10 **Abstract.** A closed-path quantum cascade tunable infrared laser direct absorption spectrometer (QC-TILDAS) was outfitted
with an inertial inlet for filter-less separation of particles, a custom-designed aircraft inlet, a custom-built vibration isolation
mounting plate, and a custom-built system for optionally adding active continuous passivation for gas-phase measurements
of ammonia (NH₃) from a research aircraft. The flight-ready instrument was then deployed on the NSF/NCAR C-130 aircraft
15 during research flights and test flights associated with the Western wildfire Experiment for Cloud chemistry, Aerosol
absorption and Nitrogen (WE-CAN) field campaign. The flight-ready instrument was configured to measure large, rapid
gradients in gas-phase NH₃, over a range of altitudes, in smoke (e.g., ash and particles), in the boundary layer (e.g., during
turbulence and turns), in clouds, and in a hot aircraft cabin. Important design goals were to minimize motion sensitivity,
maintain a reasonable detection limit, and minimize NH₃ “stickiness” on sampling surfaces to maintain fast time response in
20 flight. The observations indicate that addition of a high frequency vibration to the laser objective in the QC-TILDAS and
mounting the QC-TILDAS on a custom-designed vibration isolation plate were successful in minimizing motion sensitivity
of the instrument during flight. Allan variance analyses indicate that the in-flight precision of the flight-ready instrument is
60 ppt at 1 Hz corresponding to a 3σ detection limit of 180 ppt. The option for active continuous passivation of the sample
flow path with 1H,1H-perfluorooctylamine, a strong perfluorinated base, prevented adsorption of both water and basic
species to instrument sampling surfaces. Characterization of the time response in flight and on the ground showed that
25 adding passivant to a “clean” instrument system had little impact on the time response. In contrast, passivant addition greatly
improved the time response when sampling surfaces became contaminated prior to a test flight. The observations further
show that passivant addition can be a useful tool for maintaining a rapid response for *in-situ* NH₃ measurements over the
duration of an airborne field campaign (e.g., ~2 months for WE-CAN test and research flights) since passivant addition also
helps to prevent future build-up of water and basic species on instrument sampling surfaces. Therefore, we recommend the
30 use of active continuous passivation with closed-path NH₃ instruments when rapid (> 1 Hz) collection of NH₃ is important
for the scientific objective of a field campaign (e.g., measuring fluxes, sampling from aircraft or another mobile research
platform). Passivant addition can be useful for maintaining optimum operation and data collection in NH₃-rich/humid
environments or when contamination of sampling surfaces is likely, yet frequent cleaning is not possible. Passivant addition
may not be necessary for fast operation, even in polluted environments, if sampling surfaces can be cleaned when the time
35 response has degraded.

1 Introduction

Ammonia (NH₃) is the dominant alkaline gas in the atmosphere and plays an important role in many atmospheric processes. Major sources of atmospheric NH₃ include agricultural activities (e.g., application of fertilizer and volatilization from animal wastes) (e.g., (Galloway et al., 2003; Pinder et al., 2007; Reis et al., 2009; Erisman et al., 2008; Balasubramanian et al.,

2015; Leen et al., 2013), light duty gasoline vehicles equipped with three-way catalytic converters (e.g., (Kean et al., 2009; Burgard et al., 2006), biomass burning (e.g., (Hegg et al., 1988; Bray et al., 2018), water and sewage treatment plants, and some industrial production activities (e.g., chemical production plants (Zhu et al., 2015)). Atmospheric reactions of NH_3 with acids formed from the oxidation of sulfur dioxide (SO_2) and nitrogen oxides ($\text{NO}_x = \text{NO} + \text{NO}_2$) can lead to formation of fine particulate matter (Behera and Sharma, 2010; Fenn et al., 2003), which has strong implications for human health, regional air quality, atmospheric visibility, radiative forcing, and nitrogen deposition in sensitive ecosystems (Pope, 2002; Zhu et al., 2015; Erisman et al., 2008; Asman et al., 1998; Krupa, 2003; IPCC, 2007).

Anthropogenic NH_3 emissions are becoming increasingly important to study due to intensification of agricultural activities and animal husbandry (e.g., concentrated animal feeding operations) (Galloway et al., 2008), yet NH_3 remains an unregulated pollutant (Gilliland et al., 2008). Having instruments that can collect high-sensitivity, fast-response *in-situ* measurements of NH_3 are essential for directly measuring NH_3 emissions fluxes (e.g., from animal husbandry, agricultural fertilization) and eddy covariance fluxes (e.g., associated with deposition/evaporation processes), characterizing concentrations and emissions rates in plumes (e.g., from urban areas with emissions dominated by traffic, concentrated animal feeding operations, and wildfires), and sampling from mobile platforms (e.g., instrumented aircraft and ground-based vehicles). There are several techniques and types of instruments that can be used for rapid measurements of atmospheric NH_3 , including mass spectrometric methods (e.g., (Nowak et al., 2007)) and optical methods based upon open path absorption (e.g., (Miller et al., 2014; Ni et al., 2015)), closed path absorption (e.g., (Griffith and Galle, 2000; Ellis et al., 2010; Leen et al., 2013; Martin et al., 2016; Leifer et al., 2017)), and photoacoustic spectroscopy (e.g., (Schmohl et al., 2002; Pushkarsky, et al., 2002; Pogány et al., 2009)). The mass spectrometric method has been effectively leveraged aboard research aircraft (Nowak et al., 2007; Nowak et al., 2010), and the compact footprint associated with the photoacoustic approaches are useful for many applications. Open and closed path direct absorption approaches are highly applicable to the NH_3 concentration ranges expected during ambient monitoring. Open-path instruments typically have lower power consumption, higher data collection rates, and no time delays or sampling surface interactions due to inlet tubing (e.g. (Miller et al., 2014)). Closed-path systems afford the advantage of minimal data loss when sampling in potentially high particle/aerosol conditions such as in dust, smoke, precipitation/icing, and salt deposition events (e.g., (Sun et al., 2015; Leen et al., 2013)), and allow for more control over environmental influences (e.g., temperature, pressure, and water vapor). They are also able to be directly zeroed and calibrated during operation. However, closed path systems typically rely on inlet tubing to supply ambient air to the detector, and thus the effects of inlet tubing length (and inlet complexity, especially when deployed aboard airborne research platforms) on the instrument time response can be significant. To add to these existing challenges, NH_3 is notorious for being a “sticky” molecule. Its ability to readily adsorb and/or desorb from sampling surfaces makes it a difficult gas-phase species for which to measure large, rapid changes and it is a particularly difficult measurement for which to determine accurate *in-situ* background, or zero, levels. Recent laboratory studies showed dramatic improvements in NH_3 transmission through a commercially-available, closed-path spectrometer, and thus dramatic improvements in measurement time response, when the instrument’s sampling surfaces were actively and continuously passivated with a strong perfluorinated base (e.g., 1H,1H-perfluorooctylamine) (Roscioli et al., 2016). The passivant coating works by extending a nonpolar chemical group into the sample flow path that prevents the adsorption of both water and basic species to the sampling surfaces, yet the passivant chemical does not interfere with NH_3 detection due to the highly-specific nature of detection.

Here we describe the first opportunities to evaluate and carefully characterize the effects of adding passivant to an optical absorption based, closed-path gas-phase NH_3 monitoring system aboard a research aircraft. We note that although this is not the first aircraft deployment of an optical-based NH_3 monitor (Leen et al., 2013; Hacker et al., 2016; Schiferl et al., 2016; Miller et al., 2015; Leifer et al., 2017), this is the first opportunity to evaluate the effects and the value of adding a passivant to the sample stream of an optical-based instrument for airborne measurement applications. We start by characterizing the performance of the non-passivated instrument aboard a research aircraft in flight (e.g., precision, detection limit, motion sensitivity, and stability over time) with respect to fluctuations in cabin pressure, cabin temperature, and changes in altitude. We then evaluate the instrument time response with and without active continuous passivation under a variety of operating conditions. We report several different methods for zeroing the instrument, and offer recommendations for each method based on the sampling environment. Lastly, we provide recommendations for using active passivation for atmospheric

measurements of NH_3 with optical-based, closed-path instrumentation in a variety of field measurement scenarios and environmental conditions.

2 Methods

2.1 Airborne sampling

5 Airborne measurements were collected aboard the NSF/NCAR C-130 research aircraft during the Western wildfire
Experiment for Cloud chemistry, Aerosol absorption and Nitrogen (WE-CAN) field campaign in summer 2018 and during
16 test-flight hours prior to the WE-CAN deployment. The aircraft conducted seventeen research flights of roughly 6-8 hour
10 duration between 20 July and 31 August in 2018, three test flights of 2-3 hour duration between 21 September and 29
September in 2017, and two test flights on 13 July and 17 July in 2018. Research flights were conducted in the northwestern
U.S. with aircraft operations based out of Boise, Idaho; test flights were conducted in the northeastern Colorado Front Range
based out of the National Center for Atmospheric Research (NCAR) Research Aviation Facility in Broomfield, Colorado.
The 2018 test and research flights were conducted under average ambient temperature and humidity conditions expected for
summer in Idaho and Colorado; 2017 test flights were performed under lower than average ambient temperature (e.g.,
15 average ambient temperature was 12 °C) and higher than average relative humidity (e.g., the average relative humidity was
>70%) conditions for Colorado. WE-CAN research flights provided a number of opportunities to evaluate multiple aspects
of the NH_3 instrument in flight and within concentrated smoke plumes. Several missed approaches performed at Greeley-
Weld County Airport during the test flight period provided several opportunities to characterize the instrument's time
response with and without passivant under a variety of instrument operating conditions. Aircraft maneuvers were performed
during several of the test flights and are used here to assess instrument precision, detection limit, and motion sensitivity in
20 flight. Changes in instrument zero signal level with cabin pressure, cabin temperature and changes in altitude were
extensively tested during the test flights by overflowing the inlet tip with NH_3 -free air for large periods of the flight. The
aircraft also often sampled ambient air in the free troposphere during the test flights and when in transit to wildfires during
the 2018 deployment; these measurements are used for evaluating different methods for zeroing the instrument, ambient NH_3
levels in the free troposphere, and the instrument detection limit.

25 2.2 Instrumentation

The flight-ready, closed-path, optical-based NH_3 monitoring system described here consists of a combination of
commercially-available and custom-built components including: 1) a commercially-available infrared absorption
spectrometer that serves as the heart of the NH_3 monitor, 2) a commercially-available inertial inlet that acts as a filter-less
separator of particles from the sample stream, 3) a custom-built aircraft inlet, 4) a custom-designed vibration isolation
30 mounting system for the spectrometer, and 5) a custom-built optional system for adding passivant to the sample stream.

