Abstract

OH and HO₂ radicals are closely coupled in the atmospheric oxidation and combustion of volatile organic compounds (VOCs). Simultaneous measurement of HO₂ yields and OH kinetics can provide the ability to assign site specific rate coefficients that are important for understanding the oxidation mechanisms of VOCs. By coupling a FAGE LIF detection system for OH and HO₂ with a high pressure laser flash photolysis system, it is possible to accurately measure OH pseudo-first-order loss processes up to $\sim 100000\text{ s}^{-1}$ and to determine HO₂ yields via time resolved measurements. This time resolution allows discrimination between primary HO₂ from the target reaction and secondary production from side reactions. The apparatus was characterized by measuring yields from the reactions of OH with H₂O₂ (1:1 link between OH and HO₂), with C₂H₄/O₂ (where secondary chemistry can generate HO₂), with C₂H₆/O₂ (where there should be zero HO₂ yield) and with CH₃OH/O₂ (where there is a well-defined HO₂ yield).

As an application of the new instrument, the reaction of OH with n-butanol has been studied at 293 and 616 K. The bimolecular rate coefficient at 293 K, $(9.24 \pm 0.21) \times 10^{-12}\text{ cm}^3\text{ molecule}^{-1}\text{ s}^{-1}$, is in good agreement with recent literature, verifying that this instrument can measure accurate OH kinetics. At 616 K the regeneration of OH in the absence of O₂, from the decomposition of the β -hydroxy radical, was observed, which allowed the determination of the fraction of OH reacting at the β site (0.23 ± 0.04). Direct observation of the HO₂ product in the presence of oxygen has allowed the assignment of the α -branching fractions (0.57 ± 0.06) at 293 K and (0.54 ± 0.04) at 616 K), again in good agreement with recent literature; branching ratios are key to modelling the ignition delay times of this potential ‘drop-in’ biofuel.

1 Introduction

In the atmosphere, HO₂ and OH radicals (OH + HO₂ = HO_x) are closely coupled via several reactions as shown in Scheme 1. The short lifetimes of HO_x radicals mean that concentrations are determined by chemical production and removal and not by transport processes, making them ideal candidates as test species for our understanding of atmospheric chemical mechanisms (Stone et al., 2012; Monks, 2005; Stockwell et al., 2012).

33

34 **Scheme 1.** A simplified tropospheric HO_x cycle showing the importance of these short-lived
 35 radical species both to the chemical removal of VOCs and the formation of ozone.

36

37 In Scheme 1, the reaction of alkoxy radicals with molecular oxygen is a major route to HO₂
 38 formation; however, this is not the only significant HO₂ formation process; for example, in the
 39 atmospheric oxidation of n-butanol, HO₂ can be formed via two different mechanisms. Abstraction
 40 by OH at the α position leads to a radical which reacts with oxygen to directly produce HO₂ (R1a,
 41 R2) whereas abstraction at other sites leads to alkylperoxy radical (C₄H₉O₂) formation with varying
 42 fractions of the RO₂ forming alkoxy radicals, and subsequently HO₂ (McGillen et al., 2013) on a
 43 longer timescale, see Scheme 2.

46 The fraction of alkoxy radicals formed depends on the mechanism of RO₂ removal (reaction with
 47 NO or self or cross-reactions) and the yield of HO₂ from the alkoxy radical depends on the
 48 competition between decomposition, isomerization and reaction with O₂, which in turn will depend
 49 on the structure of the alkoxy radical, temperature, pressure and concentration of oxygen (Orlando
 50 et al., 2003). Therefore, in order to determine the HO₂ yield from the OH initiated oxidation of
 51 compounds such as n-butanol, it is important to have a selective, sensitive and time resolved
 52 method of HO₂ detection.

53

54 **Scheme 2.** The potential sites for OH abstractions in the oxidation of n-butanol. Of particular
 55 importance to low temperature combustion is the ratio of α to β branching fractions where α attack
 56 leads to chain inhibition and beta to chain propagation.

57

58 The importance of HO_2 chemistry is not limited to atmospheric processes; HO_2 is a key
 59 intermediate in low temperature (500 – 1000 K) combustion processes, particularly those involving
 60 oxygenated fuels (Zador et al., 2011). The mechanisms of low temperature combustion are of
 61 particular interest in the development of new engine technologies such as reactively controlled
 62 compression ignition (RCCI) (Reitz and Duraisamy, 2015) and are closely linked to atmospheric
 63 oxidation mechanisms. Monitoring HO_2 concentrations under the elevated temperatures and high
 64 pressures of combustion processes is therefore also of interest. In low-temperature combustion,
 65 HO_2 formation is a chain inhibition process, with OH reformation a chain propagating or chain
 66 branching process. The ratio of chain branching to chain inhibition processes is often the
 67 controlling factor in modelling ignition delay times (Agbro et al., 2017). High temperatures and
 68 concentrations of oxygen may be required to convert atmospheric processes, which take several
 69 10s of seconds at ambient temperatures (and hence may be influenced by surface chemistry or
 70 secondary reactions) to the milli- or microsecond timescale where they can be studied by flash
 71 photolysis techniques without such interferences (Medeiros et al., 2018).

