our companion paper, is a graduate student and developed the AMOD (specifically the addition of the AOD sensor) in under a year as his thesis project (he also developed the solar tracking that is being used in the second generation AMOD and has worked on the cloud filtering). He also helped with training and communicating with participants and developed some of the firmware. Jessica Tryner is a postdoctoral fellow and

integrated the Plantower PMS5003 into the AMOD and helped train participants. Lizette van Zyl was a graduate student and helped communicate with and train participants and handle filters. Casey Quinn is a postdoctoral fellow and designed the mobile application and some of the device firmware. All individual CSU employee salaries are public, as well as the stipend for graduate students and salaries for postdocs. Thus, I will not list them here.

Postage was \$3 per participant and packaging was <\$1.00 per participant. For the filters, gravimetric analysis, XRF, and Sootscan costs totaled to roughly \$30 per filter (which factors in personnel costs), because it was all done in-house by co-authors John Mehaffy and Christian L'Orange. In this study, we used filters for two days, but we are moving towards longer sample periods which will help manage the amount and cost of filters when we scale up the network.

Thus, being at a research institute, we would argue that the economics still work in our favor, and we can call these “low cost”. However, we have added to the text to better emphasize our point with the following text:

“While more expensive than some commercially available low cost sensors, the AMOD is a fraction of the cost (~\$1000 for the instrument and ~\$30 per filter for materials and analysis; Wendt et al., 2019) of traditional surface-based instruments used for regulatory monitoring of air quality and can be deployed by trained citizens to measure AOD, PM_{2.5}, and I_λ.”

Minor comments:

P1 “Furthermore, model resolutions are generally too coarse (tens to hundreds of km)”: This is not completely true. Many atmospheric models are nested to allow finer resolution modules to be used, down to 1 km or better. Perhaps revise text slightly. Which models are being referred to.

We have changed the text to “Furthermore, models, particularly global models as used in the GBD, can have resolutions that are too coarse (tens to hundreds of km) to resolve small-scale variability in PM_{2.5} concentrations.”

P2 line 38 “Our companion paper (Wendt et al., 2019) describes the design and validation of the AMOD.” This is a repeat of sentence in previous paragraph, similarly on p 3 “A full description and validation of the AMOD sampler used for CEAMS is given in our companion paper, Wendt et al. (2019).” It is difficult to know how much to cite a companion paper, but a clear reason for referring to it at each point and directing to particular parts of it if necessary would be better.

We removed the first reference mentioned here. We wanted to make a clear distinction between the goals of this paper vs. the goals of part one.

Generally the paper could use an edit to remove repetition of both methods and discussion points and make it more concise, and allow more quantitative points.

We have made edits to the paper to remove repetition, as the reviewer suggests. We are not sure if it is more concise as we have added quite a bit of text to address the two reviewer comments.

A low-cost monitor for measurement of fine particulate matter and aerosol optical depth. Part 2: Citizen science pilot campaign in northern Colorado

Abstract.

A pilot field campaign was conducted in the fall and winter of 2017 in northern Colorado to test the deployment of the Aerosol Mass and Optical Depth (AMOD) instrument as part of the Citizen-Enabled Aerosol Measurements for Satellites (CEAMS) network. Citizen scientists were recruited to set up the device to take filter and optical measurements of aerosols in their backyards. The goal of the network is to provide more surface particulate matter and aerosol optical depth (AOD) measurements to increase the spatial and temporal resolution of PM_{2.5} to AOD ratios and to improve satellite-based estimates of air quality. Participants collected 65 filters and 160 multi-wavelength AOD measurements from which 109 successful PM_{2.5} to AOD ratios were calculated. We show that PM_{2.5}, AOD, and their ratio (PM_{2.5}:AOD) often vary substantially over relatively short spatial scales; this spatial variation is not typically resolved by satellite- and model-based PM_{2.5} exposure estimates. The success of the pilot campaign suggests that citizen-science networks are a viable means for providing new insight into surface air quality. We also discuss lessons learned and AMOD design modifications, which will be used in future, wider deployments of the CEAMS network.

1 Introduction

Exposure to particulate matter with diameters smaller than 2.5 μm (PM_{2.5}) is a leading contributor to the global burden of disease (GBD, Cohen et al., 2017; Forouzanfar et al., 2015; Lim et al., 2012). In the US, 3-5% of the annual deaths are attributable to PM_{2.5}, while in many Asian countries (e.g., China, India), this value is on the order of 10% (Cohen et al., 2017; <https://vizhub.healthdata.org/gbd-compare/>). The GBD values are determined using population-level exposure estimates coupled with concentration-response functions from epidemiological studies. However, determining population-level PM_{2.5} exposure can be challenging as there are a limited number of in-situ instruments that monitor ground-level PM_{2.5} concentrations worldwide. Thus, other methods must be employed to estimate exposure.

The current GBD methods employ a combination of model and “satellite-based” estimates of ground-level PM_{2.5} concentrations (Brauer et al., 2012, 2015). While these PM_{2.5} concentration estimates are considered the best available, there are

multiple limitations to these methods and inputs. Models can be limited by their emission inventories, meteorological input, and chemical mechanisms. Furthermore, models, particularly global models as used in the GBD, can have resolutions that are generally too coarse (tens to hundreds of km) to resolve small-scale variability in PM_{2.5} concentrations, while satellite products generally have finer resolutions (1-10 km). Satellite observations can provide long-term records with near global coverage of aerosols. However, satellite products relevant to air quality, such as aerosol optical depth (AOD), may have limited temporal and spatial resolution. Additionally, satellites view the entire atmospheric column; thus, fine particle concentrations at the Earth's surface (i.e., where exposures occur) are difficult to distinguish from particles aloft. A vast amount of research has been conducted relating satellite observations to surface-level air quality, either through empirical relationships between satellite observations and surface measurements (e.g., Engel-Cox et al., 2004; Weber et al., 2010; Zhang et al., 2009) or through combining satellite observations with model output (e.g., van Donkelaar et al., 2006, 2013, 2013, 2014, 2015b, 2015a; Liu et al., 2005, 2007). In particular, the original "satellite-based" PM_{2.5} estimates used satellite AOD and a model ratio of PM_{2.5} to AOD (often referred to as "I") to determine surface PM_{2.5}. The "satellite-based" estimate has since been updated to include more satellite and surface observations, regional bias corrections, and geographical data (e.g., van Donkelaar et al., 2015b). The PM_{2.5} concentration estimates developed from these endeavors have been used in a variety of health studies in addition to the GBD (e.g., Crouse et al., 2012; Evans et al., 2013; Fu et al., 2015; Hystad et al., 2012; Villeneuve et al., 2015).

However, each step of the process to estimate PM_{2.5} from satellite-based AOD and model data requires validation and/or bias correction. Satellite AOD products are often validated against ground-based observations, such as from Aerosol Robotic Network (AERONET, e.g., Levy et al., 2010; Remer et al., 2005). Model output is validated against a number of available data, both in terms of satellite and surface measurements (e.g., Ford and Heald, 2012). Unfortunately, there are a limited number of co-located, ground-based PM_{2.5} and AOD measurements available for validation of I (the PM_{2.5} to AOD ratio). The Surface PARTiculate mAtter Network (SPARTAN, <https://www.spartan-network.org/>) was developed for this purpose (Snider et al., 2015), but there are currently only 17 sites in operation (3 others ran for a limited time period), limiting the ability to determine the spatial variability in I at sub-regional scales. The difficulty in designing a robust validation network of co-located AOD and PM_{2.5} measurements is that the standard instruments used to measure these quantities are expensive and costly to maintain, both in terms of the actual instruments and staff. Thus, there is a need for more reliable, low-cost monitors that measure both PM_{2.5} and AOD.

This need is widely recognized, thus there has been an increase in the number and interest of low-cost sensors that can be deployed by citizens to collect air quality data (e.g., Kumar et al., 2015; Snyder et al., 2013). Gupta et al. (2018) used data from sensors deployed by citizens and air quality agencies as part of the PurpleAir network (purpleair.com) to examine the impact of wildfires on air quality in California. Snik et al. (2014) had participants in the Netherlands measure AOD using a mobile phone application and an optical add-on to mobile phone cameras. However, many of the lower-cost sensors used in these studies have moderate to high uncertainties (e.g., Gupta et al., 2018; Jerrett et al., 2017; Jiao et al., 2016; Zikova et al., 2017).

The Aerosol Mass and Optical Depth (AMOD) sampler was designed to provide high-quality surface-based PM_{2.5} and AOD measurements for the CEAMS (Citizen-Enabled Aerosol Measurements for Satellites) network. ~~A full description of the device and validation is given in our companion paper (Wendt et al., 2019).~~ The AMOD measures (1) time-averaged PM_{2.5} concentrations (using a ~~Polytetrafluoroethylene [PTFE]~~ filter sample that can be analyzed for mass and composition), (2) AOD at four different wavelengths (using optically filtered photodiodes), and (3) continuous PM_{2.5} concentrations (using an optically based sensor). While more expensive than some commercially available low cost sensors, the AMOD is a fraction of the cost (~\$1000 for the instrument and ~\$30 per filter for materials and analysis; Wendt et al., 2019) of traditional surface-based instruments used for regulatory monitoring of air quality and can be deployed by trained citizens to measure AOD, PM_{2.5}, and I.

Our companion paper (Wendt et al., 2019) describes the design and validation of the AMOD. In this paper, we describe the results of a pilot study where citizen-scientists were trained to deploy the AMOD at their place of residence. In addition to describing the pilot network, our goal is to demonstrate that (1) the CEAMS network measurements are representative of the regional air quality by comparing to standard surface and satellite measurements and (2) the CEAMS network has the potential to provide additional measurements that can better resolve the spatial and temporal variability of air quality than what is currently available from standard measurements. Results from the pilot network suggest that $PM_{2.5}$, AOD, and I_q often vary on spatial scales that are finer than what is currently resolved by satellite- and model-based $PM_{2.5}$ exposure estimates.