2.2.1 NH_3 detection

The NH_3 detector used for these experiments is a compact, single-channel, closed-path, quantum-cascade tunable infrared
laser direct absorption spectrometer (QC-TILDAS), model TILDAS-CS, that is commercially available from Aerodyne
Research Inc. The QC-TILDAS has been described in detail in the literature (McManus et al., 1995; McManus et al., 2007;
35 McManus et al., 2010; Zahniser et al., 1995). Briefly, a high sample flow rate (e.g., >10 standard liters per minute, SLPM,
with standard conditions defined as 760 Torr and 0°C) is drawn through a 76-m multipass absorption cell into which the
output of a single-mode quantum cascade laser is coupled. The optical output of the laser is swept across an NH_3 absorption
feature located at 967.34634 cm^{-1} . This strong rotational-vibrational (ro-vibrational) absorption feature is within the Q-
branch of the ν_2 band of NH_3 . The instrumental linewidth is typically 0.012 cm^{-1} (360 MHz) FWHM, and is largely defined
40 by the operating pressure of the absorption cell, which was held constant at 40 Torr for these experiments. The laser is
scanned across 0.315 cm^{-1} , and the resulting absorption features are detected on fast mercury cadmium telluride (MCT)
detector (Vigo System). The pressure- and doppler-broadened spectral peaks are fit using a Voigt lineshape model. The QC-

TILDAS detector is capable of up to 10 Hz collection of absolute NH_3 concentrations. NH_3 mixing ratios were typically collected at 10 Hz, and subsequently averaged to 1-Hz for WE-CAN research flights and for selected analyses described below.

5 Figure 1a is a schematic of the NH_3 monitoring system as it was configured for use on the NSF/NCAR C-130 aircraft. With WE-CAN objectives in mind, the instrument was configured to measure NH_3 over a range of altitudes, in smoke (e.g., large and rapid gradients in NH_3 and in ash and particle-rich air), while systematically following a smoke plume in the mixed boundary layer (e.g., in turbulence with frequent turns), and during summer near Boise, ID (e.g., large, rapid gradients in cabin temperature and average temperatures often exceeding 30 °C). In ground-based field studies and laboratory
10 experiments, the optical bench of the QC-TILDAS is ideally operated between 20 and 25°C for maximum stability of the laser power, optical alignment, and spectroscopic absorption signal. In anticipation of cabin temperatures exceeding 30°C, the set point for the QC-TILDAS optical bench temperature was intentionally set to the upper end of this range at 25°C.

Further, the instrument flow path was purged with ultrahigh purity (UHP) N_2 overnight and when there was no power or
15 access to the aircraft in order to keep the sampling surfaces as clean as possible. Previous experiments (Nowak et al., 2007) found that the rise/decay characteristics of NH_3 instruments operated during aircraft missions (e.g., running for several hours, sitting idle overnight, and running again the next day) were only reproducible when a flow of clean, dry N_2 was used to purge the inlet during periods of instrument inactivity. Therefore, anytime the instrument is powered off, a purge flow of 40 standard centimetres per minute (sccm) of UHP N_2 is introduced just upstream of the pressure control valve to flush the
20 instrument in the reverse direction of the sample flow path, as indicated in Fig. 1a. We found that the instrument could reach a stable zero signal level more quickly when it had been purged overnight compared to times when the instrument sat idle without purge flow. The instrument response time could also be maintained for a longer operational time period (e.g. weeks to months) between cleanings when the instrument flow path was purged between uses.

25 2.2.2 Inertial Inlet

The QC-TILDAS detector is typically operated with a heated inertial inlet positioned upstream of the spectrometer to provide filter-less separation of particles >300 nm from the sample stream, as shown in Fig. 1a. Coupling an inertial inlet
30 with a QC-TILDAS has been well established following several laboratory and ground-based field experiments (Ellis et al., 2010; Ferrara et al., 2012; Tevlin et al., 2017; von Bobruzki et al., 2010; Zöll et al., 2016).

2.2.3 Aircraft Inlet

A heated aircraft inlet constructed of perfluoroalkoxy fluoropolymer (PFA) allows for maximum transmission of NH_3 from the inlet tip to the detector, as shown in Fig. 1a. Inlet components are housed inside a 36 cm long stainless steel strut that extends beyond the boundary layer of the aircraft, and consists of: 1) an inlet tip made of 6 cm long 3/8" o.d. PFA tubing, 2)
35 a machined PFA block serving as an injection manifold for calibration and passivation gases, and 3) a 107 cm length of 3/8" o.d. PFA tubing leading down the length of the strut and to the inertial inlet mounted in an equipment rack inside the aircraft cabin. The inlet tip is designed to be mounted with a standard stainless steel, bored-through compression fittings from the inside of the strut to minimize protrusions from the inlet end cap and to maintain the inlet tip at 35°C in flight to prevent it from freezing. The tip of the PFA inlet tubing was cut with a slight rear-facing bias from the direction of flight and extended
40 only ~6 mm from the face of the inlet end cap to minimize particle ingestion and disruption of the boundary layer near the inlet tip. The PFA injection block located just inside the inlet strut end cap has outer dimensions of 8.3 cm long x 3.6 cm wide x 1.5 cm thick and a 6-cm long 1/4" i.d. inner sample channel to match the i.d. of the tubing used for the inlet tip and sample line. Aircraft inlets of similar design and construction were used during the 2014 Front Range Air Pollution Experiment (FRAPPE) aboard the C-130 aircraft and during the 2017 Utah Winter Fine Particulate Study aboard the NOAA
45 Twin Otter. Another 36 cm long segment of 3/8" o.d. PFA tubing then brings sample flow from the inertial inlet to the QC-TILDAS spectrometer, which is co-located in the same equipment rack in the aircraft. As shown in previous studies, PFA tubing and fittings are used wherever possible along the sample pathway, and tubing lengths are kept to a minimum and heated wherever possible (Neuman et al, 1999; Schmohl et al., 2001; Mukhtar et al., 2003; Leifer et al., 2017). Components

housed within the aircraft inlet strut are heated to 40°C. The tubing between the inlet strut and the inertial inlet and between the inertial inlet and the QC-TILDAS are not actively heated; however, they are wrapped in flame-resistant polymer felt (DuPont Nomex) for thermal isolation. Although several reports specifically highlight the benefits of heated inlet components for measurements of NH₃ (Ellis et al., 2010; Nowak et al., 2007; Tevlin et al., 2017), these sections of tubing were left unheated in order to reduce the instrument's power load on the aircraft and because the residence time in these segments of tubing is short (e.g., <0.15 s due to the high sample flow rate and low pressure) and aircraft cabin temperatures were anticipated to exceed 30°C in flight.

2.2.4 Vibration isolation system

To reduce motion sensitivity in-flight, the QC-TILDAS detector was mounted on a custom-designed, vibrationally-isolated plate (e.g., Fig. 1b) before being mounted in the aircraft equipment rack as shown in Fig. 1c. The mounting plate consisted of eight total vertically mounted wire rope vibration isolators (Enidine) that allow the spectrometer enclosure (containing the optical cell, laser, MCT detector, and optical bench) to float in all three dimensions and remain isolated from direct contact with the aircraft equipment rack. Two isolators (Enidine, WR3 series) were mounted along the inner face of each of the fore-aft facing legs of the mounting plate frame and spaced 13 cm apart; two additional isolators (Enidine, WR4 series) were positioned on top of the outboard and inboard legs of the mounting plate frame base and spaced 22.5 cm apart. The QC-TILDAS is then affixed to the mounting frame via the isolators as indicated in Fig. 1b and 1c. The advantage of this “springed” mounting plate is that it mitigates the effects of high frequency vibrations endemic to the aircraft, which can result in acoustic noise in the instrument, uncontrolled vibration of the optical bench, and general misalignment of the optics. In addition, it relieves strain on the instrument chassis when the frame of the aircraft equipment rack flexes during aircraft maneuvers. Hard stops were added to the mounting plate frame to satisfy aircraft crash loads in the forward and aft directions. Hardware was selected based on structural analysis calculations including finite element analysis given the vibrations and the loads expected aboard the NSF/NCAR C-130 aircraft. The mounting plate is similar in design to previous vibration isolation apparatuses used on research aircraft with Quantum Cascade Laser Systems (QCLS) (B. Daube, Personal Communication, 2017); although, this specific mounting system was unique to the NH₃ instrument deployed during the 2017 and 2018 WE-CAN flights. Additionally, the laser objective, an optic that guides the laser beam into the optical cavity, is vibrated at a high-frequency (~200 Hz) to wash out etalon fringe motion induced by aircraft accelerations. The frequency and amplitude of the vibrations applied to the laser objective can be adjusted to accommodate a variety of moving platforms. Several months prior to installation on the C-130 aircraft, a cabled tilting system (located at Aerodyne in Billerica, MA) was used to simulate the effects of in-flight forces on the QC-TILDAS detector as it was mounted to the vibration isolation plate within the aircraft equipment rack. Additional tests were performed on the hangar floor in Broomfield, CO immediately before installation of the instrument aboard the aircraft by manually tipping and shaking the equipment rack. The “tilt and shake” tests performed in both locations were conducted with the instrument powered on and operating under “zero” measure conditions by overblowing the sample inlet port with NH₃-free air. The center frequency and frequency sweep of the piezoelectric stack mounted on the laser collection objective as well as the general optical alignment within the enclosure were optimized during these tests. From these tests, we additionally learned that external forces acting on the inlet and outlet tubing associated with the sample stream were putting strain on the optical bench and resulting in notable deviations from zero in the NH₃ absorption signal. Therefore, the strain relief of the sample stream inlet and outlet ports to the QC-TILDAS enclosure was reinforced prior to installation on the aircraft.

2.2.5 Passivant addition system

Owing to the “stickiness” of NH₃, the QC-TILDAS and inlet sampling surfaces can be compromised when they are coated with as little as a single monolayer of adsorptive matter; the build-up can cause the instrument's time response to gradually become slower (Roscioli et al., 2016). Although sampling surfaces can be periodically refreshed by cleaning them with solvents, frequent cleaning may not always be possible or practical during field intensives. One solution, recommended by Roscioli et al. (2016), is to actively and continuously passivate the instrument sampling surfaces with a chemical coating that prevents adsorption of water and basic species. Therefore, we designed and deployed a non-commercial system that allowed for the option of passivant addition to the sample stream to this NH₃ instrument system. This work reports the first-time

application of adding passivant to a closed-path, optical-based NH_3 instrument aboard a research aircraft, and serves as an evaluation of the flight-ready instrument's time response on the ground and in-flight under a variety of conditions and with and without passivant.