72 Direct measurements of HO_2 rely on absorption techniques, and kinetic information on
 73 HO_2 reactions has been determined mainly using absorption spectroscopy. This can be achieved
 74 either with conventional absorption techniques, often in the UV, (including multipass optics to
 75 enhance the pathlength) or in the IR with cavity ring down spectroscopy (CRDS) (Assaf et al.,
 76 2018; Onel et al., 2017). However, the HO_2 UV absorption spectrum (200 - 260 nm) is broad and

77 featureless (Crowley et al., 1991), and as such, overlaps with the UV absorptions of many other
78 species present in atmospheric degradation pathways or combustion systems (particularly H₂O₂
79 and RO₂). To utilize the selectivity of the structured IR spectra, absorption methods have been
80 developed in both the mid and near-IR (NIR) (Taatjes and Oh, 1997). Mid-IR absorption features
81 for HO₂ provide sufficient absorption cross-sections for study (Jemialade and Thrush, 1990) but
82 suffer from severe pressure broadening, reducing sensitivity under the conditions relevant to
83 atmospheric and combustion systems (Thiebaud and Fittschen, 2006). Detection in the NIR has
84 similar advantages in terms of a structured spectrum providing greater selectivity; the weaker
85 absorption cross-sections are compensated by the higher powers and ease of use of NIR laser
86 sources (Gianella et al., 2016). However, pressure broadening and interference from H₂O
87 absorptions can make these measurements difficult at even low concentrations of water (10¹⁴
88 molecule cm⁻³).

89 In the atmosphere (Stone et al., 2012) and in chamber studies (Glowacki et al., 2007), HO₂
90 is detected using a sensitive, but indirect method via conversion to OH, with detection of OH via
91 laser induced fluorescence (LIF) (Hard et al., 1984; Brune et al., 1995; Fuchs et al., 2011) or
92 conversion to H₂³⁴SO₄ with subsequent detection of the acid via mass spectrometry (Edwards et
93 al., 2003; Hanke et al., 2002). In the LIF method, also known as Fluorescence Assay by Gaseous
94 Expansion (FAGE (Hard et al., 1984)), which is the technique used in this study, OH is sampled
95 into a low pressure region through a pinhole. Low pressures allow for the temporal separation of
96 resonant 308 nm fluorescence from the excitation pulse. Following the first detection axis for OH,
97 a flow of NO is introduced which reacts with HO₂ (R3):

99 The resulting OH is monitored at a second detector. The high sensitivity with which OH can be
100 detected gives HO₂ detection limits in the 10⁸ molecule cm⁻³ range for 5 – 10 s averaging, however,
101 to extract concentrations, both OH detection methods require calibration (Winiberg et al., 2015).
102 For chamber measurements of HO₂, comparisons with direct CRDS measurements have verified
103 the reliability of the calibration process (Onel et al., 2017).

104 HO₂ detection by LIF can be potentially sensitive to interferences from certain RO₂ species
105 which may also be converted to OH on short timescales. Interferences can be minimized by short
106 conversion times between NO injection and OH monitoring, utilizing low pressures, high flow

107 rates of the sample gas, and low NO concentrations to separate OH generation from HO₂ and RO₂,
108 reduced conversion of HO₂ reduces the sensitivity of this technique and as such in practice a
109 compromise between selectivity and sensitivity is used (Fuchs et al., 2011;Hard et al.,
110 1984;Whalley et al., 2013).

111 The current paper describes a significant development on our earlier FAGE based
112 instrument for time-resolved OH detection (Stone et al., 2016). In this improved system, laser flash
113 photolysis in a high pressure (up to 5 bar), temperature controllable (300 – 800 K) reactor (shown
114 in Figure 1) generated radicals which were then sampled through a pinhole forming a jet within
115 the low pressure detection region (shown in more detail in Figure 2). OH radicals were monitored
116 by LIF close to the pinhole. The jet breaks down after ~20 mm and NO was injected after this
117 point to convert some HO₂ into OH which was then detected by a second monitoring system. In
118 general, LIF becomes less sensitive at higher temperatures (due to distribution of population over
119 more rotational levels) and O₂ concentrations (due to quenching). Sampling into the low-pressure
120 region reduces both the effect of collisional quenching and temperature on the sensitivity of LIF
121 detection, although there is a reduction in the number density of the HO_x species in the expansion.
122 We report the adaptation of our time-resolved OH-FAGE instrument to allow HO₂ detection, the
123 characterization of the instrument (including development of a calibration method for HO₂ yields
124 of OH initiated reactions), and the investigation of the influence of RO₂ species. Finally, we discuss
125 the application of the technique to determine the yield of HO₂ from the reaction of OH with n-
126 butanol. The instrument has some similarities to that presented by Nehr et al. (2011) where a
127 conventional OH lifetime instrument was altered to allow for chemical conversion of HO₂ to OH
128 and hence the sequential determination of OH and HO₂.

129

130 **2 Experimental**

131 Reactions were carried out in a high pressure (0.5 – 5 bar) reaction cell which is described in
132 greater detail in Stone et al. (2016) and schematics of which are shown in Figures 1 and 2. The
133 high-pressure reactor was a 0.5 m stainless steel tube with a 22 mm internal diameter. Gas flows
134 were delivered to the high-pressure cell from a mixing manifold where calibrated mass flow
135 controllers (MFC) allowed for accurate control of flow rates. Low vapour pressure compounds:
136 OH precursors (H₂O₂), and substrates methanol and butanol, were delivered to the mixing manifold

137 from, thermostatted bubblers in pressure regulated backing flows of nitrogen (N_2). Ethane and
138 oxygen were delivered directly from cylinders into the mixing manifold through MFCs. The gas
139 flowrate through the cell was kept under laminar conditions with typical Reynolds values (Re) of
140 480 (corresponding to a flow rate for an experiment of 10 SLM at 2 bar); in general conditions
141 were maintained between 400-800 Re ($Re < 2400 =$ laminar flow), with some experiments carried
142 out with higher flowrates, up to 1800 Re .

143 Temperature control of the reactor between room temperature and 800 K was achieved by
144 altering the voltage applied to a coil heater (WATROD tubular heater, Watlow) over the last 30
145 cm of the stainless-steel tube. The heated region was fitted with a quartz liner (inner diameter 18
146 mm) to reduce wall-initiated chemistry. A temperature readout, from a type K thermocouple in the
147 gas flow, close to the pinhole, was calibrated for given flow rates, pressures and voltage settings
148 by measuring the highly temperature sensitive OH and methane rate coefficient, using the
149 temperature dependence reported by (Dunlop and Tully, 1993). A more detailed description of
150 this method is described within instrument characterization (Section 3.4).