2 Methods

2.1 AMOD device and measurement data

A full description and validation of the AMOD sampler used for CEAMS is given in our companion paper, Wendt et al. (2019). In brief, the AMOD sampler has three main components for measuring air quality: (1) a filter-based $PM_{2.5}$ measurement, (2) an AOD instrument, and (3) real-time/continuous $PM_{2.5}$ sensor (Plantower PMS5003). The AMOD also measures meteorological variables (temperature, pressure, and relative humidity) and GPS location. The sampler is powered by an internal lithium-ion battery pack that is charged before the start of each sampling event, and participants were provided with an optional solar panel attachment to extend battery life. During our pilot study, each sampling event lasted for 48 hours and 15 minutes (the additional 15 minute periods accommodates the extended AOD sampling at the 48-hour mark). A diagram of measurements taken during a sampling event is given in Fig. S1. The Plantower PMS5003 was not included in the first generation of instruments; thus, Plantower PMS5003 results are only available for measurements later in the pilot campaign period.

The design of the filter-based $PM_{2.5}$ measurement in the AMOD is similar to that of the ultrasonic personal aerosol sampler (UPAS) device described by Volckens et al. (2017). Ambient air is drawn into the AMOD at two liters per minute (using a mass flow sensor and calculating instantaneous changes in air density) by an internal piezoelectric micropump, and $PM_{2.5}$ mass is collected on a 37-mm Polytetrafluoroethylene [PTFE]PTFE filter after passing through a size-selective cyclone inlet. Previous laboratory and field comparisons between $PM_{2.5}$ mass concentrations measured using the UPAS and an EPA Federal Equivalent Method (FEM) instrument found good agreement (R^2 values from 0.87 - 0.96) across a broad range of concentrations (5 to 1000 $\mu g/m^3$, Kelleher et al., 2018; Volckens et al., 2017). Additional validation of the filter-based $PM_{2.5}$ measurement in the AMOD sampler against an in-situ FEM instrument was done concurrently with our pilot study ($R^2=0.86$) as described in our companion paper (Wendt et al., 2019). The average mass added to the filters that were used for sampling was $42 \pm 19 \mu g$. The average difference in pre- and postweight mass for blank filters was $5 \pm 4 \mu g$. Filter mass had to be greater than the corresponding blank mass and greater than 10 μg to be included in our analysis. Average $PM_{2.5}$ concentrations were calculated using the added mass and the amount of sampled air.

In our pilot campaign, participants were given filters stored in barcoded sampling cassettes to minimize contamination during handling. In addition to filters for sampling, each participant was given an additional cassette that contained a filter blank for quality control. Filters were weighed to the nearest microgram (MX5 or XS3DU, Mettler Toledo) for total mass before and after sampling. Filters were also analyzed using the Magee Scientific SootScan instrument, which estimates the black carbon content of filter-bound aerosol via optical transmission (e.g., Ahmed et al., 2009; Kirchstetter and Novakov, 2007). Transmission data were converted to mass concentrations based on published mass-absorption values for combustion aerosol (Chylek et al., 1981). Elemental composition analysis was done using X-ray fluorescence (XRF) spectroscopy (Kellogg and Winberry, 1999); this analysis can give values for magnesium, aluminum, silicon, sulfur, potassium, calcium, titanium, chromium, iron,

nickel, copper, zinc, gallium, arsenic, selenium, cadmium, indium, tin, tellurium, iodine, and lead. Only a subset of filters (those collected later in the campaign) were analyzed for composition. These filter-based PM_{2.5} mass and composition measurements were used to determine average concentrations for each sampling event.

The AOD instrument has four optically filtered photodiodes at 440 nm, 520 nm, 680 nm, and 870 nm. The spectral bandpass of each photodiode is less than 15 nm. AOD measurements are a direct sun measurement that require participants to align the instrument (using a pinhole aperture and target) at the start of sampling. The AOD measurements were calibrated with AERONET measurements at one AERONET site and then validated at a different AERONET site (Wendt et al., 2019). The mean relative error between AMOD AOD and AERONET AOD was less than 0.0079 (~10%) across all wavelengths (Wendt et al., 2019). AOD measurements were taken every 24 hours during the sampling period (so as to not require participants to re-align every day), yielding three possible AOD values during the sampling event. The first AOD measurement is single and instantaneous; on subsequent days, the AMOD takes AOD measurements at 30 second intervals over a 30-minute window centered around the 24-hour and 48-hour marks. The 30-minute measurement window facilitates compensation for daily sun-position deviations and provides operators a chance to correct for mechanical misalignment (due to movement of the device or human error).

The four wavelengths were chosen so that AMOD AOD values could be compared directly with AOD values from AERONET and from satellite products. By having multiple wavelengths, we can also calculate the spectral dependence of the AOD, which can provide insight into the size and source of the aerosols (e.g., Eck et al., 1999). In particular, we calculated the Ångström exponent using the 440 nm and 870 nm wavelengths (as is commonly done). However, there can also be variability in the Ångström exponent based on the pair of wavelengths chosen. Thus, multiple sets are often used to calculate the curvature (or 2nd derivative) of the log of the AOD and the log of the wavelength (e.g., Eck et al., 1999; Kaskaoutis and Kambezidis, 2008). We do not present those results in this paper, but we plan to explore this further in future campaigns when we have a larger dataset. Additionally, we used the Ångström exponent for filtering our data.

For the pilot campaign, some minimal quality checks on the AOD values were conducted to screen out measurements that were impacted by clouds or misalignment of the instrument. These checks were implemented manually after sampling was completed. The requirements to be considered a successful AOD were as follows: (1) AOD had to be greater than zero, (2) AOD had to be less than 1 (which under heavy smoke or dust might be incorrect), (3) the Ångström exponent had to be greater than 0 (which under heavy dust might be incorrect), (4) measurements taken during the 30-minute measurement window had to pass the triplet test (for three measurements taken in a one minute period, the maximum and minimum AOD difference had to be less than 0.02 at all wavelengths following Holben et al., 1998; Smirnov et al., 2000), and (5) the air mass factor had to be less than 5 (Smirnov et al., 2000). The data collected from the pilot campaign and ongoing testing will be used to improve and automate the AOD quality-control process in the future.

The continuous PM_{2.5} sensor (Plantower PMS5003) estimates the PM_{2.5} mass concentration based on the amount of 650-nm laser light scattered at a 90° angle. The resolution of the Plantower PMS5003 is 1 ug/m3, and it is stated by the manufacturers to be effective for measuring concentrations in the range of 0-500 ug/m3 with an accuracy of ±10–15 ug/m3 (Yong, 2016). Our use of the PMS5003 estimates the wet PM_{2.5} mass in equilibrium with the ambient relative humidity. Because PM_{2.5} mass in equilibrium with 35% relative humidity is used as a standard for the US EPA measurements (commonly used in health studies), we corrected continuous PM_{2.5} measurements using time-averaged PM_{2.5} concentration measured with the concurrent filter sample. Our correction of the PMS5003 PM_{2.5} using the filter PM_{2.5} also potentially provides correction for PMS5003 errors due to variability in the aerosol size and optical properties. This correction was done by multiplying the continuous PM_{2.5} measurements by the ratio of the average concentration determined from the filter mass to the average concentration reported by the Plantower PMS5003 sensor over the full filter sampling period; hence, variability in the water uptake, size distribution, and optical properties on

timescales shorter than the 48-hour filter sampling period may not be wholly resolved by this correction. For Plantower PMS5003 validation, we co-located an AMOD sampler with a FEM monitor at the Colorado State University main campus in Fort Collins, CO (Wendt et al., 2019). In general, for non-filter-corrected Plantower PMS5003, we found good agreement with a slight low bias ($\sim 1 \mu\text{g}/\text{m}^3$) at lower concentrations ($<10 \mu\text{g}/\text{m}^3$) and a slight high bias ($\sim 2\text{--}3 \mu\text{g}/\text{m}^3$) at higher concentrations ($10\text{--}20 \mu\text{g}/\text{m}^3$; Wendt et al., 2019). These results are similar to those reported by Kelly et al. (2017), ~~and~~ Gupta et al. (2018), ~~and~~ Bulot et al. (2019) during laboratory and field evaluation of Plantower sensors. Laboratory testing (using set aerosol concentrations) by the South Coast Air Quality Management District (SCAQMD) suggests a precision of 95-100% with regards to temperature, relative humidity, and mass loading comparisons, with slightly lower precision occurring when temperature, relative humidity, and mass loading were all low (SCAQMD, 2017b). When compared to a GRIMM FEM monitor in the lab, the sensors were well-correlated ($R^2>0.99$) and had moderate to good accuracy (54-96%) over the range of $0\text{--}250 \mu\text{g}/\text{m}^3$ (SCAQMD, 2017b). In field tests, the Plantowers PMS5003 sensors were co-located with a GRIMM and a BAM monitor and concentrations were well correlated with both ($R^2>0.93$ and $R^2>0.86$, respectively; SCAQMD, 2017a). However, these SCAQMD field tests were limited in duration, and there is some concern that the devices will degrade over time. Sayahi et al. (2019) did find lower correlation between hourly Plantower compared to TEOM ($R^2=0.87$) and 24-hour average to FRM ($R^2=0.88$) for Plantowers deployed for 320 days. They also noted that there was some seasonal variability in the agreement, and the bias was not consistent between instruments over time. Bulot et al. (2019) also deployed Plantower PMS5003 sensors for almost a year and found good correlations with a reference instrument ($R^2=0.72\text{--}0.77$). They also show that the performance is only minimally impacted by temperature and relative humidity, and that high mass loading leads to periods of poor performance. Continuous $\text{PM}_{2.5}$ measurements and meteorological data measured by the AMOD were recorded every 30 seconds. For the results section, we average the filter-corrected continuous $\text{PM}_{2.5}$ measurements to hourly increments.

The AMOD was mounted on a stationary camera tripod, and sampling and data collection were controlled by participants using the CEAMS app on a smartphone through a Bluetooth connection with the device as described in Wendt et al. (2019). After each sampling event, participants used the smartphone application to download data from the instrument to their phone and then send the data to our server using file transfer protocol (ftp).

We also calculated $\text{PM}_{2.5}$ to AOD ratios (I). Normally, I is calculated using the instantaneous AOD from the satellite (or a model AOD for the satellite overpass time) and the 24-hour average $\text{PM}_{2.5}$ concentration (e.g., van Donkelaar et al., 2013). Here, we calculate the I for each of the three days in the sampling period using the instantaneous AOD and the 48-hour average $\text{PM}_{2.5}$ filter concentration. In future measurements, we plan to analyze the sub-daily variability in I by using the $\text{PM}_{2.5}$ concentrations from the real-time Plantower PMS5003. However, only a limited number of devices included the Plantower PMS5003 in the pilot network.