5 For these tests, the flight instrument is outfitted with an option for adding 1H,1H-perfluorooctylamine ($\text{C}_8\text{H}_4\text{F}_{15}\text{N}$, CAS
Number: 307-29-9) vapor to the sample stream using a similar apparatus as that used in laboratory experiments by Roscioli
et al. (2016). 1H,1H-perfluorooctylamine (purchased from Synquest Laboratories and used without further purification) is a
liquid at room temperature and pressure (e.g., 20°C and 760 Torr). Vapors of the passivant are entrained in a 200 sccm flow
10 of UHP N_2 regulated with a mass flow controller (Alicat) and introduced to the sample flow path as close to the inlet tip as
possible. Given the configuration for WE-CAN, this means that the C8 passivant is injected roughly 10 cm downstream of
the aircraft inlet tip via the middle port of the PFA injection block as shown in Fig. 1a. The liquid passivant is contained in a
PFA impinger (Saville), and a pair of stainless steel quick connects (Swagelok) are used to connect the impinger inline
between the mass flow controller and the injection port (e.g., Fig 1d). N_2 carrier gas was intentionally not bubbled through
the liquid to avoid splattering the liquid onto the impinger walls and/or lodging droplets of passivant in the delivery tubing.
15 When disconnected, the quick connects isolate the supply of passivant from the flow path allowing it to be safely removed
from the aircraft overnight and for refilling. Tests without passivation could also be easily performed simply by
disconnecting the quick-connects from the impinger and re-connecting them to each other without the impinger in line.
Bypassing the impinger in this manner allows for constant dilution of the sample stream by a known amount of N_2 carrier
gas flow regardless of whether the passivant chemical is being added. For future applications, a set of solenoid valves can be
20 added to the impinger system for automated computer control of passivant addition or passivant bypass. For the laboratory
experiments and WE-CAN flights described here and with the passivant liquid held near room temperature (e.g., 25°C), the
typically usage rate of the C8 compound was ~ 5 grams in 20 hours.

A C7 version of the passivant chemical, 1H,1H-perfluoroheptylamine ($\text{C}_7\text{H}_4\text{F}_{13}\text{N}$, CAS Number: 423-49-4), was used in a
25 separate set of tests performed in the laboratory between the 2017 and 2018 flight period, and is discussed further in Sect.
4.3. Disadvantages of adding passivant to the sample stream for NH_3 measurements include the use of hazardous materials
and the cost of consumable chemicals. Both the C8 compound (1H,1H-perfluorooctylamine) and the C7 version (1H,1H-
perfluoroheptylamine) are strong corrosives, contain an amine group, and are highly fluorinated. While these chemicals pose
no immediate danger when properly handled, the long term exposure effects are unknown. In addition, these compounds
30 have been identified as potentially potent, long-lived greenhouse gases (Hong et al., 2013); although, we anticipate the
environmental impacts to be minor given the small quantities and low addition rates used for this application.

2.3 Calibration

The PFA injection block is configured such that calibration and passivation gases can be introduced to the sample flow path
within 6-12 cm of the inlet tip (e.g., Fig. 1a). The TILDAS is calibrated via standard addition to the sample stream with a
35 known concentration of NH_3 generated from a temperature-regulated ($40 \pm 0.1^\circ\text{C}$) permeation device filled with anhydrous
 NH_3 (Kin-Tek), and zeroed by overflowing the inlet tip with a source of NH_3 -free air. As described in detail in Ellis et al.
(2010), three-way switching solenoid valves and a vacuum manifold are used to actively flush zero and calibration gases
from the injection tubing when measuring ambient air. A continuous flow of UHP N_2 at 40 sccm was sufficient to transport
all of the NH_3 vapor emitted from the permeation device to the inlet tip. The stability of the permeation device was
40 maintained overnight when there was no power and access aboard the aircraft by removing it to a laboratory where it could
be kept heated and under a constant (40 sccm) flow of UHP N_2 . The emission rate of the permeation device was calibrated
before and after the test flight period using the NOAA ultraviolet optical absorption system (Neuman et al., 2003). The
average emission rate measured with the NOAA system before and after the WE-CAN deployment period was 407 ± 10 ng
 min^{-1} . The NOAA calibration has a reported uncertainty of $\pm 10\%$, which is mainly due to the uncertainty in the 185 nm
45 absorption cross section for NH_3 used for interpreting results from the optical absorption system (Neuman et al., 2003). For
this work, and in contrast to Neuman et al. (2003), we use an average cross section value of $4.69 \pm 0.03 \times 10^{-18} \text{ cm}^2$, which is
determined from more recent assessments of the NH_3 cross section by Froyd and Lovejoy (2012) ($4.67 \times 10^{-18} \text{ cm}^2$), Chen et
al. (1998) ($4.687 \times 10^{-18} \text{ cm}^2$) and Bing-Ming et al. (2006) ($4.72 \times 10^{-18} \text{ cm}^2$). Using this cross section, the uncertainty in the

NH₃ permeation tube calibration by the NOAA UV system is closer to ±7%. The permeation rate of the NH₃ permeation device was specifically selected for NH₃ concentrations expected while sampling concentrated plumes of wildfire smoke during WE-CAN (e.g., mixing ratios ≥ 50 ppbv). During flight, the instrument sample flow rate varies with altitude due to changes in ambient pressure upstream of the critical orifice inside the quartz inertial inlet. As a result, calibration concentrations range from 50 ppbv at 620 Torr (e.g., on the ground in Broomfield, CO at 1.729 m AMSL (above mean seal level)) to 100 ppbv at 310 Torr (e.g., near 7.4 km AMSL). Since the orifice inside the inertial inlet is truly critical, the in-flight sample flow rate can be calculated as $F_{alt} = F_{grd} * (P_{alt}/P_{grd})$ from a pre-flight measurement of pressure and sample flow on the ground using a primary flow calibration unit (DryCal Definer 220) and the pressure measured in flight just upstream of the critical orifice inside the inertial inlet using a 0-1000 Torr Baratron pressure transducer (MKS Instruments, model 722B), as shown in Fig. 1a.

3 Methods for measuring instrument zero

Ellis et al. (2010) recommended that background checks of the NH₃ instrument would optimally be performed by removing NH₃ from ambient air while keeping the humidity level constant. Historically, ambient NH₃ monitors have been zeroed in several ways, including overblowing the inlet tip with dry synthetic air or UHP N₂ from a cylinder (Nowak et al., 2010; von Bobruzki et al., 2010), overblowing the inlet tip with chemically scrubbed ambient air sources (Nowak et al., 2007; Nowak et al., 2006; Fehsenfeld et al., 2002), sampling through oxalic acid coated filters (Norman et al., 2009), or passing ambient air through heated metal catalysts (Norman et al., 2007; Tevlin et al., 2017). However, significant effort and cost can be required to routinely generate a large enough supply of NH₃-free air to overblow the inlet of the NH₃ instrument described here (e.g., >10 SLPM), and at low enough zero levels to be considered truly NH₃-free by instruments with low detection limits of a few hundred pptv or less. Our evaluation and recommendations reported below take these factors into consideration.

In the months leading up to the 2017 test flights, we tested five different sources of NH₃-free air in the laboratory. First, we used dry, ultrapure synthetic “zero” air (UZA) from a compressed gas cylinder (AIRGAS). We assert that this bottled source of UZA provides a measure of the “true” instrument zero to which we then compared all other tested sources. Second, we tested the output of a commercial zero air generator (ZAG) (Teledyne, model 701H). Third, we tested a chemical NH₃ scrubbing system that included a compressor pump (KNF Neuberger) for pushing ambient air through a single all-metal trap filled with an NH₃ scrubbing reagent (Permapure). Fourth, we tested 4 Å molecular sieve (Delta Absorbents). And, fifth, we combined the chemical scrubber in tandem with the 4 Å molecular sieve. Scrubber materials were contained individually in separate traps constructed from KF-40 stainless steel tubing and vacuum fittings (LDS Vacuum). The endcaps were outfitted with stainless steel mesh screens to prevent solid scrubber materials from migrating towards the instrument inlet and detector. Traps were warmed from the outside using heating tape (Omega Engineering) for selected experiments. Traps were cleaned prior to being filled with scrubbing media by rinsing the surfaces with water and then ethanol before baking the empty housings and fittings overnight at 250 °C.

We found UZA cylinders to provide the lowest and most reliable zero measure. The ZAG was also able to achieve a zero signal level consistent with that measured from a UZA cylinder. Although not ideal for use in flight owing to its weight, space and power needs, the ZAG is a plentiful and cost-effective source of NH₃-free air for laboratory and ground-based field experiments. We also found the ZAG useful for pre-flight operations exceeding 3 hours and for ground-based maintenance days aboard the aircraft, so that consumable cylinders could be conserved. For the chemical scrubber, we elected to use a hygroscopic phosphoric acid scrubbing reagent (Permapure) that does an acid-base neutralization reaction to remove gas-phase NH₃ from an ambient air sample, as this product had been found to be successful for generating a source of NH₃-free air in previous airborne field campaigns (Nowak et al., 2007). However, we found that this particular chemical scrubbing reagent could not achieve a true zero on its own. The lowest possible zero level achieved with a fresh trap of the chemical scrubber was 200 pptv above true, which is larger than the on-ground detection limit (100 pptv, see Sect. 3.1) and on par with the in-flight detection limit (200 pptv). The NH₃ signal from the chemical scrubber increased with usage and was closer to 1 ppbv after several days. Cleaning the trap and refreshing the scrubbing media reagent did not result in any

improvement. It is possible that the volume of the chemical scrubber trap was not large enough to scrub all of the NH_3 from the supply of ambient air required to overflow the instrument. However, similar offsets above true zero were observed in a separate experiment where the chemical scrubber was supplied with UZA from a cylinder instead of ambient air via the compressor, suggesting that the scrubbing reagent actually outgassed small amounts of NH_3 . An independently purchased supply of this chemical scrubbing media produced similar results confirming that the original reagent material had not been compromised prior to these tests. In a fourth test, we used 4 Å molecular sieve to remove NH_3 from an ambient air sample. While this was able to achieve a true zero, the volume of material that could be used and the flow rate required to overflow the instrument inlet limited the lifetime of the trap. The lifetime of this trap could be extended by increasing surface area contact time with the absorbing material, which could be achieved by increasing the length of the trap or by linking multiple traps in series. A disadvantage of 4 Å molecular sieve is that it also absorbs water. This means that the operational lifetime of the molecular sieve is greatly limited in humid environments, and since the molecular sieve dries the NH_3 -free air source the output is no different than that of a bottled source of UZA or the ZAG. In a fifth experiment, the chemical scrubber was used to remove the bulk of NH_3 from ambient air and followed in series by a trap filled with 4 Å molecular sieve to remove any remaining NH_3 . The combined trap was successful in achieving a true zero, and the lifetime of the trap was noticeably longer (2-4 hours) than that of molecular sieve alone (1-2 hours).

Although the chemical scrubber (operated with or without the molecular sieve) may be the closest option to a source of NH_3 -free ambient air, the NH_3 scrubbing reagent is hygroscopic and needs to be carefully monitored for condensate accumulation even when heated. Heavy contamination of the instrument sampling surfaces is possible from species outgassing from the chemical scrubbing reagent, especially if the chemical reagent becomes moisture saturated. Contamination of the instrument from the scrubber system is hard to predict and time consuming to remedy once it happens. While the molecular sieve effectively absorbs residual NH_3 in the combined trap, it does not prevent contamination from compounds larger than 4 Å that could result from the moisture-saturated chemical reagent. A contamination of this type was observed during the 2017 test flight period and is described in Sect. 5. Further, while the cost of molecular sieve is negligible and the material can easily be regenerated, the non-regenerative chemical reagent can significantly accumulate in expense over time depending on usage rate. In our tests, the chemical scrubbing reagent lasted a few weeks before being compromised. However, the actual lifetime depends on how NH_3 -rich and humid the operational environment is and how consistently the trap is heated.