151

152 **Figure 1.** Schematic plan of the apparatus.

153

154 The photolysis of the OH precursor, H_2O_2 , at 248 nm (Lambda Physik, Compex 200
155 operated using KrF at 1 or 5 Hz) or 266 nm (frequency quadrupled Nd-YAG output, Quantel, Q-

156 smart 850 at 1 or 10 Hz) initiated the chemistry. No significant difference was noted in the kinetics
157 or yields as a function of laser repetition rate.

159 Hydrogen peroxide was used as the OH precursor for all experiments where HO₂ detection was
160 performed, because it also acts as an internal calibrant to relate OH and HO₂, via reaction R5:

162 However, in general, other OH precursors can be used. The OH precursor was maintained at low
163 concentrations ($1 \times 10^{14} - 1 \times 10^{15}$ molecule cm⁻³) to minimise errors associated with assigning
164 pseudo-first-order kinetics for the loss of OH, and to reduce radical-radical reactions. Maintaining
165 a low radical precursor concentration had the additional advantage of minimising attenuation of
166 the photolysis beam, ensuring consistency in the initial radical concentrations generated along the
167 length of the high-pressure cell. Initial OH concentrations were in the range $2 \times 10^{11} - 5 \times 10^{13}$
168 molecule cm⁻³.

169 A pinhole (diameter < 0.15 mm) at the end of the high-pressure reactor couples the reactor
170 to the low-pressure (0.3 – 5 Torr) detection cell. Details on OH detection can be found in Stone et
171 al. (2016). The accuracy of the instrument for OH measurement has recently been verified by
172 measurements of the rate coefficient of the reaction of OH with isoprene (Medeiros et al., 2018)
173 which are in excellent agreement with the literature. A more detailed schematic for the low-
174 pressure detection cell is shown in Figure 2.

175 In the first low pressure detection cell, the OH was probed within the jet expanded gas,
176 close to pinhole (<5 mm), perpendicular to the gas flow. The OH was detected by off-resonance
177 laser induced fluorescence (LIF) at 308 nm following excitation with 282 nm light ($\text{A}^2\Sigma(v' = 1)$
178 $\leftarrow \text{X}^2\Pi(v'' = 0), \text{Q}_{11}$). The 282 nm light was the frequency doubled output of a dye laser
179 ((Rhodamine 6 G, Spectron) pumped at 532 nm by a Nd:YAG laser (Spectron), or (Rhodamine 6
180 G, Continuum) pumped by a Nd-YAG laser (Quantel, Q-smart 850)). Measuring the off-resonance
181 fluorescence allowed the use of a filter (308 ± 5 nm, Barr Associates) before the photomultiplier
182 (Perkin-Elmer C1943P) to remove scattered light and improved the signal to noise ratio.

183
 184 **Figure 2.** Detailed schematic elevation of the low-pressure detection region of the reactor. The
 185 blue line represents the jet expanded gas; the jet breaks down after approximately 2 cm. NO was
 186 injected through a 1.5 mm id stainless steel tube after the breakdown of the jet.

187
 188 A delay generator (BNC DG535) was used to vary the delay (time resolution ~10 ns)
 189 between the photolysis and probe laser, facilitating generation of time profiles of the OH
 190 concentration. The traces, typically 200 – 300 data points and ranging in time from ~50 μ s – 20
 191 ms, were scanned through multiple times (5 – 20) and the signal at each time point was averaged,
 192 giving high precision OH loss traces. An example OH trace from the first detection cell for reaction
 193 R5 is presented in Figure 3. As reactions were carried out under pseudo first order conditions
 194 ($[\text{OH}] \ll [\text{substrate}]$), the time dependence of the OH LIF signal, I_f , (proportional to the $[\text{OH}]$)
 195 was given by:

$$I_{f,t} = I_{f,0} e^{-k_{\text{OH}} t}$$

196
 197 where $k_{\text{OH}} = k_5 [\text{H}_2\text{O}_2]$. In Figure 3 two traces are presented from the first, OH, detection axis, these
 198 two traces were taken in consecutive experiments with a constant $[\text{H}_2\text{O}_2]$ where the first trace
 199 ($k_{\text{OH},1\text{st}} = (2351 \pm 22) \text{ s}^{-1}$) was taken where N_2 was flowed into the low pressure region, the second

200 trace ($k_{\text{OH},1\text{st}} = (2389 \pm 18) \text{ s}^{-1}$) was taken when this flow had been switched to NO to allow HO₂
201 detection in the second detection cell, errors are given as 2σ . The similarity of the OH decay traces
202 when either N₂ or NO was injected shows that there was no back streaming of NO in the low-
203 pressure cell and hence no HO₂ conversion at the first detection axis.

204
205 **Figure 3.** An example of the OH signal (solid blue triangles) collected at the first detection axis
206 for the reaction of OH with H₂O₂ ($[\text{H}_2\text{O}_2] \approx 1.4 \times 10^{15} \text{ molecule cm}^{-3}$, with a flow of N₂ into the
207 low-pressure cell, with open black squares representing the subsequent trace taken with a flow of
208 NO. The red lines represent the non-linear least squares fits to an exponential decay ($k_{\text{OH},1\text{st}} =$
209 $(2351 \pm 22) \text{ s}^{-1}$ and $k_{\text{OH},1\text{st}} = (2389 \pm 18) \text{ s}^{-1}$), 2σ errors.

