S1 Abstract – description of the supporting material

This Supporting Information material is intended to clarify and extend the analysis presented in the manuscript text and includes sections S1-S6: S1 Abstract – description of the supporting material, S2 Experimental setup and conditions, S3 Ion signal to concentration conversion, S4 Calibration measurement, S5 Product distributions – specific reaction products, S6 Organic ion peaks devoid of the reagent ion. In addition, this material includes Supporting Figures S1-S3 showing example spectra obtained with the MION.

S2 Experimental setup and conditions

All experiments were performed in tubular flow reactors under ambient conditions, at about 293 K and 1 bar pressure of air. Two flow reactors were used to vary the reaction time with a constant 20 *liters-per-minute* (lpm) inlet flow rate to the MION. A 2.44 cm *inner diameter* (i.d.) and 80 cm length, and 7.7 cm i.d. and 120 cm length reactors were utilized, which allowed for reaction times of around 2 and 10 seconds. Cyclohexene ($\geq 99\%$ Sigma-Aldrich) and α -pinene (98% Sigma-Aldrich) were obtained either by bubbling through a liquid reservoir or from self-made, premixed gas cylinders, embedded in N₂. The hydrocarbon precursor was turbulently mixed with the bath gas and ozone few centimeters upstream of the flow reactor. In most of the experiments the hydrocarbon precursor concentrations utilized were close to 100 *parts-per-billion* (ppb) but were also varied to inspect the concentration dependence of the detection of the current inlet design (*see for example manuscript Figure 5*). The oxidant ozone (O₃) flow was kept constant, resulting at about 50 ppb concentration in the reactor, and was produced by a commercial O₃-generator (UVP, SOG-2), and quantified by an ozone analyzer (Thermo Scientific model 49i). All the gas flow rates were regulated by calibrated mass flow controllers (Bürkert T8742 and MKS GM100A). The mass spectra were obtained with a *chemical ionization atmospheric pressure interface time-of-flight mass spectrometer* (CI-APi-ToF, Tofwerk).

S3 Ion signal to concentration conversion

The measured raw ion signals were converted into concentrations by normalizing them with the reagent ion current, *i.e.*, dividing the measured ion signals by the amount of available charge carriers, and multiplying them by a calibration factor determined separately. For the NO₃⁻ reagent ion mode the measured ion signals [S] are divided by $\Sigma[(\text{HNO}_3)_x\text{NO}_3^-]$, where $x=0-3$, to account for the most prominent reagent ion adducts (*equation S1; see Figure S1 for reagent ion spectra*). In the Br⁻ case the charge carrier is solely Br⁻ (*or potentially Br⁻ + Br*H₂O*). These normalized signals are then further multiplied with a ion-specific calibration factor ($C_{\text{H}_2\text{SO}_4/\text{NO}_3^-, \text{Br}^-}$, *see below*). The conversion procedure can be depicted by equation (S1):

$$[\text{Product}] = C_{\text{H}_2\text{SO}_4/\text{NO}_3^-, \text{Br}^-} \frac{[\text{S}]}{\Sigma[(\text{HNO}_3)_x\text{NO}_3^-]}, \quad x = 0-3 \quad (\text{S1})$$

S4 Calibration measurement

The ion modes of the MION were independently calibrated against photochemically produced sulfuric acid (SA) (Kürten et al., 2012), which has been the general method for calibrating NO₃⁻ based CI-APi-ToF response to highly-oxidized multifunctional product (=HOM) detection (*e.g.*, Ehn et al., 2014; Rissanen et al., 2014; Jokinen et al., 2015) and bases on the assumption that SA and HOM are both charged with collision frequency in the NO₃⁻ CIMS (Ehn et al., 2014). Manuscript Figure 2 showed the obtained calibration plots, in which the measured and normalized H₂SO₄ signals were compared to values determined by a simulation of a set of reactions describing the OH initiated SO₂ photo-oxidation, and the relevant gas motion within the tubular CIMS inlet. The intensity of the light source was determined in separate actinometry measurements and the [OH] generated by H₂O photolysis at 185 nm was corrected for reactive and diffusional loss, as was done also for other reactive species in the mechanism. The whole SA calibration procedure is described in detail in Kürten et al., 2012.