Following this assessment, we elected to only evaluate and compare the UZA cylinder and the combined chemical scrubber/molecular sieve during the 2017 test flights. Even though cylinders are rapidly consumed at the high sample flow rate and thus were replaced prior to each of our flights, we ultimately found this source to be the most convenient and cost-effective method for zeroing the NH_3 instrument system during WE-CAN test and research flights. As might be expected, cylinders of dry UHP N_2 produced the same zero signal level as a bottled source of UZA, and thus can be utilized as an alternative (and sometimes less costly) NH_3 -free source for zeroing the instrument. It should also be noted that the calibration signal from standard addition of NH_3 on top of a zero background signal generated with UHP N_2 can be different by as much as 10% from a calibration signal measured on top of a background produced with UZA owing to differences in pressure (or collisional) broadening of the NH_3 spectral lines in the ν_2 absorption band with different carrier gases (Pearman and Garratt, 1975; Owen et al., 2013).

4 Evaluation of the non-passivated instrument on the ground and in flight

4.1 Precision, detection limit, and stability

Continuously overflowing the inlet tip with NH_3 -free air (>500 sccm) during one of the test flights allowed for characterization of any flight-induced artifacts in the detected absorption signal above a constant, low-level background. The measured zero signal level on the ground and in flight was the same when tested with a UZA cylinder, a UHP N_2 cylinder, or the combined chemical reagent/molecular sieve scrubber. Ambient signal levels were checked periodically for a few minutes at a time throughout the flight to confirm that measured ambient levels were greater than or equal to the measured zero signal level. Measured zero signal levels were consistently within a factor of three of the in-flight instrument precision with

changes in altitude up to the 5 km AGL (or ~6 km AMSL, which was the upper range of the C-130 with the WE-CAN payload). Ambient measurements were consistently greater than zero and frequently above the 200 pptv detection limit, even in the free troposphere.

5 Figure 2 depicts two time segments of data collected at 10 Hz while measuring NH_3 -free air. One is a 10-minute segment collected in flight in the boundary layer near 1.4 km AGL (e.g., Fig. 2a); the other is a 2-hour segment collected in the laboratory (e.g., Fig. 2b). The instrument was operated without passivant in both cases. Instrument precision, calculated as the Allan deviation or the square root of the Allan variance (Werle et al., 1993), is 430 pptv at 10 Hz and 60 pptv at 1 Hz in flight and 130 pptv at 10 Hz and 40 pptv at 1 Hz on the ground. An offset was applied to the Allan variance from the 10-Hz data collected in flight, and reflects the effects of a frequency-swept vibration applied to the laser objective to reduce motion sensitivity due to optical feedback from the objective. The frequency and amplitude of the vibration were specifically tuned to minimize motion sensitivity at 1 Hz for this flight application. If we define the detection limit as three times the instrument precision, then the estimated 1-Hz detection limits are 180 pptv in flight and 120 pptv on the ground. Therefore, vibrations associated with the C-130 in flight lead to larger detection limit by a factor of 1.5. Since the instrument was not operated without the vibration isolation mounting plate or high frequency vibration of the laser objective during the test flight period, we have no direct comparison for how these added features impacted the measurements. The same precision and detection limit are determined from an Allan variance analysis of NH_3 data at a constant mixing ratio of 50 ppbv, collected when calibration gas was added to the sample stream. With averaging, the Allan variance plots suggest that the in-flight detection limit can be reduced to 75 pptv over and averaging period of 5 seconds and 60 pptv over 10 seconds.

20 Zero and calibration signal levels were largely insensitive to in-flight fluctuations in cabin pressure and temperature within the ~200 pptv detection limit, as shown in Fig. 3. A slight positive trend was observed in the zero signal level with increasing altitude during an ascent profile between the ground in Broomfield, Colorado and 6.5 km AMSL; however, there is little variability in the average zero signal measured during constant altitude legs and the 3σ standard deviation of each average is within the 200 pptv detection limit. Constant altitude legs were performed roughly every 1 km for a period of 5-10 minutes during the ascent profile. The more apparent increasing trend between NH_3 zero signal level and increasing altitude between these straight and level flight legs likely reflects a change in the measured zero signal level due to motion sensitivity of the instrument during vertical accelerations associated with the aircraft's ascent, as described in detail in the next section. Overall, changes in the zero signal level with altitude are largely within the ~200 pptv detection limit over the entire altitude range tested.

35 Instrument stability was evaluated over the 2-month duration of the WE-CAN intensive and test flight period. Zero signal levels drifted <10% from average, and calibration signal levels drifted <2% from average over the entire period. Variability in the calibration correction factor applied to the measured data to generate final NH_3 mixing ratios is <1%. We estimate that the total uncertainty associated with the reported 1-Hz measurement is $\pm 12\%$ of the measured NH_3 mixing ratio plus the 200 pptv detection limit, where the uncertainty of the measured NH_3 mixing ratio is calculated by quadrature addition of the associated individual uncertainties. The individual uncertainties include: the permeation rate of the calibration source as measured by the NOAA UV calibration system ($\pm 7\%$), the stability of calibration ($\pm 2\%$) and zero ($\pm 10\%$) measurements over the deployment period, changes in NH_3 mixing ratio with changes in flow rates (e.g., $\pm 1\%$ each for dilution of calibration gas into the sample flow, calibration gas addition to the sample flow, and passivant addition to the sample flow as measured with the DryCal flow calibrator), and changes in NH_3 calibration signal with changes up to 10 Torr in QC-TILDAS optical cell pressure ($\pm 1\%$). Changes in measured NH_3 signal with deliberate changes in optical cell temperature over a 5°C range were <0.1%, and thus are considered negligible in the uncertainty calculations.

4.2 Motion sensitivity

45 Figure 4 shows the sensitivity of the QC-TILDAS to in-flight accelerations measured during the test flight period. Maneuvers performed at 2.6 km AGL while measuring NH_3 -free air at 10-Hz show excursions in the NH_3 signal with respect to acceleration (denoted here as $\Delta\text{NH}_3/\text{g}$). The $\Delta\text{NH}_3/\text{g}$ observed for each direction of motion is determined from the slope of a scatter plot of NH_3 (in ppb) versus acceleration (in g). Slopes are 3 ppb g^{-1} , 1 ppb g^{-1} and 5 ppb g^{-1} for the side-side, up-

down, and fore-aft motions, respectively. These excursions are not due to real changes in NH_3 mixing ratios in the ambient air sample; instead they reflect an artifact in the measured zero signal associated with physical movement of the absorption cell optics with accelerations in the side-side, up-down, and fore-aft motions of the aircraft during flight. In particular, excursions in the absorption measurements are likely affected by micro displacements in the distance between the laser and laser objective. Owing to the orientation of the laser objective with respect to the direction of flight in the spectrometer box, micro displacements in the fore-aft direction are expected to have the largest effect. For atmospheric research objectives, accelerations during ascent/descent, turbulence and turns are of particular importance since most flight plans require sampling in the mixed boundary layer, transecting emissions plumes, and performing spirals and/or sawtooth-shaped vertical profiles. Figure 4 shows that the largest accelerations of aircraft motion, specifically during turbulence and turns, are experienced in the vertical plane. Scaling accelerations observed during turbulence in the mixed boundary layer at 0.3 km AGL and turns performed near 2.6 km AGL to the $\Delta\text{NH}_3/\text{g}$ observed in all three dimensions during maneuvers indicates that changes in NH_3 signal during turbulence and turns are < 50 pptv, a factor of four less than the detection limit.

4.3 Time response of the non-passivated instrument

The time response of the NH_3 instrument can be determined from a step change response in NH_3 concentration, as described in detail by Ellis et al. (2010) and Roscioli et al. (2016). Briefly, for these experiments, a step change in NH_3 concentration is generated by switching off calibration gas while overblowing NH_3 -free air at the inlet tip. As shown in Fig. 5, the decrease in NH_3 mixing ratio is well represented by a bi-exponential decay as shown in Eq. (1):

$$y = y_0 + A_1 \exp\left(\frac{-(t-t_0)}{\tau_1}\right) + A_2 \exp\left(\frac{-(t-t_0)}{\tau_2}\right) \quad (1)$$

where y_0 represents the mixing ratio reached at the end of the decay, A_1 and A_2 are constants that sum to the stable mixing ratio of NH_3 prior to the calibration being switched off, and τ_1 and τ_2 are the decay time constants. τ_1 is typically fast and corresponds largely to the gas exchange time of the flow path and optical cell (~ 0.4 s); τ_2 can be significantly slower and is commonly associated with the interaction of NH_3 molecules with sampling surfaces. The instrument time response can then be quantified as the time (t) that it takes for the NH_3 calibration signal to return to some percent of the final zero signal level after the calibration gas was switched off (t_0). Given the double exponential nature of the decay, the ratio of A_2 to $(A_1 + A_2)$, defined as parameter D and reported as percent in previous works (Ellis et al., 2010), can also be a useful tool for describing the fraction of NH_3 slowed in reaching the detector due to interactions with the sampling surfaces.

Instrument time response is commonly reported as the $1/e$, 75%, and 90% signal recovery times (with the latter denoted here as t_{90}). With an overall instrument uncertainty of $\pm 12\%$, this instrument's time response is adequately characterized using t_{90} . Further, owing to this particular instrument's low detection limit and robust stability over time, we also report for reference t_{99} , the response time associated with a 99% signal recovery.

Table 1 summarizes the coefficients and corresponding 1σ standard deviations from a fit of each bi-exponential decay shown in Fig. 5. Reduced chi-square values from fits of the bi-exponential decay profiles shown in Fig. 5 and Table 1 ranged from 0.4 to 1.3. Also included in Table 1 are the resultant values for $\%D$, t_{90} and t_{99} extrapolated from the fit coefficients, with uncertainties for these values reflecting propagation of the 1σ standard deviations of the fit coefficients and an uncertainty of ± 0.1 s for t_0 . All step change profiles were measured with the instrument configured for use aboard the aircraft, as shown in Fig. 1, and were collected during pre-flight operations on the ground prior to the test flights or in the laboratory between test flight periods. As indicated in Fig. 5 and Table 1, the instrument time response has a clear dependence with the cleanliness of the instrument sampling surfaces. Specifically, an instrument with "clean" sampling surfaces has a much faster time response ($t_{90} < 1$ s) compared to an instrument with "dirty, or "contaminated", sampling surfaces ($t_{90} = 180$ s).