210

211 HO₂ radicals were monitored by the chemical transformation of HO₂ to OH via reaction
212 with NO (R3) in the low-pressure cell. Following the breakdown of the jet, after the Mach disk
213 (>2 cm beyond the pinhole), a small flow (5 sccm) of NO or N₂ was introduced into the low-
214 pressure cell via a 1.5 mm i.d. stainless steel pipe (for a typical 0.5 Torr pressure in the FAGE cell
215 the NO concentration was 5.5×10^{13} molecule cm⁻³). After passing through the first detection cell,
216 the probe beam was redirected through the second low-pressure detection cell downstream of the
217 NO pipe allowing for the measurement of the OH concentration by LIF in the same manner as in
218 the first cell.

219 By switching between a flow of N₂ and NO, through the pipe, traces for OH loss and HO₂
220 formation could be elucidated, examples of which are shown in Figure 4. Subtraction of the two
221 OH traces in Figure 4, (upper, red trace is with NO injection and the signal corresponds to reactant
222 OH and OH produced from the titration of HO₂ to OH, lower, blue trace with N₂ injection is
223 reactant OH only) gave a resultant signal associated with HO₂ production in the high-pressure
224 reactor, shown the pink trace in Figure 4. The signal from the first PMT allowed for correction of
225 the signal heights at the second PMT for changes in the probe laser power or wavelength, any
226 variations in laser power or wavelength affect the absolute signal retrieved from both PMTs;
227 however, the relative signals retrieved from the PMTs remain consistent.

228 Fits to the HO₂ formation traces and OH loss traces from the second cell generated kinetic
229 parameters which differed from the accurate parameters collected at the first detection axis, $k_{\text{OH},2\text{nd}}$
230 = $(1390 \pm 44) \text{ s}^{-1}$ and $k_{\text{HO}_2,2\text{nd}} = (1080 \pm 150) \text{ s}^{-1}$ where the accurate loss parameters from the first
231 cell were $k_{\text{OH},1\text{st}} = (2389 \pm 18) \text{ s}^{-1}$, 2 σ errors. This difference was the result of transport effects. By
232 comparison of the loss and formation parameters derived for OH + H₂O₂, for the first and second
233 detection cells, HO₂ formation rates could be assigned from a calibration plot (Figure 7).

234

235 **Figure 4.** Examples of OH fluorescence traces collected at the second detection axis under the
 236 same conditions for Figure 3. The blue triangles are where N₂ has been injected through the pipe,
 237 i.e. no HO₂ to OH conversion. The OH signal profile differs from that in Figure 3, with $k_{\text{OH},2\text{nd}} =$
 238 $(1390 \pm 44) \text{ s}^{-1}$ (2 σ errors), additionally, there is a time-delay to peak OH, representing the
 239 transport time (primarily the time taken to travel from the breakdown of the jet to the second
 240 detection axis). The red circles are the OH signal obtained with NO injection. At short times the
 241 signal is dominated by reactant OH, but at times greater than 2 ms, the signal is dominated by OH
 242 titrated from the HO₂ product. The resultant OH trace associated with HO₂ formation in the high-
 243 pressure cell obtained by subtracting the two OH traces, obtained with either NO or N₂ injection
 244 prior to the second detection axis, shown as black triangles, a biexponential growth and decay fit,
 245 black curve, gave a formation rate coefficient, $k_{\text{HO}_2,2\text{nd}} = (1080 \pm 150) \text{ s}^{-1}$ (2 σ error).

246

247 Neither of the OH determinations in the two detection axes provide absolute measurements
 248 of radical concentrations. Each detection axis could be calibrated as for chamber measurements,
 249 but for our purposes a calibration reaction linking photolytically produced OH and HO₂ removes

250 many sources of error compared to an absolute calibration. The reaction of OH with the radical
251 precursor H₂O₂ which directly forms HO₂ with a 100 percent yield was used for calibration.

253 For reactions carried out where a reagent was added in addition to the H₂O₂, the resulting ratios
254 can be compared with those from the calibration reaction to allow assignment of an observed HO₂
255 yield. To assign the HO₂ yield from the test reaction required accounting for secondary HO₂
256 production in the high-pressure reactor, from OH + H₂O₂ and photolysis processes. From the
257 known rate coefficients, it was possible to calculate the fraction of OH reacting with the H₂O₂
258 (typically 5 – 10%) and hence the expected contribution to the HO₂ signal. Photolytic production
259 of HO₂ was accounted for by measuring the observed HO₂ signal in the absence of any H₂O₂.

260 In a typical experiment, the reaction of OH and H₂O₂ would be carried out four times, twice
261 in the absence of NO and twice with the addition of NO to calibrate the instrument. Exponential
262 fits to the OH decay as monitored in the first cell determine the peak OH signal. The OH signals
263 at the second detector recorded with only N₂ addition (reagent OH reaching the second detector)
264 and subtracted from the signal with NO added (reagent OH and HO₂) to give the net HO₂ signal.
265 This profile was fitted to, a biexponential growth and decay function, to extract the peak HO₂
266 signal for that set of conditions. Combinations of traces were then used to obtain an averaged value
267 (and uncertainty) of the signal on the first PMT (OH) to the net HO₂ signal at the second PMT for
268 this calibration reaction where OH reactant and HO₂ product have a 1:1 relationship. The same
269 process was then performed in the presence of the compound of study. The removal pseudo-first-
270 order rate coefficient with H₂O₂ and the reagent of study ($k'_{\text{OH},1\text{st}} = k_{\text{OH}+\text{H}_2\text{O}_2}[\text{H}_2\text{O}_2] +$
271 $k_{\text{OH}+\text{TEST}}[\text{TEST}]$) was compared to the removal pseudo-first-order rate coefficient with only H₂O₂
272 ($k'_{\text{OH},1\text{st}} = k_{\text{OH}+\text{H}_2\text{O}_2}[\text{H}_2\text{O}_2]$) to assign what fraction of the OH reacted with the H₂O₂ precursor and
273 hence the resulting contribution to the observed HO₂. Comparison of the remaining peak ratio to
274 the ratio from the H₂O₂ and OH calibration experiment provided the experimentally derived HO₂
275 yield for reaction of OH and the reagent of study.