2.2 Citizen-science participants and pilot measurements

Participants were recruited through a partnership with the Community Collaborative Rain, Hail, and Snow (CoCoRaHS) network and through Colorado State University (graduate students and staff). CoCoRaHS is a citizen-science network focusing on precipitation measurement collections (Cifelli et al., 2005). Recruitment emails with an initial survey were sent to CoCoRaHS participants in Larimer and Weld counties in northern Colorado to gauge interest in air quality monitoring, general demographics, and participant motivation. A second survey was sent to participants who expressed interest in being contacted for sampling. This second survey provided information on the actual sampling process and the requirements for participation. This survey was used to determine which participants to invite to a training session, with selection based on availability for sampling, availability for training, and location.

Measurements for the pilot network were taken between October and December 2017. Each participant deployed the AMOD for provided at least one 48-hour sampling ing event (Fig. S1)e. A map of sampling locations is shown in Fig. 1. Participants were allowed to initiate sampling on their own schedule; however, there were two 48-hour periods (1-3 December 2017 and 9-11 December 2017) when select participants were asked to sample concurrently to better determine the spatial and temporal variability of air quality across the Fort Collins metropolitan area during these distinct time periods.

2.3 Datasets used for comparisons

To contextualize our citizen science measurement data, we compared our results from the CEAMS pilot study to routine air quality datasets collected in northern Colorado. The AMOD PM_{2.5} measurements were compared to measurements taken by a US EPA Air Quality System (AQS, <https://www.epa.gov/aqs>https://www.epa.gov/aqs_monitoring_site_08-069-0009) Federal Equivalent Method (FEM) light scattering PM_{2.5} monitor (EDM 180, GRIMM, Ainring, Germany) located on the Colorado State University campus in Fort Collins, CO. The AMOD AOD measurements were compared to ground-based and satellite-based AOD. Note, here we are comparing our measurements to nearby monitors; the validation of the AMOD using co-located measurements is detailed in Part 1 (Wendt et al., 2019).

For ground-based AOD, we compared the AMOD results to AOD from AERONET sites, a network of sun photometers which has been in operation for more than 25 years (Holben et al., 1998). Specific sites used for comparison are listed in Supplementary Table S1; and each site had to have at least one valid measurement during the duration of the pilot network campaign (data available here: <https://aeronet.gsfc.nasa.gov/>). The Cimel Electronique Sun/Sky radiometers in the network measure direct sun, aureole, and sky radiance at multiple wavelengths in the range of 300 nm - 1020 nm (with 440, 670, 870, 940, and 1020 nm being standard). The AOD derivation from these stationary, ground-based instruments requires minimal assumptions, and the instruments are well calibrated; thus, the data has been found to be highly accurate. AERONET AOD is considered ground truth for the validation of satellite and other remotely sensed products. Holben et al. (1998) estimate that the total uncertainty in (cloud-free) AOD retrieved from a newly calibrated instrument is less than ± 0.01 for wavelengths greater than 440 nm ($< \pm 0.02$ for shorter wavelengths).

The most widely-used satellite AOD products come from the Moderate-resolution Imaging Spectroradiometer (MODIS) instruments aboard the Terra and Aqua satellite platforms, which measure scattered radiances at 36 wavelengths (King et al., 1999). Different algorithms have been developed for AOD retrievals over ocean and land to account for the contribution of surface reflectance (e.g., Kaufman et al., 1997; Tanre et al., 1997). The standard AOD products are at 550 nm (Collection 6.1, Level 2 AOD data available here for Aqua: https://adsweb.modaps.eosdis.nasa.gov/archive/allData/61/MYD04_L2/ and here for Terra: https://adsweb.modaps.eosdis.nasa.gov/archive/allData/61/MOD04_L2/). Numerous studies have evaluated MODIS AOD through comparisons with ground based AERONET sites. Expected uncertainties in the MODIS-derived AOD over land are $\pm(0.05 + 0.15 \times \text{AOD})$ (Levy et al., 2010). When comparing MODIS AOD to the CEAMS AOD, we use MODIS AOD values within a 15 km radius and a two-hour window centered around the CEAMS measurement. Because AERONET measurements are more frequent, we average the AERONET AOD within a two-hour window around the time of the MODIS AOD value closest (less than 15 km) to the AERONET site on a given day.

3 Results and discussion

3.1 PM_{2.5} filter measurements

During the pilot campaign, 65 filters were collected by participants. ~~Not~~ Not all filter results are shown because some of the filters had low or unrealistic weights due to issues with a device inlet, a device falling over, and a microbalance used for weighing

the filters; our analysis includes results from 51 filters). A distribution of the 48-hour average PM_{2.5} mass concentrations measured using these filter samples is shown in Fig. 2. To note, in the figure, we are comparing the CEAMS 48-hour average PM_{2.5} concentrations to 24-hour averages from the EPA-AQS site in Fort Collins. This is not an exact comparison, as the CEAMS measurements have overlapping days and different sampling periods (different start and end times). However, our goal is not to validate our measurements (for validation, see Part 1 by Wendt et al., 2019), but to demonstrate that our measurements are able to capture a similar view of air quality as a traditional reference monitor. Concentrations were relatively low, and only a few filters measured concentrations above 12 µg/m³. This distribution is as expected in wintertime Colorado as shown by the comparison to the distribution of daily average concentrations in Fort Collins for the same time period. Higher PM_{2.5} concentrations in the wintertime in northern Colorado are often associated with lower boundary layer heights and stagnant air masses. Additionally, higher concentrations measured by CEAMS participants were generally located near city centers (discussed later, Fig. 3 and 4).

An example of 48-hour average filter concentrations measured by CEAMS participants and AQS monitor 24-hour average PM_{2.5} concentrations measured on 13 November 2017 is given in Fig. 3. During this sample period, the highest concentrations were recorded by the AQS monitors in Greeley and Longmont, while the lowest concentrations were measured by CEAMS participants along the foothills northwest of Loveland (Fig. 3). ~~The variability in PM_{2.5} concentrations highlights the variability in local air quality in Colorado and the potentially different emission sources.~~

In Fig. 4, we show the 48-hour average PM_{2.5} mass concentrations, the BC concentrations, and the percents of PM_{2.5} that are BC for two different sampling periods in Fort Collins in December 2017. There are notable differences between the results from the two sampling periods. The first sampling period (1-3 December 2017) generally saw higher concentrations in total PM_{2.5}. Black carbon concentrations on the western edge of the city were higher during the first period compared to the second (potassium mass—which can be a marker for soil dust or biomass burning [e.g., Kreidenweis et al., 2001]—was also slightly higher [Supplementary Fig. S24]). Meteorological differences between the two sampling periods could explain some of these differences. While temperatures were similar, conditions were slightly warmer, sunnier, drier, and windier during the second sampling period. Additionally, winds during the first sampling period were more variable, while winds during the second sampling period mainly came from the south/southeast where there are more sources (Fig. S32). For both sampling periods, the highest BC concentrations were measured in high traffic areas (e.g., the city center) and are likely associated with vehicular combustion sources; however, BC concentrations in the city center were slightly lower during the first sampling period compared to the second sampling period. It is important to note that the two sampling periods do not cover the same weekday period: the first sampling period was from Friday through Sunday and the second was from Saturday through Monday. Thus, differences in weekday and weekend traffic patterns could also impact the concentrations. This is corroborated by comparing the distribution of daily average concentrations by weekday for monitor sites in northern Colorado. At these sites, concentrations are generally highest on Fridays and lower on weekends (Fig. S4).

We had several citizen scientists participate in both December sampling periods; thus, we have measurements collected for both sampling periods at some sites. One site in central Fort Collins saw similar concentrations between the two sampling periods, while the northwest site (in Laporte, CO) measured PM_{2.5} and BC concentrations that were twice as high during the first sampling period compared to the second. These differences could be due to the aforementioned differences in meteorology; however, the participant in Laporte, CO also noted a nearby idling vehicle overnight with high exhaust emissions during the first sampling period (this will be further noted in Section 3.3).

The highest 48-hour PM_{2.5} concentration (13 µg/m³) from these two sampling periods was measured by a participant in Milliken, CO during the second sampling period (not shown in Fig. 4 due to this location being ~25 miles away from other participants and outside the map area). The metal analysis of this filter found high concentrations of silicon and aluminum,

potentially suggesting that the nearby (<0.5 miles) concrete operation impacted air quality in the participant's residential neighborhood. Across all participants, non-carbonaceous elemental mass accounted for 10-40% of the blank-corrected PM_{2.5} concentration. The elements with the highest concentrations were aluminum, iron, silicon, potassium, and calcium, which suggest soil or dust sources (Fig. S5). Potassium can also be a marker for biomass burning, particularly when the ratio of potassium to iron is higher (e.g., Calloway et al., 1989; Kreidenweis et al., 2001, Fig. S24).

3.2 AOD measurements

Over 160 AOD measurements were taken during the pilot campaign. These measurements were taken once per day during each 48-hour sampling event. Not every sampling event yielded three useable AOD values due to the following reasons: some of the device's batteries died before finishing the sampling event, some of the devices fell over due to wind, and some devices were ~~completely~~ misaligned. Out of the 160 AOD measurements, ~~several~~ more AOD values were filtered out by our quality check procedure (~~to remove clouds and measurements taken with a high air mass factor, etc. [detail~~see in the Methods section]). However, there could still be some erroneous values due to a slight misalignment or the presence of thin clouds. After removing measurements that did not meet our criteria, we ended up with 115 AOD values for our analysis; as we used the same filtering criteria in Wendt et al., (2019), we would assume the same quality as quantified in those validation experiments.