S5 Product distributions – specific reaction products

Figure S1 shows examples of NO₃⁻ and Br⁻ reagent ion distributions obtained with the MION setup. The top panel shows the full mass spectrum with reagent, monomer and dimer mass ranges indicated by dotted rectangles. The bottom panel shows a zoom into the reagent ion mass range and the inset in the bromide spectrum shows the detected HO₂ and H₂O₂ adducts with Br⁻. The mass axis of the Br⁻ spectrum has been displaced by 17 Th to position the same product compositions on top of each other.

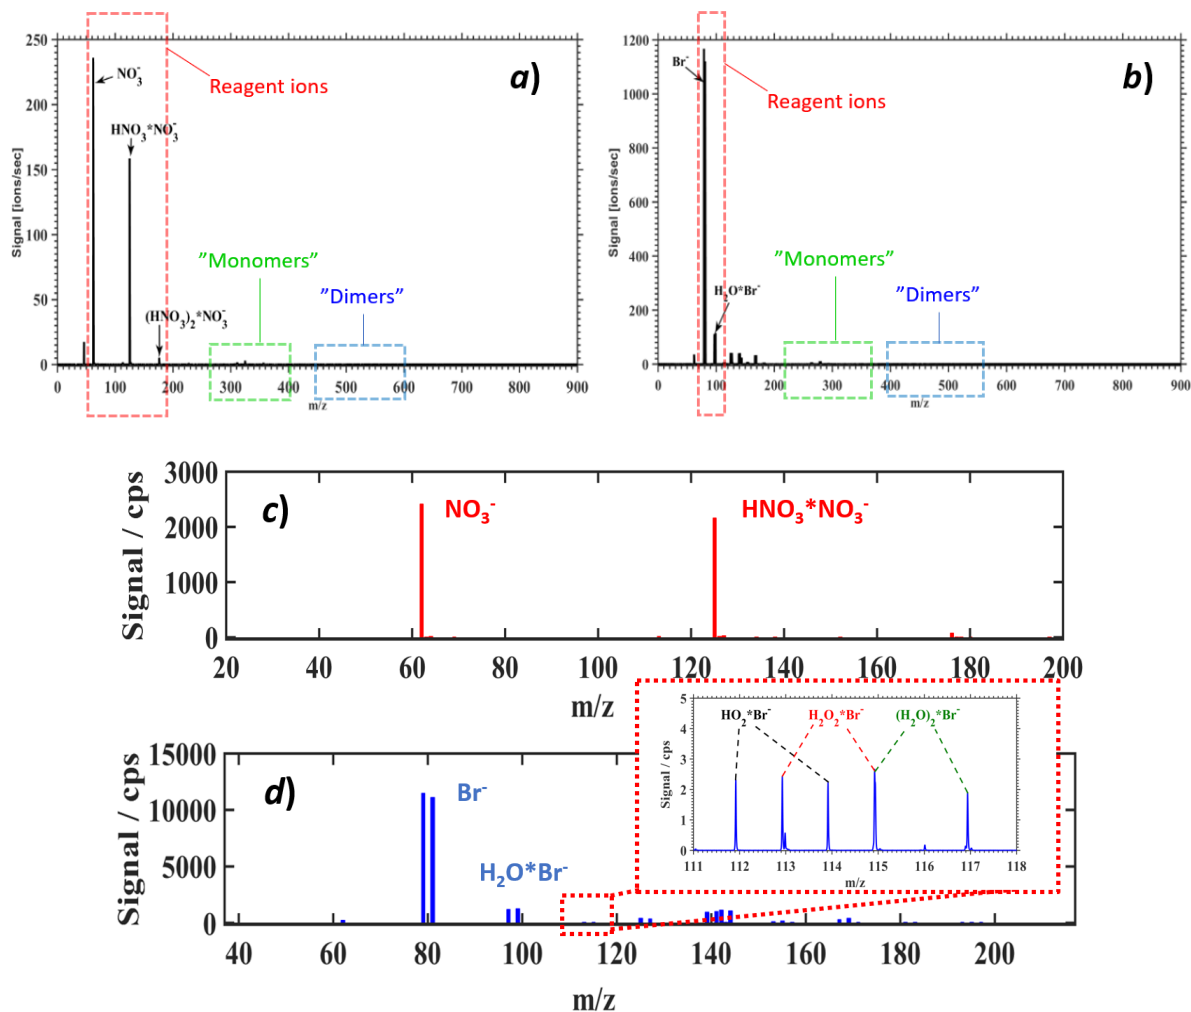

Figure S1 *a)* NO₃⁻ (nitrate) and *b)* Br⁻ (bromide) spectra recorded during an α -pinene ozonolysis experiment. Specific regions of the spectra associated with denser populations of product peaks have been labelled, and correspond to reagent ions (red), monomers (green), and dimers (blue). *c)* Shows the nitrate, and *d)* the bromide reagent ion spectrum. Also shown in the inset of figure d) are a few product peaks measured with Br⁻: hydroperoxy radical (HO₂*Br⁻), hydrogen peroxide (H₂O₂*Br⁻) and a water dimer adduct (H₂O)₂*Br⁻.