276 Branching ratios to direct HO₂ formation could be assigned with an accuracy of ~10 %, the
277 limitations to this were signal to noise effects, where improved signal to noise could be achieved
278 by increasing the precursor concentration and photolysis energy. However, this was limited by the

279 need to ensure pseudo-first-order conditions were maintained and to minimize radical-radical
280 processes. Ensuring the dominant reaction was between OH and the reagent of study, whilst still
281 being able to accurately measure the initial OH conditions, provided a limit to the maximum
282 removal rates achievable ($k_{\text{OH},1\text{st}} < 30,000 \text{ s}^{-1}$).

283

284 **3 Instrument Characterization**

285 Many reactions of atmospheric and combustion interest are studied in the presence of oxygen
286 leading to the generation of peroxy radicals (RO_2). For certain RO_2 there is a potential to generate
287 OH and HO_2 on a fast timescale and therefore three well known reactions were chosen to
288 characterize the instrument, OH and ethane, OH and ethylene, and OH and methanol.

293 OH and ethane (R6) gives an assessment of any false yields generated from RO_2 and NO from
294 prototypical alkyl RO_2 species that will be formed from many atmospherically relevant reactions.
295 Ethylene and OH (R7) forms a hydroxy alkyl peroxy radical, the typical RO_2 species known to
296 create interferences in FAGE HO_2 detection systems (Fuchs et al., 2011; Hard et al., 1984; Whalley
297 et al., 2013). Minimizing and understanding the HO_2 yield from this reaction allowed for limits to
298 the selectivity of the instrument to be known. The reaction of OH with methanol is a well
299 understood reaction; the two isomeric radical products react with oxygen on differing timescales
300 to generate HO_2 . Complete conversion of both isomers should yield 100 % HO_2 .

301 As discussed in the experimental section, transport effects after the breakup of the sampling
302 jet mean that rate coefficients measured in the second cell $k_{\text{X},2\text{nd}}$ ($\text{X} = \text{OH}$ or HO_2) differ from each
303 other (transport effects scale with mass) and from those made in the first detection axis ($k_{\text{OH},1\text{st}}$).
304 Pseudo-first-order rate coefficients from the two detection axes were compared to ascertain
305 whether measurements in the second detection axes can be used to make quantitative kinetic
306 measurements.

307 Finally, the layout of the apparatus makes it hard to accurately measure the temperature at
308 which the reaction occurs; for reactions occurring on a millisecond timescale, the relevant reaction
309 distance from the sampling pinhole is approximately 0.05 - 0.5 mm. Compared to a conventional
310 slow flow laser flash photolysis/laser induced fluorescence apparatus, where the reaction volume
311 is the overlap of the perpendicular photolysis and probe laser beams, it is hard to accurately
312 position the thermocouple and additionally, any thermocouple located close to the sampling
313 pinhole may affect the flow into the low pressure system. In addition to the difficulties in correctly
314 siting a thermocouple, there are additional errors (flow, conduction and radiative) that derive from
315 measuring the temperature of a flowing gas with a thermocouple. We have therefore performed
316 additional experiments to determine the temperature based on the well characterized and
317 temperature sensitive reaction of OH and methane.

318

319 **3.1 Interference by RO₂ species**

320 Selectivity in measuring HO₂ concentrations plays an important role in the viability of detection
321 methods for monitoring reactions important for atmospheric chemistry. At high pressures, the
322 reaction of NO with many atmospherically relevant RO₂ species in the presence of oxygen induces
323 HO₂ formation. By performing the titration in the low-pressure cell with the NO + HO₂ reaction
324 under ‘starved NO’ conditions minimized this effect. This premise was validated by measuring the
325 OH + ethane and OH + ethylene HO₂ yields under high oxygen conditions. In our system the
326 typical oxygen concentrations in the high pressure reactor were varied between 1×10^{16} and $5 \times$
327 10^{17} molecule cm⁻³ which led to concentrations in the low pressure cell of 3×10^{12} to 2×10^{15}
328 molecule cm⁻³.

329 The reaction of OH + ethane (R6) under high oxygen conditions permits the rapid
330 formation of the ethylperoxy radical, which is an RO₂ radical that has a typical slow, NO
331 propagated, route to HO₂ formation (R11 – R12).

333 ($k_{11, 298 \text{ K}} = 8.70 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$) (Atkinson et al., 2006)

335 ($k_{12, 298 \text{ K}} = 9.48 \times 10^{-15} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$) (Atkinson et al., 2006)

336 Under a variety of NO flows the apparent HO₂ yield for the OH + C₂H₆ system was 3 ± 6 %, which
337 indicates that for most reactions carried out in our system, chemical transformation by reaction
338 with NO, was sensitive to HO₂ rather than RO₂ species, where the RO₂ radical was the product of
339 O₂ addition to a simple alkyl radical.

340 The reaction of ethylene and OH (R7) in the presence of oxygen forms the
341 hydroxyethylperoxy radical (HOCH₂CH₂O₂), and reaction of the HOCH₂CH₂O₂ with NO in the
342 presence of O₂ provides a route for the prompt regeneration of OH. For this reaction, an apparent
343 HO₂ yield of 100 ± 15 % was observed; however, by varying the concentration of NO added to
344 low pressure cell (between 5 × 10¹³ and 5 × 10¹⁴ molecule cm⁻³), the formation rate of OH was
345 reduced minimizing the apparent yield observed (<70 %) and slowing the observed rate of OH
346 regeneration (<1000 s⁻¹).