4.4 In-flight measurements with the non-passivated instrument

NH₃ was measured over a range of altitudes, including several kilometers in the free troposphere (e.g., Fig. 6a). Measured NH₃ mixing ratios were as much as 80 ppbv during missed approaches at Greeley-Weld County Airport and in the boundary layer (< 1 km AGL) over animal husbandry and agricultural operations in northeastern Colorado during the test flights. In contrast, NH₃ mixing ratios in the boundary layer near Akron, Colorado were around 1 ppbv following a few days of rain during the 2017 test flights. We were also fortunate to have the opportunity to sample clear air in the free troposphere for a 10-20 minute period during each of the 2017 and 2018 test flights. A histogram of the NH₃ measured in the free troposphere over the northeastern Colorado Front Range during the test flights (e.g., Fig. 6b) indicates that free tropospheric NH₃ mixing ratios were frequently greater than 0.4 ppbv during the September 2017 test flight period, a factor roughly two times greater than the detection limit, and frequently greater than 1 ppbv in July 2018 following a period of higher ambient temperatures and less rain. It should be noted that calibrations at very low NH₃ mixing ratios (e.g., sub 1 ppbv to 10 ppbv) were not performed during the test flights because the in-flight calibration source was optimized for the NH₃ mixing ratios expected in concentrated wildfire smoke during WE-CAN research flights (e.g., >50 ppbv). However, calibrations of the QC-TILDAS detector performed by the manufacturer and during separate experiments in the laboratory prior to installation on the aircraft show linearity within the instrument uncertainty for NH₃ calibration mixing ratios ranging from a few ppbv to hundreds of ppbv.

5 The effects of adding passivant

5.1 Passivated instrument time response on the ground

5.1.1 “Clean” vs. “dirty” instrument conditions

As indicated in Fig. 5 and Table 1, the improvement in instrument time response when passivant is added has a clear dependence with how “clean” or “dirty” the instrument system is. More specifically, there is no difference in time response for the “clean” instrument when operated with and without the C8 passivant, yet the time response increasingly improves with passivant addition to an instrument with increasingly compromised sampling surfaces (e.g., Fig. 5a compared to Fig. 5c). In these tests, the “clean” case refers to a new instrument that had only been operated for a few months after being built and always under relatively pristine conditions (e.g., operated in a laboratory with dry NH₃-free air). In this “clean” case, the instrument can recover from a 50 ppbv step change in NH₃ in $t_{90} < 1$ s regardless of whether passivant is applied. The step change profiles collected under “typical” and very dirty, or “contaminated”, operating conditions demonstrate that adding passivant can greatly improve the overall instrument time response and that the effect of adding passivant can be increasingly beneficial as sampling surfaces are further exposed to “dirty” sampling conditions.

Before the instrument response could be characterized in flight with passivant under typical ambient operating conditions during the 2017 test flight period, the instrument sampling surfaces experienced a case of extreme contamination. The contamination was likely caused by the chemical scrubbing reagent, which had been used in several prior experiments to evaluate a scrubbed source of NH₃-free air, that was compromised by exposure to excessive moisture (e.g., the 2017 test flight period was particularly cold and rainy). Fortunately, this “contaminated” case, albeit an atypical and non-optimal operating condition, presented a unique opportunity to test the power of passivation for improving, or in this case recovering, instrument time response. Under “contaminated” conditions, accumulation of NH₃ on the sampling surfaces was so severe that NH₃ was more prone to sticking on the contaminated inlet surfaces rather than being transmitted to the detector. The time response of the contaminated system was so long (e.g., hours) that it could not be accurately measured (e.g., the instrument would need to run for several hours to achieve 99% signal recovery, which was not possible to accomplish in the time frame of the aircraft operations). Thus, Fig. 5c shows the time response of the “contaminated” instrument after one cleaning, where a 99% signal recovery could be observed within a few hours. The “contaminated” surfaces degraded the instrument time response from $t_{90} < 1$ s to 180 s and $t_{99} = 37$ s to 1200 s. As shown in Fig. 5c, adding a continuous flow of the C8 passivant to the contaminated system brought t_{90} back to 7 s and t_{99} to 180 s. Table 1 also shows a similar value of

$%D$ in the passivated case compared to a factor of 4 difference in $%D$ for the non-passivated case when comparing the “contaminated” versus “clean” systems indicating that the time response of the contaminated system is dominated by interaction of NH_3 with the instrument sampling surfaces (τ_2).

- 5 Even though adding passivant to an already “contaminated” instrument cannot instantaneously reset the sampling surfaces to near pristine “clean” condition, the results in Table 1 show that passivant addition has a greater factor of improvement for increasingly “dirty” instruments (e.g., a factor of 2 improvement for “typical” conditions, and a factor of 25 improvement for “contaminated” conditions). Although NH_3 accumulation should be avoidable during normal operation even in polluted environments with frequent checks of the step-change time response and cleanings, we conclude that the option of adding
10 passivant can be a useful tool for recovering instrument time response when fast measurements are required and routine maintenance/cleaning is not possible (e.g., when contamination occurs before or during a research flight or at a remote field site).

- 15 It should also be noted that the instrument’s time response following the contamination event could only be fully recovered by replacing contaminated tubing and performing multiple cleanings of any non-replaceable components between the inlet tip and the QC-TILDAS optical cell. Cleaning consisted of vigorously rinsing components with deionized water several times, followed by a few rinses with 200-proof ethanol, and finally blowing out each component for several minutes with compressed UZA or UHP N_2 until all traces of solvent were gone.

5.1.2 The effects of increasing passivant concentration

- 20 Previous experiments performed in the laboratory showed improvements in instrument time response with increasing addition of C8 passivant (Roscioli et al., 2016). In these experiments, Roscioli et al. (2016) observed nearly a factor of 6 improvement in t_{90} when passivant addition was increased from 1 ppm to 40 ppm. Our tests, reported in Fig. 7 with the instrument operated under near “typical” conditions, confirm that the instrument time response can be increasingly improved by increasing the amount of passivant added at the inlet. While the improvement increases with increasing addition of
25 passivant chemical, the improvements observed for this particular instrument system appear to be exponential with limited improvement when passivant concentrations exceed 60 ppmv.

5.1.3 The effects of humid vs. dry sampling conditions

- In all cases presented in Table 1, except for the “contaminated” case, D is $< 10\%$ indicating that the time response of the instrument as configured for these experiments is not overly dominated by surface interactions, even when operated under
30 typical in-field ambient measurement operating conditions and without passivant. This is likely because the instrument sampling surfaces are heated to prevent absorption of water and basic species, as described in Ellis et al. (2010). All the same, it should be noted that the time response tests reported here were performed on top of a sample stream of NH_3 -free air supplied from a synthetic, dry bottled source or generated using a hygroscopic scrubbing media. Sample humidity is alleged to increase the relative importance of NH_3 surface interactions (Ellis et al., 2010), and thus differences in the instrument time
35 response determined in a laboratory using dry air compared with that determined from data collected in a moist field environment could be significant (Nowak et al., 2007). However, previous observations with respect to sample humidity are inconsistent. One study showed that humidity addition increased surface interactions (e.g., more NH_3 adsorption on sampling surfaces, (Ellis et al., 2010)), while another study showed NH_3 adsorption on sampling surfaces to decrease with increasing water content (Vaaitinen et al., 2014). Although the differences may be attributed to whether the sampling surfaces were
40 sufficiently heated to prevent water absorption on the sampling surfaces, we were compelled to further test the effects of humidity on this instrument’s time response with and without passivant addition. This was done by overflowing a sample of dry versus 80% humidified air at the inlet tip. Dry air was sourced directly from a UZA cylinder; humidified air was generated by passing 9.2 slpm of UZA through a bubbler filled with dionized water and allowing it to re-mix with 2.2 slpm of dry UZA before overflowing the humidified air mixture at the inlet tip. Humidifying the sample stream to 80% instead of
45 100% was intentional to avoid condensation of saturated water vapor onto the sampling surfaces while still providing a

rigorous test of the instrument time response in a humid environment (e.g., the average annual relative humidity in morning in the continental U.S. is ~80%).

5 Figure 7 shows a slight difference in instrument time response between the humidified versus the dry air sample when the instrument is operated with heated inlet surfaces and without passivant, although the difference is close to being within one standard deviation of the measurement uncertainties. The observations in Fig. 7 are consistent with that observed by Ellis et al. (2010), which were performed using similar instrumentation and similar magnitude step changes in NH_3 mixing ratios. The time responses for both the dry and humidified air samples are increasingly improved when an increasing amount of the C8 passivant is added to the sample stream. This trend is similar to that observed by Roscioli et al. (2016) in dry air samples with the exception of a plateau in the time response improvements at high concentrations of passivant addition. 10 Improvements in time response with passivant addition for the humidified air sample seem to be limited to the same ~60 ppmv threshold as the dry air sample. Overall, the differences in time response between the humidified and dry air samples appear to be small when using a heated inlet system regardless of whether passivant has been added.

5.1.4 Other possible passivant chemicals

15 Table 1 demonstrates a similar improvement in instrument time response when a C7 passivant, 1H,1H-perfluorheptylamine, is implemented instead of the C8 passivant. Of significant difference is the usage rate of the C7 passivant, which is ~2 hours per gram compared to ~4 hours per gram for the C8 compound at a typical passivant addition flow rate of 200 sccm and room temperature (~22°C). Longer carbon chain versions of the passivant chemical are expected to produce similar improvements in time response; however, longer chain species are likely to be more difficult to introduce into the sample stream due to reduced volatility. 20

5.2 The effects of adding passivant in flight

5.2.1 Test flights in the Colorado Front Range

Missed approaches at the Greeley-Weld County Airport in Colorado (40.4375° N, 104.633056° W, and 1,432 m AMSL) were performed on multiple occasions during 2017 and 2018 and provided opportunities to sample large, rapid gradients in gas-phase NH_3 while operating the instrument with and without passivant addition. The aircraft often sampled emissions from nearby concentrated animal operations located south and east of the Greeley-Weld County Airport during the 29 September 2017 (e.g., flight tracks in Fig. 8) and 13 July 2018 flights. The aircraft reached a minimum altitude of 50 m AGL during the missed approaches; the maximum NH_3 mixing ratios were intercepted between 300 and 400 m AGL, and wind speeds were consistently between 4 and 5 m s⁻¹. 25

30 NH_3 enhancements observed near 13:30 Mountain Daylight Time (MDT) and 14:00 MDT during the 29 Sept 2017 flight represent intersects of the same NH_3 plume, yet differ by whether the “contaminated” instrument was operated without (e.g., cyan shaded areas near 13:30 MDT in Fig. 8) or with (e.g., orange shaded areas near 14:00 MDT in Fig. 8) the C8 passivant. Passivant addition is turned off by bypassing the impinger using the quick-connect fittings as described in Sect. 2. The large drop in NH_3 signal at 13:23 MDT when the passivant impinger is bypassed indicates that the passivant coating is quickly stripped from the sampling surfaces (in about ~60 s) when the coating is not actively and continuously applied. As depicted in the cyan shaded area of the time series in Fig. 8, NH_3 mixing ratios measured by the non-passivated, “contaminated” instrument are significantly reduced. Only 5 ppbv was observed out of the ~45 ppbv of NH_3 expected during this plume transect suggesting that only ~10% of ambient gas-phase NH_3 molecules were actually transmitted to the QC-TILDAS detector while ~90% were absorbed to the “contaminated” sampling surfaces. In contrast, a time series of NH_3 enhancements sampled during plume transects collected with a “clean” instrument system during the flight on 13 July 2018 (e.g., Fig. 9) shows little difference in NH_3 transmission to the detector when the instrument is operated with passivant (e.g., orange shaded area at 13:46 MDT in Fig. 9) and without passivant (e.g., cyan shaded area at 13:55 MDT in Fig. 9). Therefore, we attribute the reduced transmission of NH_3 to the detector in the non-passivated and “contaminated” instrument system to 40 increased retention of NH_3 due to absorption on the walls of the “contaminated” sampling surfaces. 45