In Figure S2 the cyclohexene HOM distribution obtained with both ion modes is presented analogously to the manuscript Figure 4 of α -pinene product distribution. The mass axis of the Br⁻ has again been displaced by 17 Th to position the same product compositions on top of each other.

Figure S2 Example spectra obtained from cyclohexene ozonolysis experiments in both ion modes shown with a common product mass axis, *i.e.*, the Br^- spectrum is displaced by 17 Th (=difference between reagent ion Br^- and NO_3^- masses) to overlap the same composition products horizontally. Upper panels (red) show nitrate spectra and lower panels (blue) bromide spectra. **a)** Illustrates the reagent ion peaks, **b)** the monomer range (*i.e.*, oxidation products which have the same number or less carbon atoms than cyclohexene), and **c)** the dimer range (*i.e.*, oxidation products with about two times the carbon number of cyclohexene), respectively.

S6 Organic ion peaks devoid of the reagent ion

Several organic product ions (*i.e.*, ionized products observed without the adduct forming reagent ion) were detected with both ionization modes. Whereas the NO_3^- only deprotonates few of the strongest inorganic acids (*e.g.*, H_2SO_4 and HIO_3) and a collection of dicarboxylic acids (*e.g.*, adipic acid, $\text{C}_6\text{H}_{10}\text{O}_4$), bromide ionization results in significantly more organic ions as evident from Figure S3. The observed product ion compositions indicate deprotonation by Br^- as the most likely source for these species. However, dehydroxylation of peroxy acids by $\text{Br}^+\text{H}_2\text{O}^-$ could be expected in analogy to $\text{I}^+\text{H}_2\text{O}^-$ (Mielke et al., 2012; Iyer et al., 2017). While the current purely experimental approach does not give insight into the mechanism of generation of these organic ions, it is obvious they are much more prevalent with Br^- than with NO_3^- ionization.

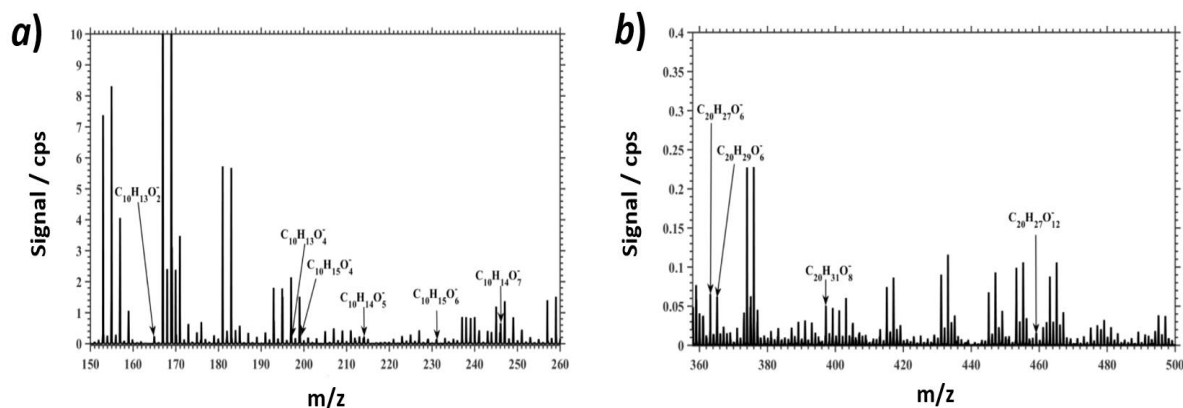

Figure S3 Examples of organic ion peaks detected during α -pinene ozonolysis experiment applying bromide ionization. Organic ion peaks were observed in both **a)** monomer and **b)** dimer mass ranges and were generally minor peaks in the spectra.