348 ($k_{13, 298 \text{ K}} = 9.00 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$) (Atkinson et al., 2006)

350 ($k_{14, 298 \text{ K}} = 1.3 \times 10^5 \text{ s}^{-1}$) (Orlando et al., 1998)

352 ($k_{9, 298 \text{ K}} = 9.60 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$) (Atkinson et al., 2006)

353 For test reagents which can generate radicals similar to hydroxyethylperoxy, our instrument will
354 detect both HO₂ and RO₂ with some selectivity to HO₂. Potential RO₂ interference can be tested
355 by examining the ‘HO₂’ yield as a function of added [NO].

356

357 **3.2 OH + methanol**

358 To verify the accuracy of the method for determining HO₂ yields the reaction of OH and methanol
359 (R8) was examined. The branching ratio for the α abstraction to yield CH₂OH (R8a) reported by
360 the IUPAC evaluation and based on the experimental data of McCaulley et al. (1989), is
361 α = (85 ± 8)% at room temperature with the methoxy yield as (15 ± 8)%. Reaction R8 was studied
362 at room temperature with the reaction being initiated by the photolysis of H₂O₂ at 248 nm. In the
363 presence of low concentrations of oxygen (< 1 × 10¹⁶ molecule cm⁻³), the α abstraction still
364 leads to prompt formation of HO₂ via R9, but R10, CH₃O + O₂, occurs on a much longer timescale

365 (the ratio $k_{9,298\text{ K}}:k_{10,298\text{ K}}$ is ~ 5000 (Atkinson et al. 2006)) and is not observed under these
 366 conditions. The observed HO₂ yield, $(87 \pm 10)\%$ (first row of Table 1) gives the fraction of reaction
 367 R8 forming CH₂OH and the value is consistent with the IUPAC evaluation.

368

369 **Table 1.** HO₂ yields from the reaction of OH with CH₃OH with varying [O₂] carried out 295 K.
 370 Errors given as 2σ .

[O ₂]/ molecule cm ⁻³	HO ₂ Yield (%)				Average HO ₂ Yield (%)
	Expt 1	Expt 2	Expt 3	Expt 4	
$<1 \times 10^{16}$	90	89	79	88	(87 ± 10)
$>2 \times 10^{18}$	93	94	100	99	(97 ± 6)
6×10^{18}	103	97	101	97	(99 ± 2)
6×10^{18}	98	102	98	98	

371

372 When higher concentrations of oxygen are used, the timescale for HO₂ production from
 373 reaction R10 decreases and now both abstraction channels lead to HO₂ detection in our apparatus.
 374 The resulting observed yield (final three rows of Table 1) is consistent with 100% conversion of
 375 OH to HO₂ and is statistically different from the low oxygen measurements based on a Welch t-
 376 test at the 98% level. The reproduction of the literature HO₂ yields from the reaction of OH with
 377 methanol under varying [O₂] demonstrates that the instrument can accurately measure HO₂ yields
 378 with good precision. It has additionally been demonstrated that the instrument had sufficient
 379 accuracy and precision to assign the branching ratios for differing abstraction channels when it
 380 was possible to separate the channels by the timescale for HO₂ generation.

381 A possible interference that could distort the yield of HO₂ is the role of the radical-radical
 382 reaction OH + HO₂ (Assaf and Fittschen, 2016):

384 At the low radical concentrations used in many experiments in this work, this reaction could
 385 contribute 5 – 10% of the OH loss in an OH + H₂O₂ calibration experiment. However, we have
 386 looked at the dependence of the HO₂ yield from both OH/H₂O₂ and from OH/CH₃OH, but see no

387 significant effects of secondary radical-radical reaction (<5%) as the calculated $[\text{OH}]_0$ is changed
388 from 5×10^{11} to 5×10^{12} molecule cm^{-3} . For the OH/CH₃OH the much larger concentrations of
389 substrate used lead to faster pseudo-first order decays, so radical-radical contribution is
390 significantly reduced. The work of Assaf and Fittschen suggests that a more significant deviation
391 in the OH loss rates, and one that we ought to be to detect given the precision of our data, should
392 be observed. It is possible that our calculations of $[\text{OH}]_0$ are over-estimated, but we note that a
393 study of the OH + H₂O₂ reaction by Wine et al. (1981), where they specifically looked for the
394 interference on OH decays from R15, could find no evidence for an increase in the loss of OH,
395 when $[\text{HO}_2]$ was artificially increased.