To further test this hypothesis, we quantify the relative amount of NH_3 ejected from the sampling surfaces when passivant is re-introduced to the sample stream (e.g., the red shaded areas in Fig. 8) following a non-passivated plume intersect (e.g., the cyan shaded area in Fig. 8 that represents a period of sampling large NH_3 mixing ratios without passivant). Ejection occurs when passivant is re-added to the system and any NH_3 molecules that have adhered to the sampling surfaces during the non-passivated sampling period are released from the surfaces and replaced with the passivant coating. The ejection signal is a measure of the NH_3 molecules that are kicked off of the sampling surfaces and transmitted to the QC-TILDAS detector, and manifests in the time series as an intense increase followed by a slightly less intense decrease in measured NH_3 mixing ratio and an exponential decay (as depicted in Fig. 8). By adding up the amount of NH_3 ejected from the sampling surfaces with the amount of NH_3 measured by the non-passivated instrument, we can quantify the total amount of NH_3 that should have been transmitted to the detector for a specific sampling event (aka. NH_3 expected) compared to NH_3 actually detected (NH_3 measured) to quantify how much NH_3 was absorbed to the sampling surfaces when the instrument was operated without passivant. To do this, we integrate the highlighted segments of Fig. 8, which represent plume transects sampled with and without passivant and ejection; results are reported in Table 2. From these results, we can make the following conclusions. First, the NH_3 ejected from the sampling surfaces when passivant is re-added accounts for nearly all of the missing NH_3 detected by the QC-TILDAS when the instrument system is operated without passivant. Second, passivant addition is capable of recovering a near-optimal instrument sampling capability even when the instrument is operated under non-optimal cleanliness conditions. These results are evident from the small percent difference between expected versus measured NH_3 during the feedlot plume intersects. Third, the likelihood of NH_3 absorption to sampling surfaces increases with increasing build-up of water and basic species on the sampling surfaces, thereby decreasing the amount of NH_3 transmitted to the detector when the instrument is operated without passivant. This is demonstrated by a factor of six greater fraction of NH_3 ejected from the sampling surfaces during the 2017 “contaminated” case compared to the 2018 “clean” case. In general for both cases, the small percent difference in measured and expected NH_3 additionally demonstrates that the NH_3 plumes used for each case analysis likely originated from the same feedlot source and was intersected by the aircraft under similar meteorological (e.g., wind) conditions.

Additional qualitative information was unintentionally gained from a Proton Transfer Reaction Time of Flight Mass Spectrometer (PTR-ToF-MS) that was simultaneously deployed aboard the C-130 aircraft. The PTR-ToF-MS was operated with H_3O^+ reagent ion and positioned just aft of the QC-TILDAS-based instrument in the aircraft cabin. While previous studies have shown a PTR-ToF-MS to be successful in quantifying *in-situ* NH_3 mixing ratios from airborne measurement platforms (Müller et al., 2014; Norman et al., 2007), the PTR-ToF-MS deployed during WE-CAN was not optimized for measuring NH_3 and seemed to suffer from a previously-identified issue (e.g., high background signal correlated with the instrument’s ion source (Müller et al., 2016)). Since the primary objective of the PTR-ToF-MS during WE-CAN was to measure non-methane volatile organic compounds in smoke, the PTR-ToF-MS instrument inlet is non-specific and not calibrated for NH_3 . However, we were able to kinetically calculate an NH_3 mixing ratio from the raw PTR-ToF-MS instrument signal collected during the flight on 29 Sept 2017, and thus the PTR- NH_3 measurement (e.g., blue line in Fig. 8) can be used to qualitatively confirm the QC-TILDAS-based instrument observations in this study. It is clear by visual comparison to the PTR-ToF-MS that the non-passivated, “contaminated” QC-TILDAS instrument did not capture all of the expected ambient NH_3 from the plume intersect at 13:30 MDT even though the integrated NH_3 signal from the plume intersect at 13:30 MDT was 14% less than the integrated NH_3 signal measured during the plume intersect at 14:00 MDT. It should be noted that a large and variable background, which appeared to be inversely correlated with the H_3O^+ ion signal, prevented PTR- NH_3 from being determined for any of the 2018 WE-CAN test and research flights. NH_3 mixing ratios for the test flight on 29 Sept 2017 could only be calculated from the PTR-ToF-MS raw instrument signal because the H_3O^+ ion signal was ~10% lower in magnitude and significantly more stable than ion signal during the 2018 flights.

For further perspective, we would like to highlight that NH_3 measurements could only be collected with the “contaminated” instrument during the test flight on 29 September 2017 because of the option to add passivant to the sample stream. The contamination occurred only hours before take-off leaving too little time to disassemble and clean the instrument sampling surfaces prior to flight. In this case and without the option for passivant addition, the alternatives would have been to either cancel the flight and potentially miss an ideal sampling opportunity for addressing the project’s scientific goals or conduct

the research flight without NH₃ measurements. The latter would have been a significant loss if the NH₃ measurements were central to answering the project's scientific questions, as was the case for the 2018 WE-CAN field campaign.

5.2.2 Research flights in concentrated wildfire smoke during WE-CAN

Concentrated wildfire smoke plumes from the South Sugarloaf Fire in Nevada (41.812° N, 116.324° W) were sampled during a WE-CAN research flight on 26 August 2018 (RF15). The fire originated on 17 August 2018 and was caused by lightning. Winds were 12 to 16 m s⁻¹ and consistently blowing from the southwest to the northeast. Figure 10 shows NH₃ and carbon monoxide (CO) measurements from RF15 that were collected during two crosswind intercepts of the South Sugarloaf Fire smoke plume. Intercepts of the smoke plume were performed at 4400 m AMSL at roughly 75 and 200 km downwind of the South Sugarloaf Fire, and correspond to roughly 1 to 4 hours of aging since emission. The first smoke plume intercept at 20:08 UTC was conducted with passivant addition to the NH₃ instrument; the second pass at 20:21 UTC was non-passivated. Linear regression analysis confirms that NH₃ and CO measurements are strongly correlated ($R^2 > 0.9$) during both plume intersects. CO measurements were simultaneously collected aboard the C-130 during WE-CAN using a similar compact model, QC-TILDAS detector (Aerodyne). In contrast to the NH₃ instrument, the CO detector was operated at an absorption wavelength of 2200 cm⁻¹, did not require a heated inertial inlet, was operated with a much lower sample flow rate (0.5 SLPM), and was recorded on a 1-Hz timescale. Additionally, ambient air was introduced to the CO instrument via a pressure-controlled, pumped bypass inlet system maintained at 1 SLPM and 265 Torr and constructed of 15 feet of 1/4" o.d. stainless steel tubing. We expect a slightly longer residence time (e.g., 1-2 s) for CO compared to NH₃ given the significantly lower sample flow rates and longer segments of tubing used with the CO instrument. Fine structure features in the time series (e.g., Fig. 10) highlights the slightly faster time resolution of NH₃ compared to CO. To quantify differences in the time resolution of the fine structure features observed, NH₃ measurements were incrementally averaged from 1 to 5 seconds until linear regression analysis of scatter plots of CO versus the averaged NH₃ data points resulted in a maximum R^2 value. Averaging NH₃ to 3 seconds resulted in the best fit (e.g., highest R^2 value) for both the passivated and non-passivated cases, indicating that NH₃ measurements acquired during WE-CAN were equally faster than the CO measurements regardless of whether passivant was added. Similar time resolution for the passivated and non-passivated NH₃ measurements indicates that the sampling surfaces were relatively "clean" during this research flight. We also note that only a small fraction of NH₃ (<1%) is ejected from the sampling surfaces when passivant was re-added to the NH₃ instrument at 20:29 UTC following the second transect, thereby further indicating that NH₃ molecules were not absorbed to the "clean" instrument sampling surfaces during this flight. No degradation in time resolution for the non-passivated NH₃ instrument during RF15, which was the second-to-last research flight of a 6-week field campaign where intense smoke plumes with NH₃ mixing ratios ranging from 50 to 400 ppbv were routinely sampled for 4-6 hours every 1 to 3 days, further demonstrates that routine passivant addition throughout the field deployment was instrumental in preventing sampling surfaces from getting "dirty". Cleanings were only performed twice throughout the 6-week field campaign (roughly once every two weeks) when a gray-ish "smoky" residue could be visually observed on the inner sleeve of the glass inertial inlet; cleanings followed the procedure described in Sect. 4.

6 Conclusions

A closed-path QC-TILDAS NH₃ detector was outfitted with an inertial inlet for filter-less separation of particles, a custom-designed aircraft inlet, a custom-built vibration isolation mounting plate, and the option for actively and continuously adding passivant to the sample stream. This flight-ready NH₃ instrument system was then deployed on the NSF/NCAR C-130 aircraft during test and research flights associated with the WE-CAN field campaign. The instrument was configured to measure large, rapid gradients in gas-phase NH₃, over a range of altitudes, in smoke (e.g., ash and particles), in the boundary layer (e.g., during turbulence and turns), in clouds, and in a hot aircraft cabin. Important design goals were to minimize motion sensitivity, maintain a reasonable detection limit, and minimize NH₃ "stickiness" on sampling surfaces to maintain fast time response in flight. The addition of a high frequency vibration to the laser objective in the QC-TILDAS and mounting the QC-TILDAS on a custom-designed vibration isolation plate were successful for reducing motion sensitivity. Allan variance analyses of 10-Hz data collected near 1.4 km AGL indicate that the in-flight instrument precision for this

system as configured for the C-130 aircraft is 60 ppt at 1 Hz, with a corresponding 3σ detection limit of 180 ppt. The detection limit allowed measurement over a range of altitudes, and NH_3 mixing ratios in the free troposphere were frequently < 1 ppbv. Variations in NH_3 associated with turbulence and turns were also within the instrument's limit of detection.