In Fig. 5, we compare the CEAMS AOD measurements to AERONET AOD measurements taken in northern Colorado during the same period (AERONET sites are shown in Fig. 1) for the 440 nm wavelength (chosen because it is an exact wavelength match, 870 nm wavelength comparison shown in Fig. S63). In general, our AOD results fall within the range of AOD values measured at the AERONET sites on the same day (distribution shows all AOD measured throughout the day at all AERONET sites in northern Colorado), although there are several days when the CEAMS AOD values are higher. The discrepancies could be due to several factors. AERONET uses a more rigorous quality check than our measurements, and some cloud-contaminated AOD measurements may have gone unfiltered (especially if there were thin clouds present). Additionally, most of the AERONET sites are located south of our sites (Fig. 1) and take measurements multiple times a day, so the CEAMS measurements and the AERONET measurements may not be representative of the same air masses. This is likely on at least a few of the days, as we also note a large spread among values from the different AERONET sites. Additionally, co-location of the AOD with AERONET instruments showed very good agreement (Wendt et al., 2019). Thus, our results here show (1) CEAMS measurements show similar magnitude and variability in AOD compared to AERONET sites, and (2) there is spatial and temporal variability in AOD captured by the CEAMS measurements that cannot be represented by the spatial coverage of AERONET sites.

We also compared our CEAMS AOD (520 nm) and AERONET AOD (500 nm) to satellite-based AOD (MODIS 550 nm) in the region (Fig. 6, ignoring the difference between the wavelengths). For this, we used both the MODIS Aqua and Terra 10-km AOD products. We matched the location of each measurement to the nearest satellite grid center point (distance had to be less than 15 km) for the same day (we used a two-hour window around the observations). In general, MODIS seems to overpredict compared to AERONET and CEAMS AOD. Some of these differences might be due to timing or location of the measurements (we used a two-hour window and 15 km radius centered around the CEAMS measurements), measurement bias from the CEAMS instrument (though CEAMS AOD was shown to be within 10% of AERONET AOD in Wendt et al. (2019), and CEAMS and AERONET both similarly show lower AOD than MODIS) or MODIS, or the presence of clouds. However, we would also not necessarily expect to see good agreement between the satellite and ground-based observations. Agreement between MODIS and AERONET tends to be lower in the western US compared with the eastern US (e.g., Ford and Heald, 2016; Li et al., 2015; Sayer et al., 2013), partially due to issues with the surface reflectance (most of the AERONET sites used here are in the foothills of the Rocky Mountains) and/or a larger presence of coarse mode aerosols. Furthermore, we would expect there to be variability in AOD over

northern Colorado at a resolution not captured by a 10-km satellite product due to local sources. ~~This local variability is shown in Fig. 7.~~

AOD values measured by CEAMS participants during the 9-11 December sampling days are shown in Fig. 7. AOD values were generally very low on these three days; however, most of the AOD measurements during the 9-11 December sampling days were taken in the morning (between 9 AM and 1 PM local time), when $\text{PM}_{2.5}$ concentrations were generally at their lowest value (see Fig. 8). AOD values were higher on the third day, which was a Monday. The first two days were weekend days, so these results could indicate a difference in weekday versus weekend pollution patterns. The sites with the highest AOD values correspond to the sites with the highest $\text{PM}_{2.5}$ concentrations (Fig. 4). However, the AOD values at these few sites are larger than measured at the AERONET sites (Fig. 5). Additionally, these sites had low Ångström exponent values (calculated from the 870 and 440 nm wavelengths, Fig. ~~8S64~~). As the Ångström exponent is inversely proportional to the size of the particles, this could suggest either (1) larger particles like dust or (2) thin cloud contamination in the AOD measurement. Unfortunately, with only one AOD measurement per day per site, it is difficult to attribute the source of the high AOD values; future sampling will include multiple measurements per day per site, enabled by solar tracking functionality on the second-generation AMOD.

3.3 Real-Time $\text{PM}_{2.5}$ measurements

Plantower PMS5003 sensors were only included in some of the AMOD first generation devices (they will be included in all future devices); thus, we have fewer results compared to the AOD and filter measurements, but the results do provide additional information. In particular, real-time $\text{PM}_{2.5}$ measurements provide insight into the diurnal variability of air quality. For Fig. 8, we present hourly averages of the filter-corrected $\text{PM}_{2.5}$ concentrations measured by the Plantower PMS5003 sensors during the 1-3 December and 9-11 December sampling periods. For both sampling periods, measurements showed peak concentration overnight at several sites. Northern Colorado winter nights are often marked by cold temperatures, low boundary layer heights, and weak winds, which can lead to the buildup of pollutants. Additionally, many homes still rely on wood burning for heating (potassium mass on the filters was only slightly higher during the first sampling period, which was slightly colder, Fig. ~~S24~~). These increased emissions at night, coupled with the low boundary layer heights, could be the cause of the overnight peak concentrations. This hypothesis is corroborated by the spatial distribution of $\text{PM}_{2.5}$ concentrations, as the locations with the largest overnight peaks are located in regions with older homes (e.g., the City Park and CSU campus sites [Fig. 8] in Old Town Fort Collins). The Laporte, CO site also saw high overnight concentrations on 1-2 December; and, while there is also a lot of residential wood burning in Laporte (this site had higher potassium concentrations and higher potassium to iron ratios, Fig. ~~S24~~), the participant also noted an idling vehicle with significant emissions at a neighbor's home during the middle of the night on 1-2 December.

3.4 $\text{PM}_{2.5}$ to AOD ratio

A major goal of this network is to better estimate Π , the $\text{PM}_{2.5}$ to AOD ratio; in order to improve the methods for using satellite observations to determine surface air quality in regions and time periods without extensive surface monitoring. From our measurements, we calculated ~~109~~ $\text{PM}_{2.5}$ to AOD ratios for each of the three days in the sampling period using the instantaneous AOD and the 48-hour average $\text{PM}_{2.5}$ filter concentration ~~(the distribution of these values is shown in Fig. S6). As stated in the methods, we calculate the Π for each of the three days in the sampling period using the instantaneous AOD and the 48-hour average $\text{PM}_{2.5}$ filter concentration.~~ Only 109 ratios were calculated from the 65 filters and 160 AOD values due to (1) not including filters from the device with the inlet or microbalance issue and (2) not using AOD values that did not pass our quality checks listed in the Methods section.

An example of the calculated ratio is shown in Fig. 9, which also shows the AOD from MODIS (gridded average of Aqua and Terra) and from the CEAMS measurements (using the 520 nm wavelength) for two days. In this figure, the highest ratios are nearer to the Fort Collins city center, while sites farther out have generally lower ratios. High PM_{2.5} to AOD ratios can indicate more particles near the surface, which often happens near emission sources. A low PM_{2.5} to AOD ratio can indicate (1) particles are mixed through more of the atmospheric column (or lofted above the surface), (2) the presence of larger particles, or (3) thin cloud contamination in the AOD. Thus, the variability may be due to distance from the aerosol sources, variability in the aerosol size distribution (which is supported by the variability in Ångström exponents calculated from the 870 and 440 nm wavelengths measured at the different sites, Fig. S7), or differing diurnal variability in PM_{2.5} concentrations compared to the timing of the AOD measurement.

This difference in measurement duration is likely important. Our PM_{2.5} values are an integrated 48-hour measurement while the AOD is an instantaneous measurement. In studies that use the satellite AOD to calculate η , this is generally done using an instantaneous AOD value (for some daylight time that varies based on location and overpass) and the 24-hour average PM_{2.5} concentration (e.g., van Donkelaar et al., 2013; 2013.; Ford and Heald et al., 2016). This is a methodological decision, as the desire is to use an instantaneous satellite AOD value to determine a 24-hour average PM_{2.5} concentration in a region with no surface-based measurement. Thus, while the PM_{2.5} to AOD ratio is often strongly related to the vertical distribution of aerosols in the atmospheric column (e.g., van Donkelaar et al., 2010; Ford and Heald, 2016); because of the time element, the determined η values are not necessarily indicative of the time-averaged vertical distribution of aerosols for a region. Therefore, because our measurements are not taken at a set time; we can expect some variability in the ratios just based on the timing of the AOD measurements. To explore this further, we also calculated “instantaneous” η values from our measurements. If we use the Plantower PMS5003 PM_{2.5} data (hourly average, not available for all samples) to calculate η rather than the filter, we find that using the 48-hour average concentration rather than the hourly average concentration often overpredicts η due to higher PM_{2.5} concentrations at night compared to the concentrations at the time of the daytime AOD measurement (Fig. S9). In other seasons or locations with a different diurnal pattern, we might find the opposite. We plan to further explore this temporal variability in future studies by taking multiple measurements of AOD throughout the day (there will still be some bias as we can only measure AOD during daylight hours).

In Fig. 9, we also ~~Additionally, we~~ compared the PM_{2.5}:AOD ratio from the CEAMS sites (again, calculated from the daily AOD and the 48-hour average filter concentration) to what would be the assumed η if we just used the daily average PM_{2.5} from one long-term surface monitoring site (CSU Facilities) with the MODIS AOD at that location. Our CEAMS measurements ~~The figure shows~~ high variability in η (orders of magnitude) over a relatively short distance. While some of this variability may be due to measurement error (or the timing of the measurement as discussed previously), the number of measurements with a range of values gives confidence that there should be more variability than what can be determined from the single PM_{2.5} measurement site and satellite AOD. We also looked at the distribution of ratios collected from our CEAMS measurements compared to the distribution of ratios using MODIS AOD and the PM_{2.5} concentrations from the EPA-AQS site (Fig. S10). We have a greater fraction of higher η values. This could suggest that our AOD values are biased low, or our PM_{2.5} values are biased high, or it could suggest that our CEAMS locations are located nearer to sources than the EPA-AQS monitor. Studies have shown that MODIS AOD is often biased quite high in the western US (mainly due to issues representing the surface reflectance [e.g., Ford and Heald, 2016; Li et al., 2015; Sayer et al., 2013]), which we also see in the comparison to AERONET in Figure 6. Thus, the EPA-AQS/MODIS ratios are likely biased low. Additionally, the EPA-AQS monitor is on the roof of the facilities building on the Colorado State University campus (primarily a walking campus); thus, it is slightly removed from some sources due to the height and location (for example: road dust, residential wood burning, etc.) and may show slightly lower concentrations. These

discrepancies again suggest that η calculated from a single PM_{2.5} measurement site and a satellite AOD may not correctly capture the regional variability in η . Thus, more co-located AOD and PM_{2.5} measurements are necessary.