396

397 **3.3 Assessment of transport effects on observed kinetics**

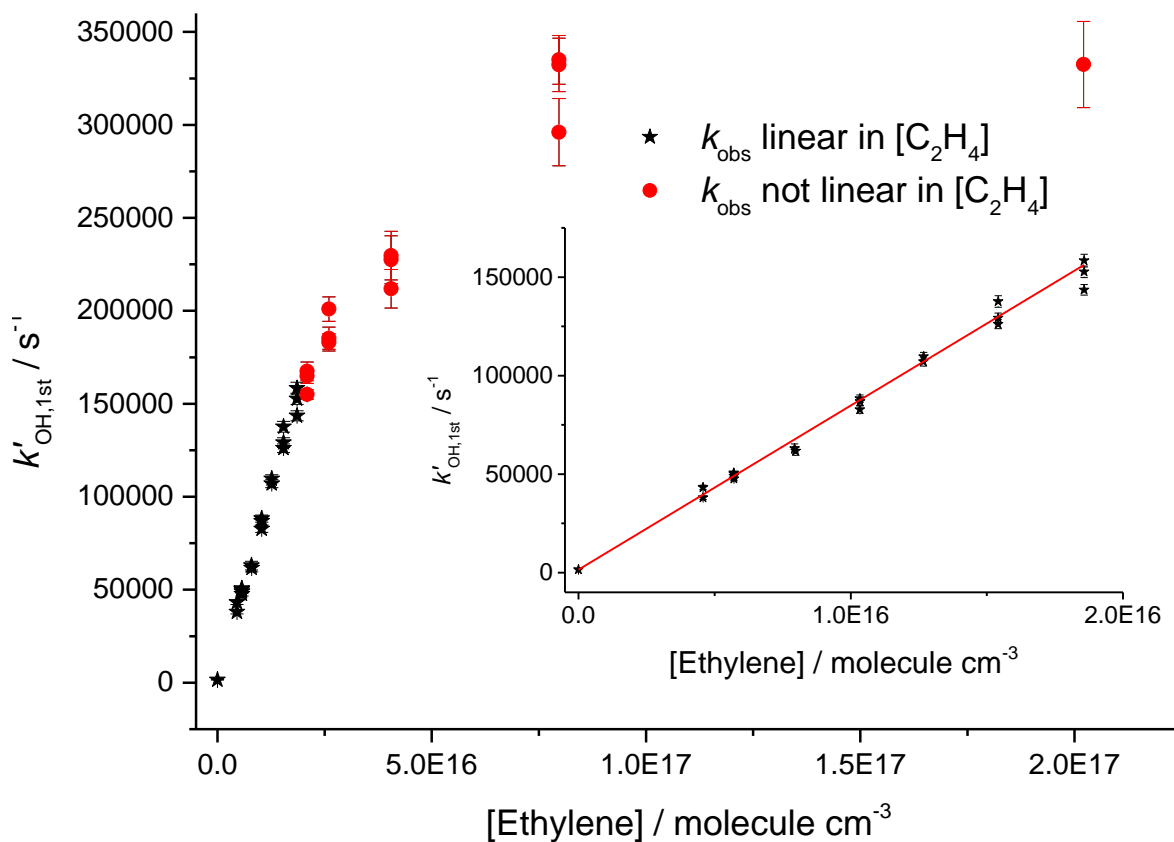

398 Due to the differing conditions in the two detection regions, the kinetics observed at the first
399 detection axis, where OH LIF was performed in the jet-expanded gas, and in the second detection
400 region, where LIF is performed 15 cm downstream from the pinhole after the breakdown of the
401 jetting gas, will be treated separately. For validating the accuracy of the OH kinetics in the first
402 cell, the reactions of OH and methane (CH₄) (Dunlop and Tully, 1993), OH and ethylene (C₂H₄)
403 (Atkinson et al., 1982; Tully, 1983) were studied. The high accuracy and precision of this system
404 for measuring OH kinetics has further been demonstrated in a recent publication on the reaction
405 of OH and isoprene (C₅H₈) (Medeiros et al., 2018).

409 When these reactions were carried out at room temperature the expected bimolecular rate
410 coefficients could be reproducibly accurately measured for observed rate coefficients less than
411 150,000 s⁻¹.

412 Studies on the reaction of OH and ethylene at room temperature and 2.2 bar, shown in
413 Figure 5, gave a value of $k_7 = (8.33 \pm 0.16) \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ (2σ errors) which matched
414 well with literature high pressure limits for OH and ethylene; where a direct pulsed laser photolysis

415 laser induced fluorescence study by Tully (1983) gave $k_7 = (8.47 \pm 0.24) \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1}$
 416 s^{-1} , and a relative rate study by Atkinson et al. (1982) found $k_7 = (8.11 \pm 0.37) \times 10^{-12} \text{ cm}^3$
 417 $\text{molecule}^{-1} \text{ s}^{-1}$. However, for pseudo-first order rate coefficients above $\sim 150000 \text{ s}^{-1}$, there was no
 418 longer a linear dependence of the rate coefficient with reagent concentration; transport effects are
 419 becoming significant even for OH detection in the jetting region.

420
 421 **Figure 5.** Bimolecular plot of the pseudo-first-order rate coefficient at the first detector, $k'_{\text{OH},1\text{st}}$,
 422 vs ethylene concentration. The figure demonstrates a linear relationship below $\sim 150,000 \text{ s}^{-1}$ (see
 423 inset for detail in linear region) but with increasing curvature, due to transport effects at higher
 424 values of $k'_{\text{OH},1\text{st}}$. Black stars symbolize where $k'_{\text{OH},1\text{st}}$ was linear with $[\text{C}_2\text{H}_4]$, red circles where
 425 $k'_{\text{OH},1\text{st}}$ showed greater than 5% deviation from linearity.

426
 427 The OH traces detected in the second cell deviated from those observed from the first cell,
 428 as shown in Figures 3 and 4. There is understandably an increased time delay from time zero (the
 429 photolysis laser pulse) to arrival of OH radicals at the second detection axis due to the increased
 430 distance travelled after sampling ($> 150 \text{ mm}$ versus $< 5 \text{ mm}$). Additionally, the arrival of OH to

431 the second axis is spread out further in time due to transport issues relating to non-linear flow
 432 conditions at the breakdown of the jet, and the arrival of the OH being affected by its velocity
 433 distribution (Moore and Carr, 1977; Taatjes, 2007; Baeza-Romero et al., 2012). Figure 6 shows a
 434 plot of observed OH rate coefficient from the first detection axis ($k_{OH,1st}$) against observed rate
 435 coefficient from the second axis ($k_{OH,2nd}$) in the reaction of OH with H_2O_2 . For values of k_{OH} below
 436 2500 s^{-1} it was possible to accurately assign an expected OH removal rate for reactions observed
 437 in the second cell ($k_{OH,2nd}$) given the observed OH kinetics at the first detection axis ($k_{OH,1st}$). This
 438 is useful to compare the kinetics of OH removal and HO_2 production.