- 5 Characterization of the instrument's time response in flight and on the ground with and without adding passivant showed that adding passivant to a "clean" instrument system had little impact on the instrument's time response. This observation is consistent with previous studies using non-passivated instruments (Ellis et al., 2010; von Bobruzki et al., 2010; Zöll et al., 2016; Whitehead et al., 2008) that clearly state the importance and necessity of careful instrument handling and rigorous experimental procedures for collecting high-quality, rapid-response measurements of NH_3 . In contrast, and as highlighted in
10 this work, passivant addition can greatly improve the time response of an instrument with "contaminated" sampling surfaces, thereby ensuring that high-quality, rapid-response NH_3 measurements can continue to be collected during field intensives where instrument components can be difficult to regularly access and keep clean (e.g., during research flights associated with an airborne field campaign). A comparison of passivated and non-passivated NH_3 measurements from a flight conducted near the end of the WE-CAN field campaign further indicates the utility of passivant addition for preventing build-up of
15 water and basic species on instrument sampling surfaces over long periods of time, thereby helping to keep the instrument clean throughout a several-week long field intensive.

- NH_3 accumulation on sampling surfaces should be avoidable during normal operation of the instrument, even in NH_3 -rich and humid environments, with frequent checks of the step-change response and routine cleanings whenever a temporal profile from a step change indicates that the instrument response time has degraded. This may be especially true when
20 sampling on the ground since a substantial volume of the sampling surfaces associated with the aircraft inlet can be eliminated. However, in the case where cleaning is not possible (e.g., when contamination occurs in flight or just prior, or when ground-based instrumentation cannot be easily accessed), adding passivant can be a useful tool for recovering time response and acts as an insurance policy for being able to continuously collect high-quality, fast-response measurements
25 from mission critical instruments. The option for passivant addition proved to be especially advantageous during the WE-CAN test flight period since it allowed for continuous collection of high-quality, fast-response NH_3 measurements even when the instrument was compromised by a known contamination. Continuous addition of passivant during WE-CAN research flights had the added advantage of maintaining an optimum level of instrument cleanliness even when used to sample concentrated wildfire smoke plumes from 15+ research flights over the 6-week duration of the WE-CAN field
30 intensive.

- The observations presented here indicate that the active continuous passivation technique combined with a closed-path, optical-based NH_3 instrument can have utility when rapid (> 1 Hz) collection of NH_3 is critical to the project's scientific objectives (e.g., measuring fluxes, sampling from aircraft or another mobile research platform). Passivant addition can help
35 maintain an optimum level of operation and data collection in NH_3 -rich/humid environments and/or when contamination of sampling surfaces is likely, yet frequent cleaning is not possible. Passivant addition may not be necessary for fast operation, even in polluted environments, if sampling surfaces can be cleaned whenever a step-change response to NH_3 shows time response has degraded.

- 40 *Data availability.* NH_3 measurements from the WE-CAN field campaign utilized in this work can be found at <https://data.eol.ucar.edu/dataset/548.022>. CO data from WE-CAN can be accessed at <https://data.eol.ucar.edu/dataset/548.016>. Navigation, state parameters, and microphysics flight-level data provided by the UCAR/NCAR Earth Observing Laboratory are available from <https://data.eol.ucar.edu/dataset/548.008>. Additionally, readers may contact the corresponding authors for data access.

- 45 *Author contributions.* IP prepared the manuscript with contributions from all co-authors. IP and JL designed and performed the laboratory and ground-based experiments and operated the NH_3 flight instrument during 2018 WE-CAN flights. All authors participated in instrument preparation and installation aboard the aircraft and in-flight data collection during the 2017 test flights.

Table 1. Summary of coefficients from fit to a bi-exponential decay and the resultant values for %D, t_{90} and t_{99} for time profiles generated from a step change in NH_3 mixing ratio under different levels of instrument “cleanliness”.

Level of instrument “cleanliness”	y_0	A_1	τ_1	A_2	τ_2	χ^2	%D	t_{90} (s)	t_{99} (s)
<i>Not passivated</i>									
Clean	0.27±0.01	95.3±0.6	0.200±0.002	5.1±0.1	18.9±0.5	0.40	5.1±0.1	0.6±0.1	37±4
Typical ^a	0.41±0.01	85.6±0.7	0.441±0.006	7.8±0.1	85±1	0.83	8.4±0.1	1.6±0.2	220±23
Contaminated	0.62±0.02	68.3±0.5	8.2±0.1	17.2±0.1	306±3	0.65	20.1±0.2	180±19	1200±127
<i>Passivated with C8 compound</i>									
Clean	0.32±0.01	90.8±0.6	0.225±0.003	7.9±0.1	18.5±0.4	0.52	8.0±0.1	0.8±0.1	45±5
Typical ^a	0.35±0.01	97.3±0.9	0.304±0.005	5.4±0.1	63±2	1.04	5.3±0.1	0.9±0.1	130±14
Contaminated	0.46±0.09	95.1±1.1	1.73±0.04	9.1±0.4	63±4	1.28	8.8±0.4	7±2	180±41
<i>Passivated with C7 compound^b</i>									
Typical ^a	0.86±0.01	109.0±0.5	0.390±0.003	5.3±0.1	36.7±0.7	0.40	4.7±0.1	1.3±0.1	135±14

^aRepresentative of the typical operating conditions of the instrument in an ambient field environment.

^bFor experiments performed in the lab after the contamination event and with the C7 compound, the aircraft inlet and inertial inlet were rinsed with solvents and dried with UZA and the sample tubing between the inertial inlet and QC-TILDAS was replaced. Several components along the sample pathway were intentionally cleaned but not replaced with pristine surfaces so that a mid-level of cleanliness could be assess and the benefits of adding C7 versus C8 passivant could be clearly observed. All sampling surfaces up to the optical cell in the QC-TILDAS were thoroughly cleaned following these tests and prior to the 2018 WE-CAN deployment.

5 **Table 2. The integrated sum of NH₃ detected (in units of ppbv) during intersect of a feedlot plume when the instrument was operated with passivant (orange shaded area in Fig. 8), without passivant (cyan shaded area), and during passivant ejection (red shaded area). Also reported for comparison is the total expected NH₃ signal from the non-passivated instrument plus ejection, the percent difference in the expected NH₃ signal from that measured with the passivated instrument, and the fraction of NH₃ ejected out of the total expected NH₃ signal.**

Test Case (Date)	NH ₃ measured without passivant	NH ₃ ejected	NH ₃ expected (=NH ₃ without passivant + NH ₃ ejected)	NH ₃ measured with passivant	Percent Difference [100*(meas-exp) / meas]	Fraction of NH ₃ ejected out of NH ₃ expected
“Clean” conditions (13 July 2018)	26,747.6	4,503.8	31,251.4	33,176.1	5.8	0.14
“Contaminated” conditions (29 Sept 2017)	2,564.0	14,159.5	16,723.5	24,353.4	31.3	0.85

Figure Captions

Figure 1: (a) Schematic the instrument as configured for flight on the NSF/NCAR C-130 aircraft. The sample flow path (blue arrows) starts at the inlet tip, which protrudes slightly from the face of the aircraft inlet strut. A PFA injection block housed inside the aircraft inlet strut allows calibration gases and passivant to be added to the sample stream within a few centimetres of the inlet tip. A 107-cm length of 3/8" o.d. PFA tubing then directs ambient air into a quartz inertial inlet where particles >300 nm are separated from the sample stream. The particle-rich stream is pumped away (orange arrows). The sample flow path is heated where possible to minimize interactions of NH₃ with sampling surfaces. The sample flow path is purged overnight in the reverse flow direction with 40 sccm of N₂ injected near the pressure control valve. A 0-1000 Torr range baratron (denoted as *P*) measures pressure just upstream of the critical orifice in the inertial inlet for active continuous determination of the sample flow rate. (b) Solid model of the QC-TILDAS vibration isolation mounting plate. (c) Photograph of the QC-TILDAS mounted to the vibration isolation plate while installed aboard the C-130 aircraft. (d) Photograph of the impinger used for active and continuous passivant addition.

Figure 2: 10-Hz measurements collected while overblowing NH₃-free air at the inlet tip (a) in flight in the boundary layer near 1.4 km AGL and (b) on the ground in the laboratory. Upper traces represent the raw 10-Hz data collected; lower traces depict the Allan variance of the corresponding data set. An offset was applied to the Allan variance in panel (a) to reflect the vibration applied to the laser objective to reduce motion sensitivity in flight; the vibration was not applied during laboratory tests depicted in panel (b).

Figure 3: In-flight variations in zero signal level (in units of ppbv of NH₃) with respect to changes in (a) altitude, (b) cabin pressure, and (c) cabin temperature. Gray symbols represent the 1 s average of all of the 10-Hz data points collected in flight while overblowing the inlet tip with NH₃-free air. Colored symbols and error bars represent the average NH₃ zero signal and 3σ standard deviation for each altitude step of an ascent profile, 5 Torr increments in cabin pressure, and 2°C increments in cabin temperature. Variations are largely within the 200 pptv detection limit (denoted by the light gray shaded areas).

Figure 4: Maneuvers performed at 2.6 km AGL in flight while overblowing the inlet tip with NH₃-free air show changes in NH₃ zero signal (in units of ppbv) with respect to aircraft accelerations (in units of g) in the (a) side-side, (b) up-down, and (c) fore-aft motions. Changes in NH₃ zero signal associated with (d) turbulence in the mixed boundary layer at 0.3 km AGL and (e) during turns at 2.6 km AGL are < 50 ppt when scaled by the ΔNH₃/g observed in each individual dimension during maneuvers. Side-side and fore-aft accelerations are offset by +0.5 g for display purposes in plots (d) and (e).

Figure 5: Normalized NH₃ signal (in %) versus elapsed time (in seconds) following a step change in NH₃ mixing ratio generated by switching off calibration gas at *t*=0 s. Temporal profiles and associated bi-exponential fits are shown for the non-passivated and passivated instrument operated under (a) “clean”, (b) “typical”, and (c) “contaminated” sampling surface conditions. Fits ranged from *t*₀ to 400, 1000, and 3000 s for the “clean”, “typical”, and “contaminated” cases, respectively, in accord with the elapsed time collected for each time profile.

Figure 6: (a) Vertical profile of NH₃ from the first and third test flight in 2017 and the second test flight in 2018 when the instrument was operated without passivant show concentrations as high as 80 ppbv in the mixed boundary layer during missed approaches at Greeley-Weld County Airport and over northeastern Colorado compared to average mixing ratios of ~0.8 ppbv near Akron, CO following several days of rain. (b) Histograms of the corresponding NH₃ measurements collected in the free troposphere above 1.5 km AGL; ambient NH₃ measurements in the free troposphere were frequently greater than the 200 pptv detection limit.

Figure 7: Response times (*t*₉₀ and *t*₉₉) and %*D* associated with increasing C8 passivant addition for a step change in NH₃ mixing ratio generated on top of a dry versus humidified background.