In Fig. 9, the highest ratios are nearer to the Fort Collins city center, while sites farther out have generally lower ratios. The variability may be due to distance from the aerosol sources, variability in the aerosol size distribution (which is supported by the variability in Ångström exponents calculated from the 870 and 440 nm wavelengths measured at the different sites, Fig. S4), or differing diurnal variability in PM_{2.5} concentrations compared to the timing of the AOD measurement. Our PM_{2.5} values used here are an integrated 48-hour measurement while the AOD is an instantaneous measurement. If we use the Plantower PM_{2.5} data (hourly average, not available for all samples) to calculate η rather than the filter, we find that the 48-hour average often overpredicts η due to higher PM_{2.5} concentrations at night compared to the concentrations at the time of the daytime AOD measurement (Fig. S76). The PM_{2.5} to AOD ratio is often strongly related to the vertical distribution of aerosols in the atmospheric column (e.g., van Donkelaar et al., 2010; Ford and Heald, 2016). High PM_{2.5} to AOD ratios can indicate more particles near the surface, which often happens near emission sources. A low PM_{2.5} to AOD ratio can indicate (1) particles are mixed through more of the atmospheric column (or lofted above the surface), (2) the presence of larger particles, or (3) thin cloud contamination in the AOD.

4 Lessons learned from the pilot campaign

Validation of the AMOD device measurements showed good agreement with standard validation measurements (Wendt et al., 2019). However, not all of our CEAMS measurements taken by participants were successful. Several participants failed to align the device correctly because it required them to find a small sunspot on the device and then tighten the camera tripod to lock the AMOD in place. In addition, AOD measurements were negatively affected by cloud contamination, high winds that shifted the alignment of the device (or toppled it completely), and the fact that the device only took a single (valid) AOD measurement per day. Overall, we obtained a limited number of useful AOD measurements from the pilot campaign (115 out of a predicted 204). In the conclusions section, we discuss improvements to the AMOD device that are being implemented to address these issues prior to expanding the network for future sampling campaigns.

In regard to participation, we found that CoCoRaHS participants were highly motivated and responsive. Participants recruited from elsewhere were less likely to finish taking their measurements and required more prompting and reminders to set up their devices. Thus, as we anticipated, partnering with the already established CoCoRaHS citizen-science network was beneficial in finding reliable and engaged participants. We plan to continue this partnership for future deployments. For training, we found that hands-on training significantly improved the success rate of participants as opposed to training videos and manuals. Participants who came to small group training sessions were also more positive about their experience and required far less “troubleshooting” feedback from CEAMS staff during their deployments than participants who relied on manuals or videos.

We also found that participants wanted immediate access to the data they collected. In the pilot campaign, we collected all the data and then later provided plotted results to the participants. However, many participants were no longer actively engaged. For the wider deployment, we plan to provide near real-time access to data and put more effort into data visualization for participants.

5 Conclusions

The pilot campaign network in northern Colorado allowed for an opportunity to test the AMOD device and an initial sampling strategy for the CEAMS network. Even with the limited number of participants and samples taken during the pilot campaign, we found that citizen scientists were able to successfully use low-cost devices to provide useful information on the spatial and temporal variability of air pollution. The measurements taken by participants were representative of the air quality measured by standard air

quality instruments during the same time period but provided information at a higher spatial resolution. The measurements also provide insight on the diurnal and spatial variability of surface pollution, emission sources, the vertical distribution of pollution, and aerosol sizes. Thus, a wider deployment of the AMOD device through the CEAMS network can be used to (1) more comprehensively investigate local air quality and (2) provide information that can be used in conjunction with satellite observations to better understand air quality worldwide.

Future deployments are planned for other regions of the western US, locations which were strategically chosen to target situations that are notoriously difficult for using satellite observations to infer surface air quality. We are using the feedback from our citizen scientists and the information gained from analysis of the collected data to improve the device and our sampling strategy. In these future campaigns, we plan to deploy more instruments for an extended period of time. An improved version of the AMOD device is also being developed to address many of the issues encountered during the pilot campaign. We are updating the wavelength selection for the AMOD to exactly match those of the AERONET instruments, which will allow for a direct comparison. Because the Plantower PMS5003 results proved interesting and useful, we are including them in all future devices. The new AMOD also includes active solar tracking and will automate the AOD measurement to reduce misalignment errors. Additionally, the device will be able to take multiple AOD measurements per day, which will increase the amount of data collected and reduce the chance of missing a measurement day due to cloud contamination. By automating the AOD measurement and including a larger battery, we will also be able to increase the sampling period from two days to five days. The set-up time required for participants will be less, thus we will get more measurements without increasing an individual's effort. Additionally, we will be able to use the multiple AOD measurements with the real-time PM_{2.5} data to understand the sub-daily variability in the PM_{2.5} to AOD ratio.

Author Contributions

BF, JRP, ML, SJ, and JV designed the study. ML, LVZ, and BF recruited scientists and created training materials. EW, DML, CQ, JT, JV, and CL designed and validated the AMOD device. CQ designed the mobile application. CL and JM led the filter analysis. BF, LVZ, EW, and JT trained participants. BF led paper with JRP and JV; and all co-authors contributed to interpretation of results and paper editing.

Acknowledgements

The authors wish to thank all the citizen scientists who participated in CEAMS. We also wish to thank the CoCoRaHS team, specifically Nolan Doesken, Noah Newman, and Peter Goble. We are thankful to the MODIS satellite teams and the AERONET teams and principal investigators for each site. This work was funded by NASA grant NNX17AF94A and 80NSSC18M0120.

Zikova, N., Masiol, M., Chalupa, D. C., Rich, D. Q., Ferro, A. R. and Hopke, P. K.: Estimating Hourly Concentrations of PM_{2.5} across a Metropolitan Area Using Low-Cost Particle Monitors, *Sensors*, 17(8), 1922, doi:10.3390/s17081922, 2017.

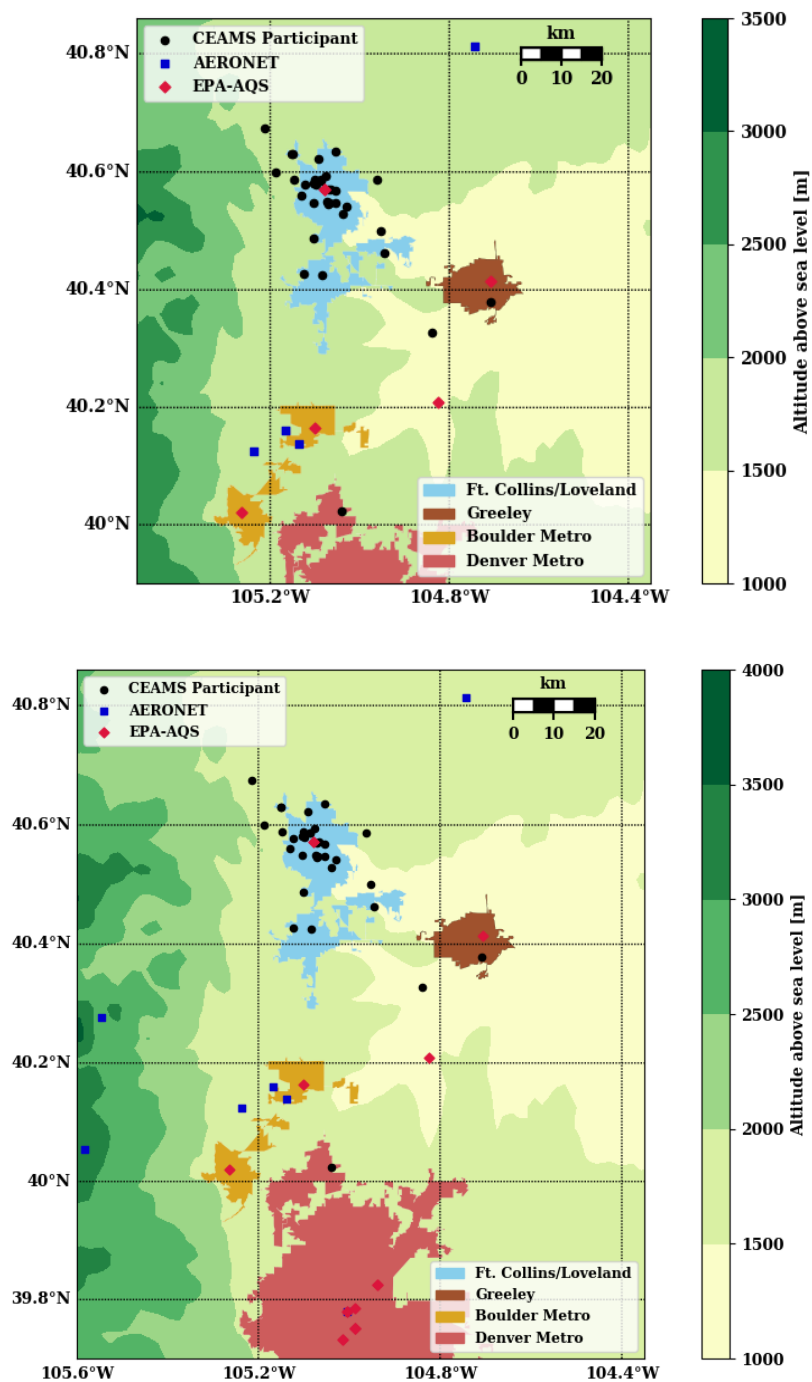

Figure 1. Map of northern Colorado with CEAMS participant locations (black), AERONET sites (blue), and EPA-AQS sites (red). Map also shows topography and major cities/metropolitan areas.

Figure 2. Distribution of 48-hour average filter mass concentrations collected by CEAMS participants during the pilot campaign in northern Colorado in fall and winter 2017 and 24-hour average PM_{2.5} concentrations measured at the EPA-AQS site in Fort Collins, CO for 28 October - 15 December 2017.

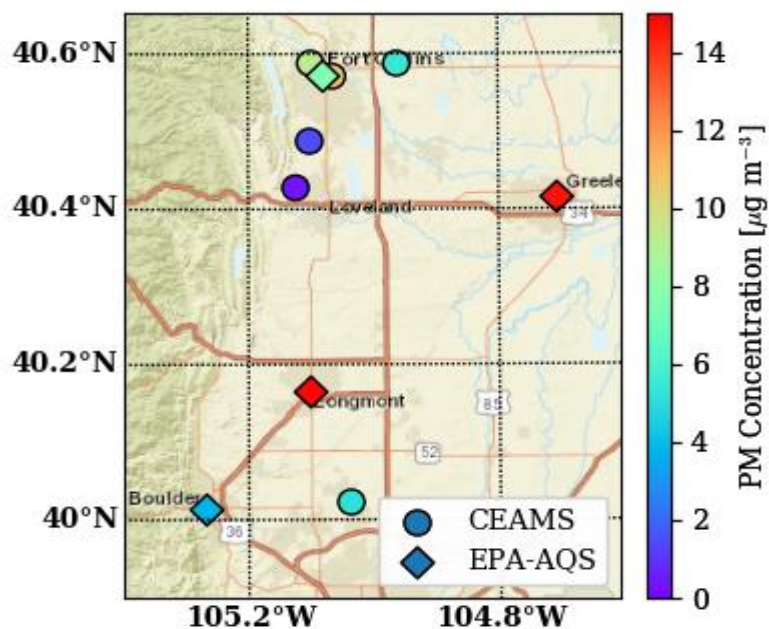

Figure 3. Average PM_{2.5} concentration measured by CEAMS participants (48-hour average) and at AQS monitoring sites (24-hour average) in northern Colorado for 13 November 2017.

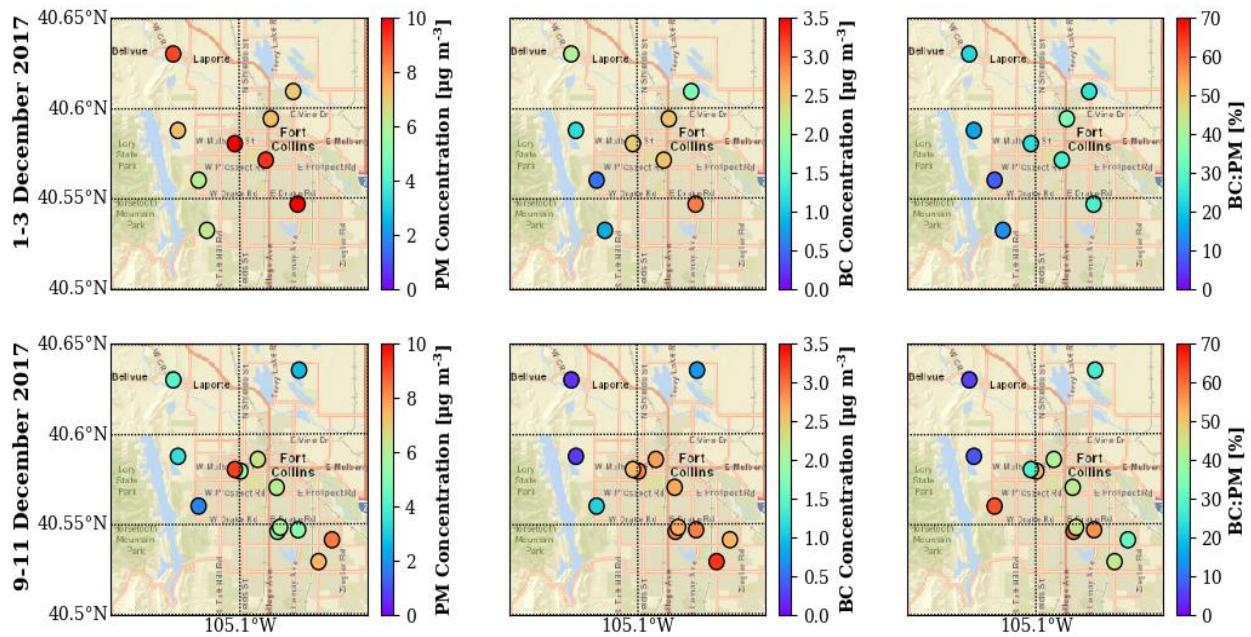

Figure 4. Map of the 48-hour average $PM_{2.5}$ concentrations, black carbon concentrations, and the percent of $PM_{2.5}$ that is black carbon measured in Fort Collins for 1-3 December 2017 (top row) and 9-11 December 2017 (bottom row).

Figure 5. Box and whisker plots showing the distribution of AERONET AOD at 440 nm (870 nm comparison Figure S3) at all sites in northern Colorado (listed in Supplementary Table S1, not all sites have values for every day) for each day from 28 October - 15 December 2017. Box denotes first and third quartile; whiskers denote maximum and minimum; and orange line shows median. CEAMS AOD at 440 nm are overlaid as black dots.

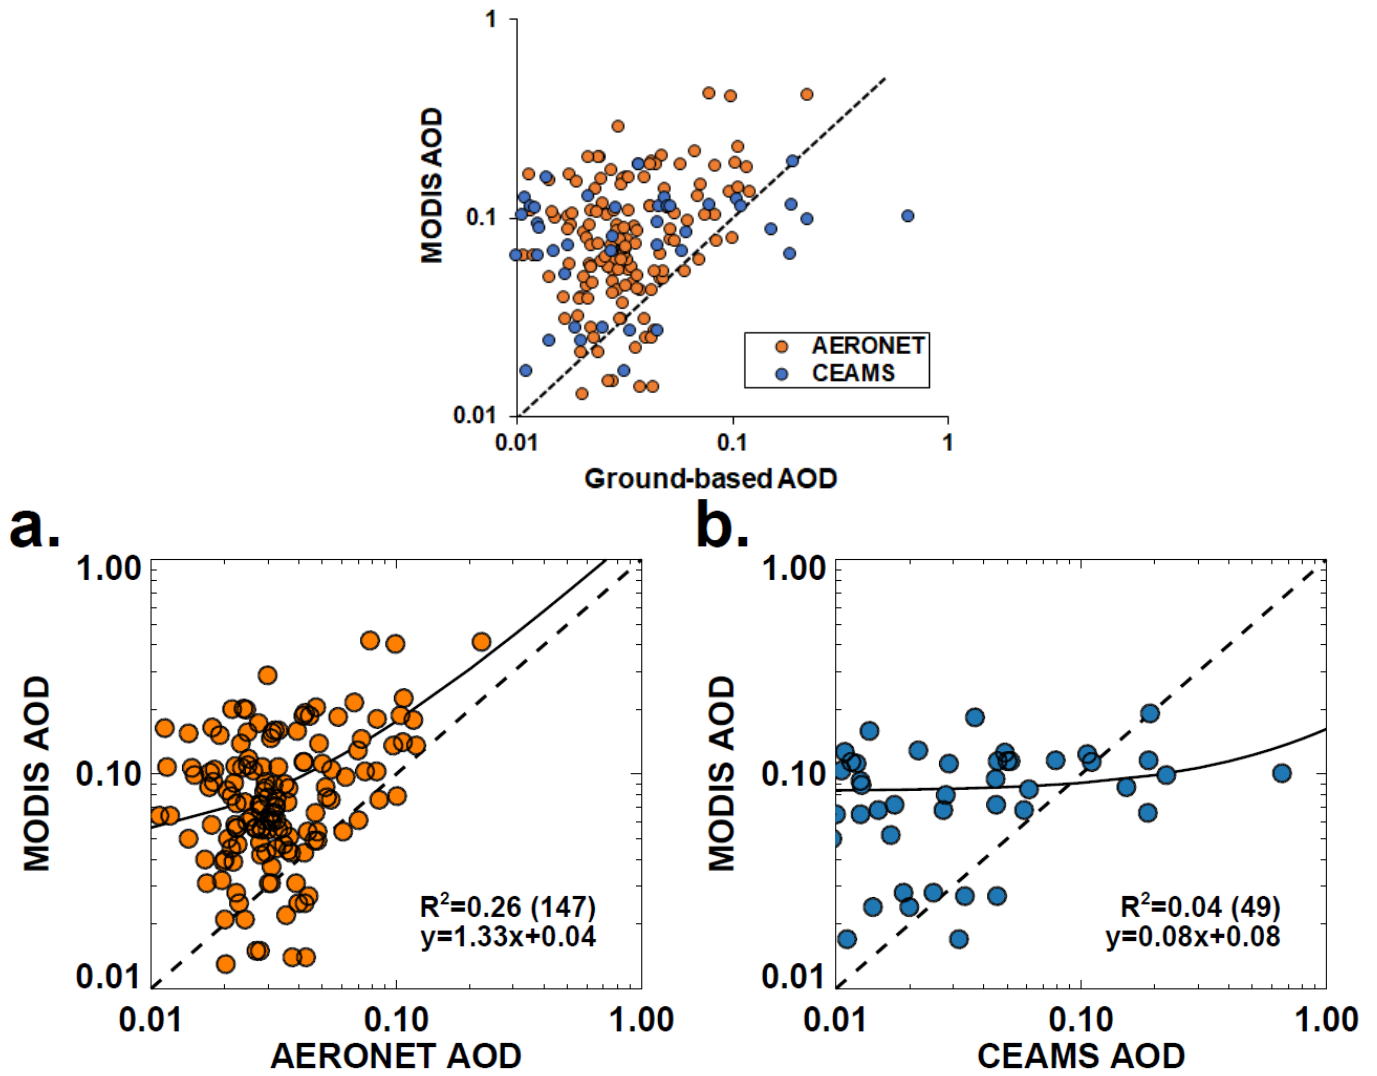

Figure 6. Satellite AOD (MODIS at 550 nm) compared to ground-based AOD in northern Colorado measured at a.) AERONET sites (500nm, specific sites used listed in Table S1, n=94) and b.) CEAMS participant sites (CEAMS at (520 nm, n= 49) and AERONET at 500 nm [specific sites used listed in Table S1, n=94]) measurements compared to measurements for 28 October - 15 December 2017 for northern Colorado. Dashed lines are 1-to-1, and the solid lines are linear fits (equations provided in figure).-