Figure 8: (upper) C-130 flight tracks and measured winds during the 29 Sept 2017 test flight. Colored segments of the flight tracks highlight enhancements in NH₃ measured downwind of concentrated animal operations located southeast of Greeley-Weld County Airport. (lower) Time series of 1-Hz NH₃ mixing ratios measured using the “contaminated” QC-TILDAS

instrument and kinetically calculated from a raw instrument signal obtained simultaneously aboard the C-130 aircraft by a Proton Transfer Reaction Time of Flight Mass Spectrometer (PTR-ToF-MS). Portions of the flight when the QC-TILDAS was non-passivated (at 13:30 MDT) and passivated (at 14:00 MDT) are highlighted by colored shaded areas in the time series. Passivant was disconnected from the instrument system between 13:23 and 13:34 MDT (as indicated by the gray shaded area); NH_3 ejection is observed when passivant is re-added to the system (red shaded area).

Figure 9: Time series of 1-Hz NH_3 mixing ratios measured with a “clean” QC-TILDAS during the test flight on 13 July 2018. Portions of the flight when the QC-TILDAS was passivated (at 13:46 MDT) and non-passivated (at 13:58 MDT) are highlighted by colored shaded areas in the time series. Passivant was disconnected from the instrument system between 13:47 and 13:58 MDT (as indicated by the gray shaded area); NH_3 ejection is observed when passivant is re-added to the system (red shaded area).

Figure 10: Time series of 1-Hz NH_3 and CO measured during a crosswind transect of the smoke plume from the South Sugarloaf Fire (RF15) on 26 August 2018. Fine structure in NH_3 measurements, displayed as a 1 s average and a 3 s average, correlate well with CO measurements. Similar time resolution for the passivated (a) and non-passivated (b) NH_3 measurements indicates that the sampling surfaces were “clean” during this research flight.

15

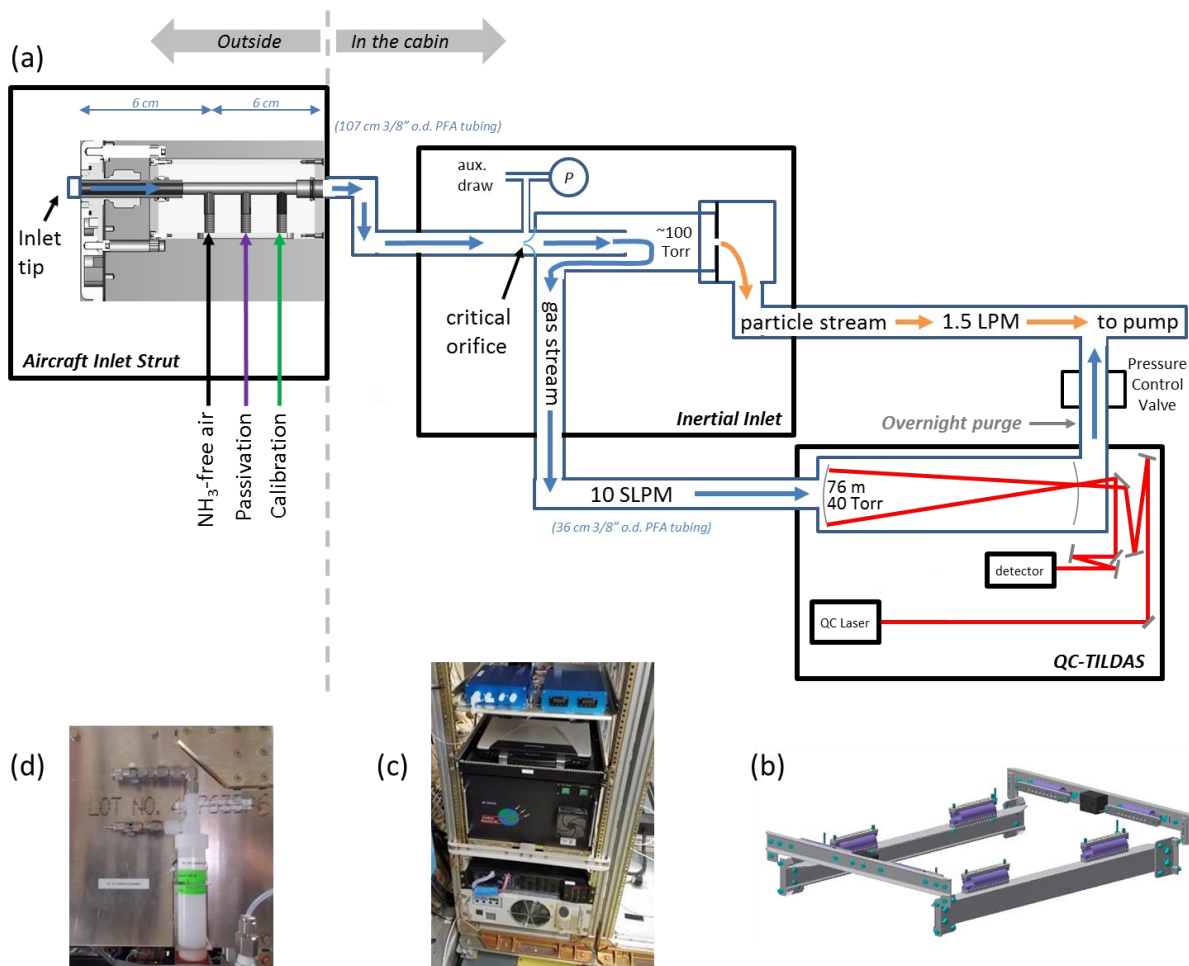

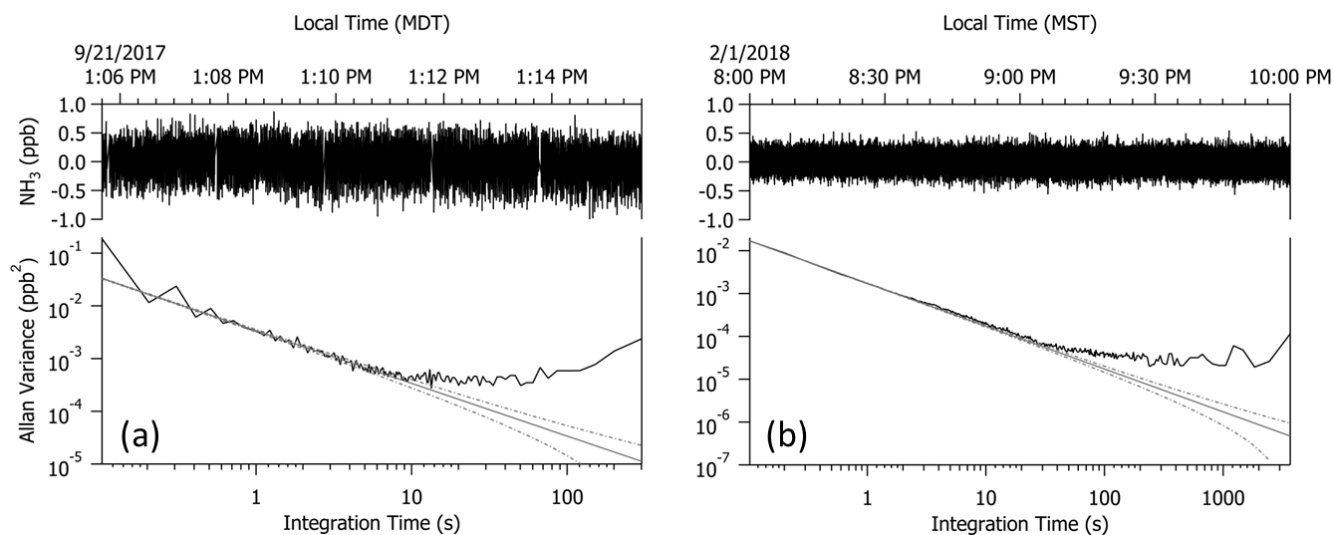

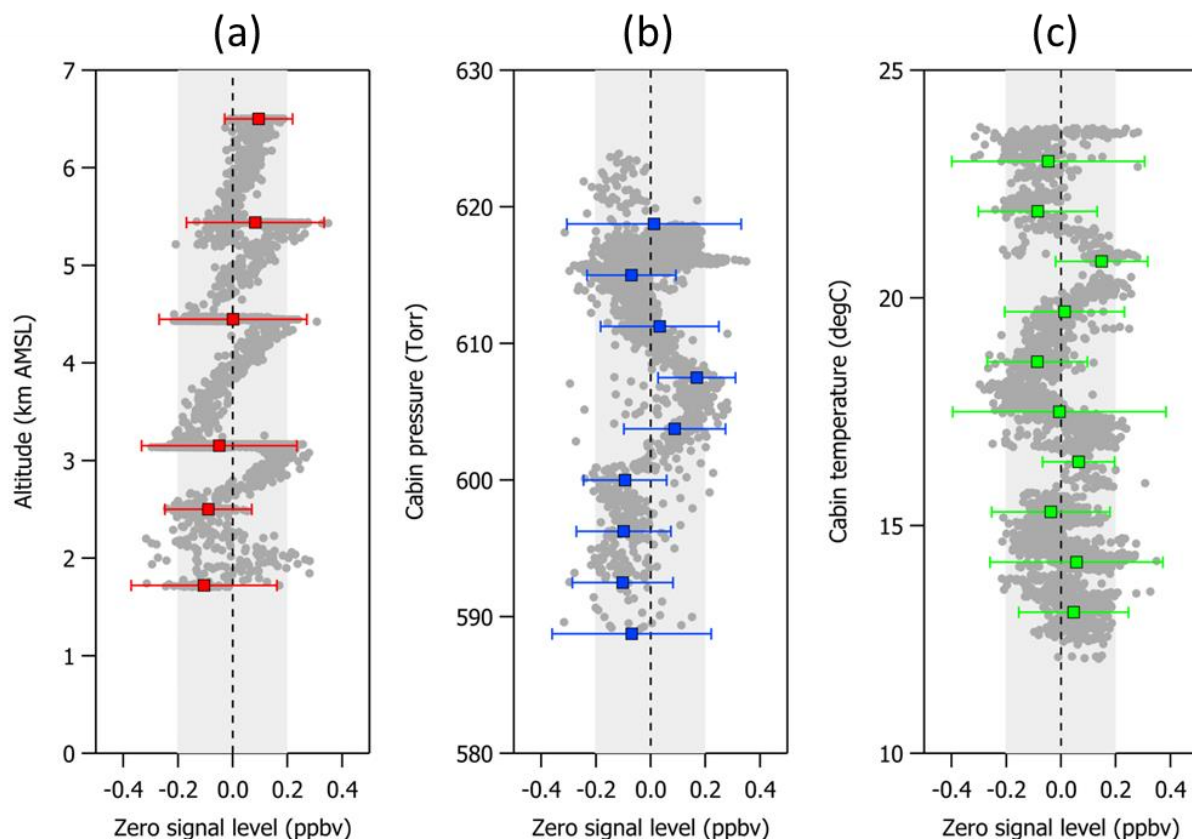

Figure 1: (a) Schematic the instrument as configured for flight on the NSF/NCAR C-130 aircraft. The sample flow path (blue arrows) starts at the inlet tip, which protrudes slightly from the face of the aircraft inlet strut. A PFA injection block housed inside the aircraft inlet strut allows calibration gases and passivant to be added to the sample stream within a few centimetres of the inlet tip.