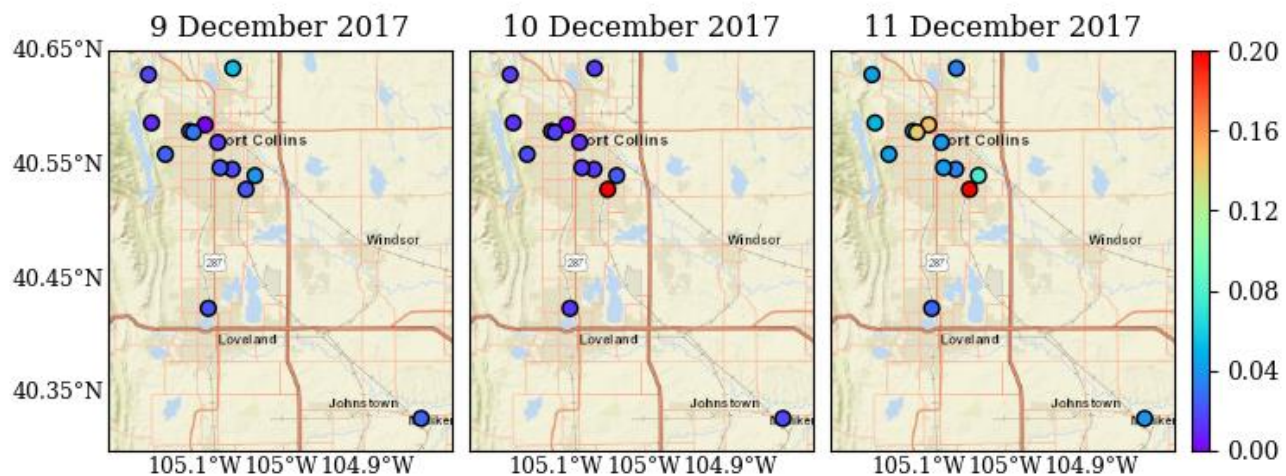

Figure 7. Map of the 440 nm AOD measurements for 9-11 December 2017.

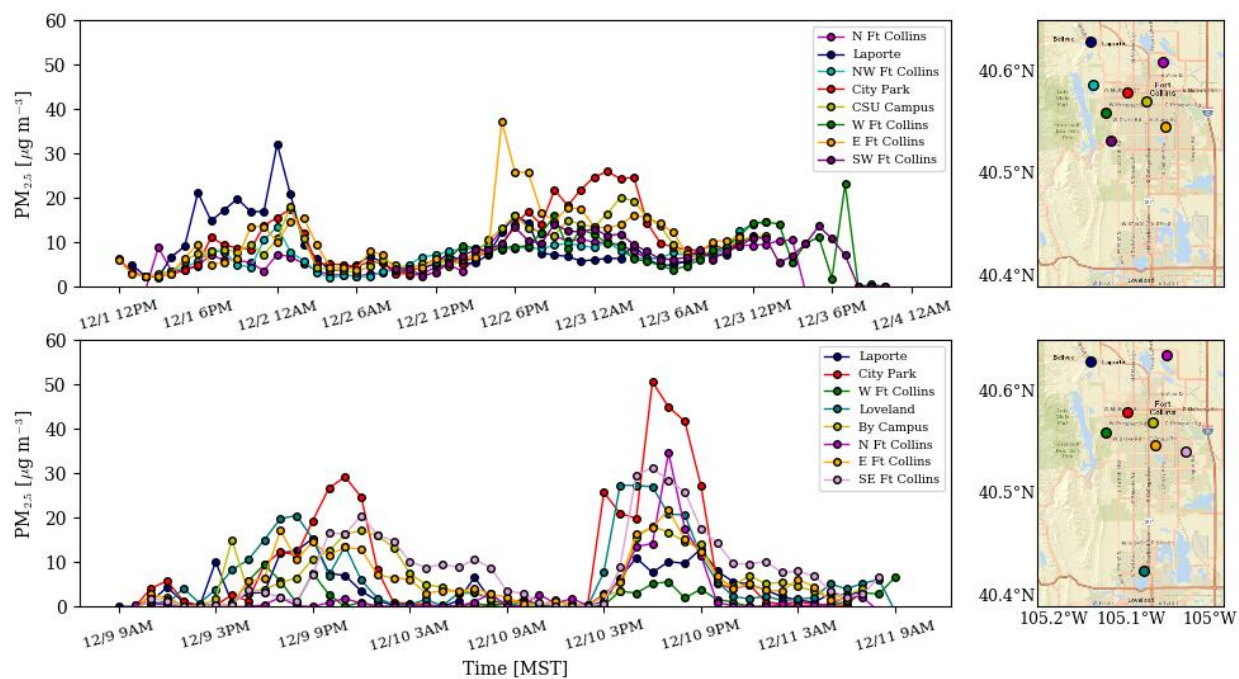

Figure 8. Time series of filter-corrected hourly-averaged $PM_{2.5}$ concentrations from the Plantower PMS5003 sensor inside the AMOD for 1-3 December (top row) and 9-11 December (bottom row) sampling periods. Maps show sampling locations for each sampling period (uncorrected time series shown in Figure S85).

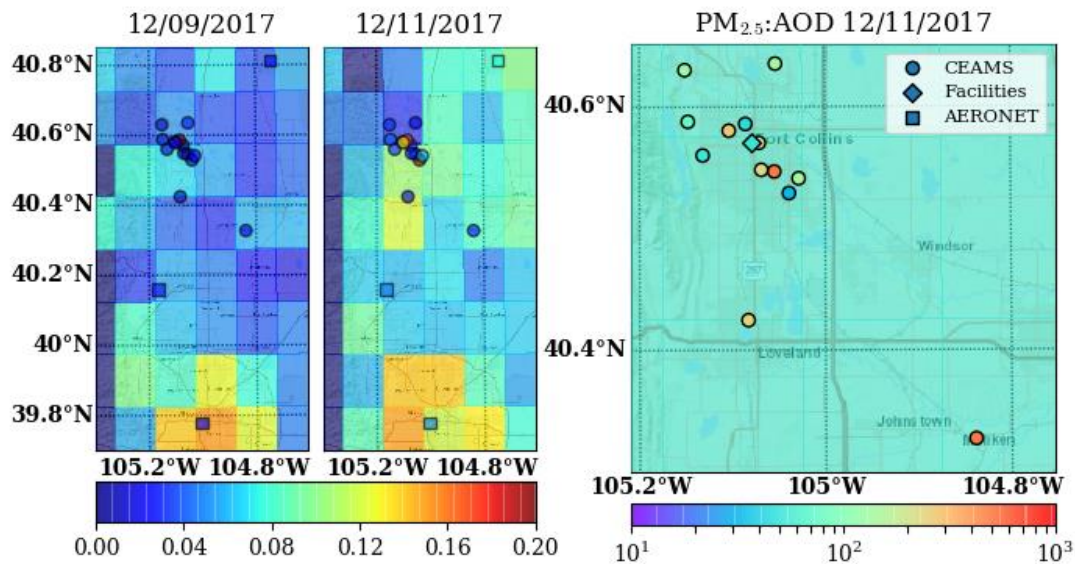

Figure 9. MODIS AOD overlaid with CEAMS (circles) and AERONET (boxes) AOD for 9 and 11 December 2017 in northern Colorado (left) and PM_{2.5} to AOD ratio (described in text) from CEAMS for 11 December 2017 (right, note different spatial scale). In the right panel, the background color represents the value that would be assumed for the whole region if relying only on the single EPA-AQS monitoring site located at the CSU Facilities.

Supplement for “A low-cost monitor for measurement of fine particulate matter and aerosol optical depth. Part 2: Citizen science pilot campaign in northern Colorado” by Ford et al.

Table S1. List of AERONET sites used for comparison.

AERONET Site	Longitude	Latitude
Denver_LaCasa	-105.005°	39.7789°
DigitalGlobe_Cal	-105.137°	40.139°
NEON-CPER	-104.744238°	40.812444°
NEON_CVALLA	-105.16725°	40.16063°
NEON_NIWO	-105.582°	40.054°
NEON_RMNP	-105.545972°	40.2759°
Table_Mountain	-105.237°	40.125°

Figure S1. Diagram of sampling event measurements. A sampling event lasts 48 hours and 15 minutes. Filter Measurements are continuous (pumps run continuously, filters collect mass during entire sampling event), providing an integrated measurement of $PM_{2.5}$. For AOD, the first value is from a single measurement at the start time, and the two subsequent are selected from a 30-minute window centered on the 24-hour and 28-hour mark after the start time of the sampling event. For devices with a Plantower PMS5003, measurements are taken every 30 seconds during the sampling event, providing a time-resolved measurement of $PM_{2.5}$.

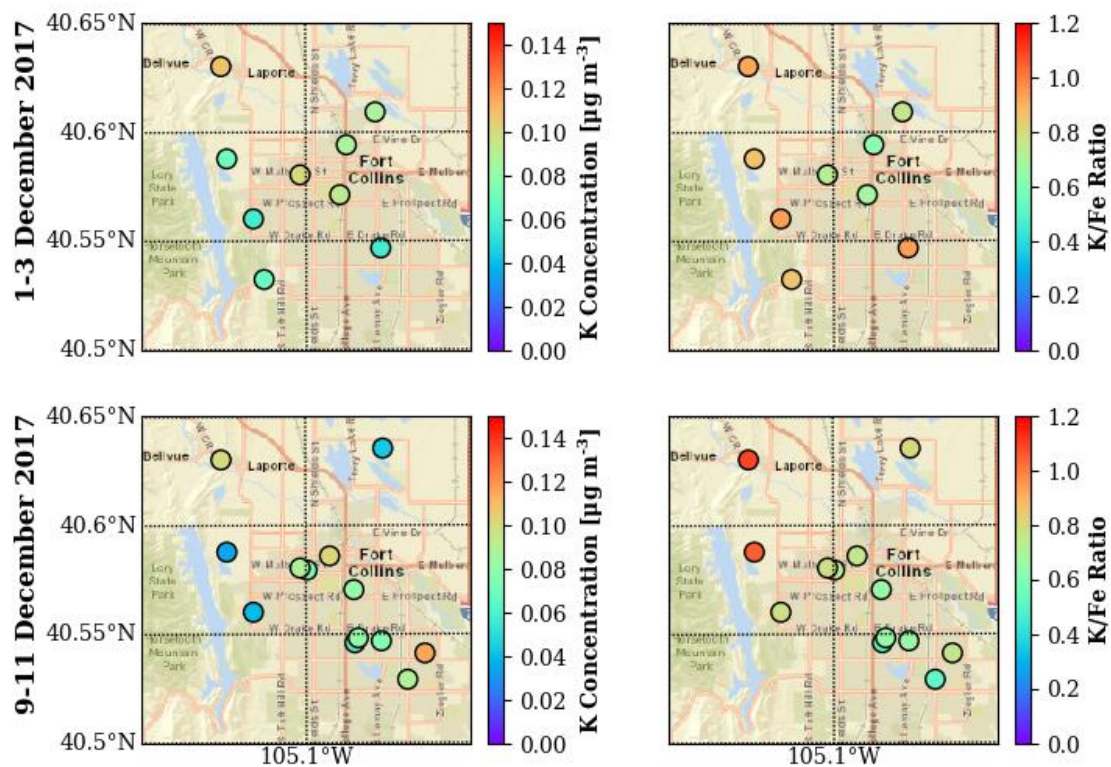

Figure S4S2. Potassium (K) concentrations and ratios of potassium to iron (K/Fe) measured in Fort Collins for 1-3 December 2017 (top row) and 9-11 December 2017 (bottom row).

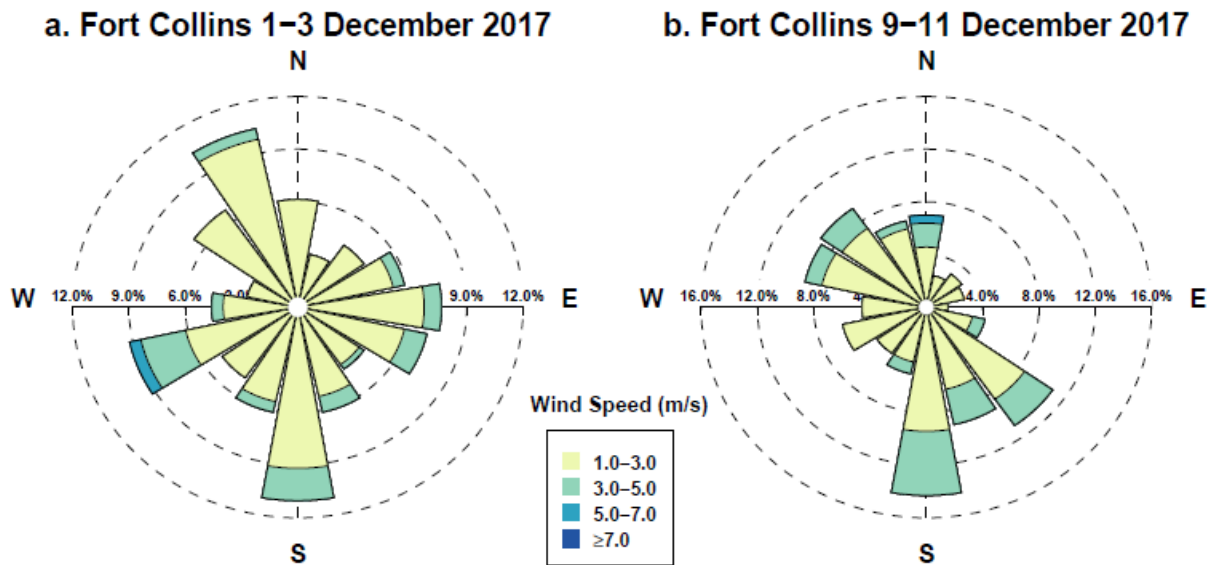

Figure S2S3. Wind rose diagrams for the two sampling periods mentioned in the main text. Measurements were taken at the Fort Collins weather station located on the Colorado State University campus (note the different scales on the panels).

Figure S4. Box and whisker plots showing the distribution of daily average $PM_{2.5}$ concentrations by day of week at two monitoring sites in northern Colorado (Fort Collins, CO monitoring site 08-069-0009 and Greeley, CO monitoring site 08-123-0006) for 1 October – 31 December 2017.

Figure S5. The calculated mass concentration of each elemental species determined by XRF for each filter.

Figure S6. Box and whisker plots showing the distribution of AERONET AOD at 870 nm at all sites in northern Colorado (listed in Supplementary Table S1, not all sites have values for every day) for each day from 28 October - 15 December 2017. Box denotes first and third quartile; whiskers denote maximum and minimum; and orange line shows median. CEAMS AOD at 870 nm are overlaid as black dots.

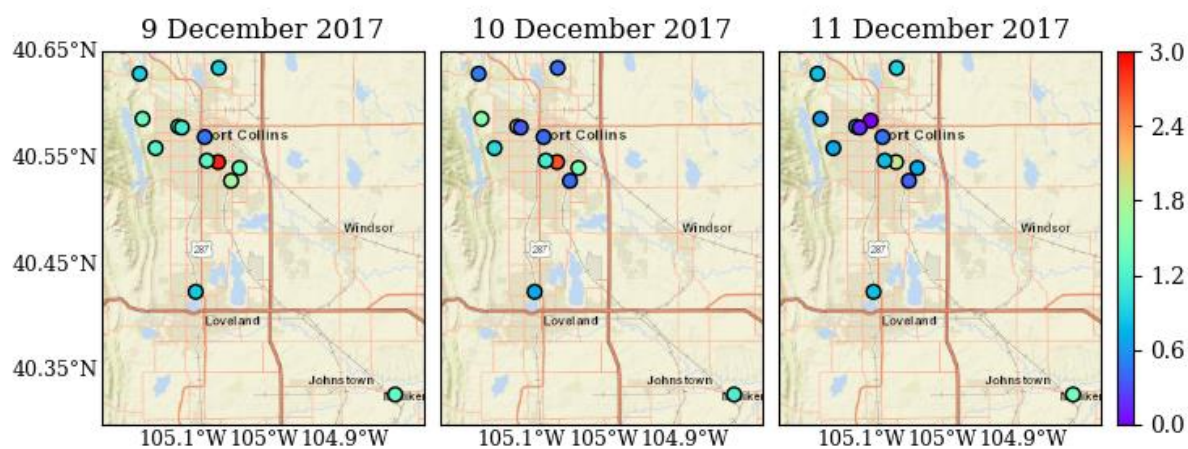

Figure S4S7. Map of the Ångström exponent values (calculated from the 870 and 440 nm wavelengths) for 9-11 December 2017.

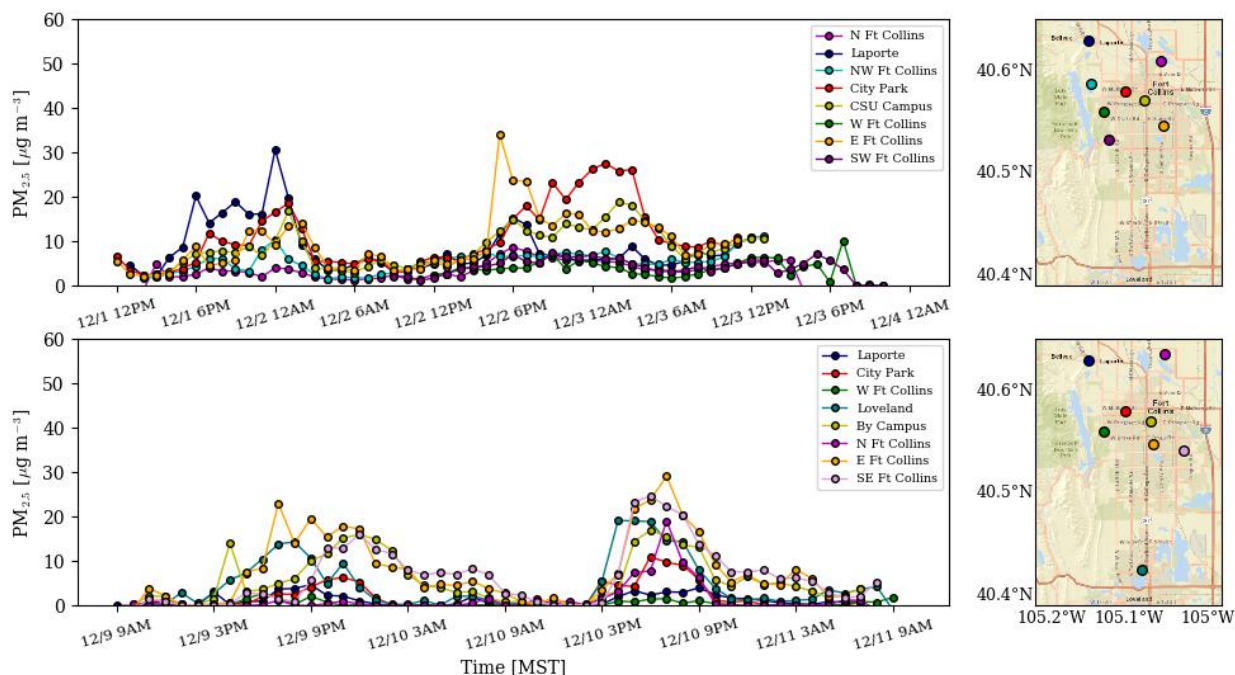

Figure S5S8. Time series of uncorrected hourly-averaged PM_{2.5} concentrations from the Plantower PMS5003 sensor inside the AMOD for 1-3 December (top row) and 9-11 December (bottom row) sampling periods. Maps show sampling locations for each sampling period.

Figure S6. Distribution of the $PM_{2.5}$ to AOD ratios calculated from CEAMS 520-nm AOD and CEAMS filter $PM_{2.5}$ concentrations (gray) and the EPA AQS site $PM_{2.5}$ in Fort Collins and the MODIS 550-nm AOD for 28 October–15 December 2017.

Figure S7S9. Comparison of η calculated using the AOD measurement and the 48-hr concentration from the filter (η_{48-hr}) and the 1-hr average concentration from the Plantower PMS5003.

Figure S10. Distribution of the PM_{2.5} to AOD ratios calculated from CEAMS 520-nm AOD and CEAMS filter PM_{2.5} concentrations (orange) and the EPA-AQS site PM_{2.5} in Fort Collins and the MODIS 550-nm AOD (gray) for 28 October - 15 December 2017.