439

440 **Figure 6.** Relationship between the observed rate coefficient for the reaction of OH with H_2O_2
 441 observed in the first cell ($k_{OH,1st}$) and the observed OH removal rate in the second cell ($k_{OH,2nd}$).
 442 The difference is non-linear but a simple fit to this could be used to assign removal rates to traces
 443 observed in the second cell below $2,500\text{ s}^{-1}$. The red line is the simplified fit of the form, $y = A * (1 - e^{-b*x})$,
 444 where A was some limit value above which no increase in measured rate coefficient
 445 would be observed.

446

447 **Figure 7.** Relationship between the pseudo-first-order rate coefficient for OH loss observed in the
 448 first cell ($k'_{\text{OH},1\text{st}}$) from the reaction of OH with H_2O_2 and the observed rate coefficients measured
 449 in the second cell ($k'_{\text{X},2\text{nd}}$ where X = OH loss (black squares, ■) or HO_2 production (red circles, ●))
 450 a non-linear fit can be used to assign removal rates and HO_2 formation rates to traces observed in
 451 the second cell below $2,500 \text{ s}^{-1}$.

452

453 As the observed kinetics in the second cell are significantly affected by the velocity
 454 distribution of the species being detected, there is again a deviation between the observed kinetics
 455 expected from the measurement of the OH radicals loss and the kinetics for HO_2 formation due to
 456 the differing masses of OH and HO_2 . Figure 7 shows the pseudo-first order rate coefficients for
 457 OH removal ($k'_{\text{OH},2\text{nd}}$) and HO_2 production ($k'_{\text{HO}_2,2\text{nd}}$) from the $\text{OH} + \text{H}_2\text{O}_2$ reaction determined at
 458 the second detection axis, plotted against the OH removal at the first detection axis. The two fits
 459 to the data shown in Figure 7 had a ratio of gradients concordant with the root of the masses for
 460 HO_2 and OH, 0.60 ± 0.14 versus the expected relationship of 0.73. As with Figure 6, it is possible

461 to establish a calibration graph that relates the kinetics of HO₂ production at the second detection
462 axis with the primary kinetics taking place in the high pressure reactor. This means that the
463 timescale over which the HO₂ yield was observed could be assigned and therefore it is possible to
464 attribute HO₂ yields to fast processes, intramolecular RO₂ decompositions or R + O₂ reactions, or
465 to slower radical-radical reactions.

466

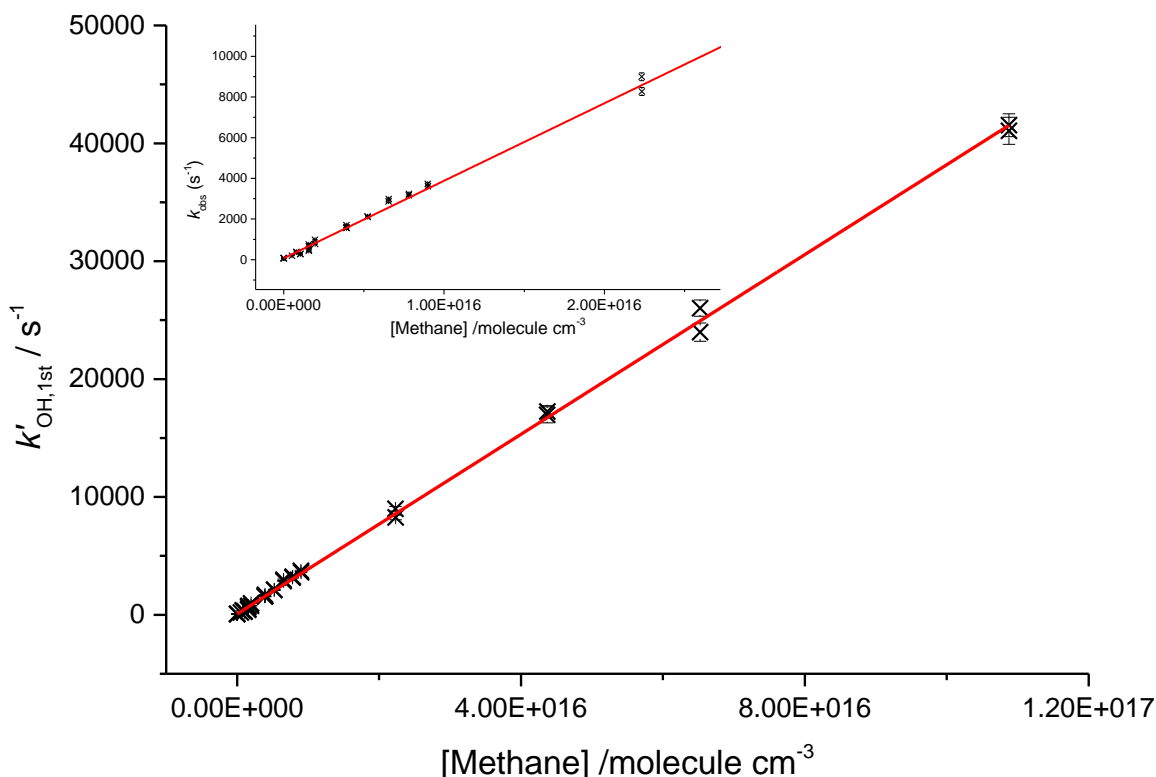

467 **3.4 Temperature corrections**

468 It is difficult to know the exact temperature at the pinhole as introducing a thermocouple close to
469 the region will affect the flows and cannot be used in routine operation. A translatable
470 thermocouple was passed along the axis of the high-pressure reactor over a variety of temperatures
471 and showed that the temperature of the gas at the pinhole varies with axial location. In addition,
472 radial profiles showed that in our system there was insufficient heating length to achieve uniform
473 radial heating of the laminar gas. From the axial measurements it was observed that slower flow
474 rates (< 5 SLM) allowed for reduced axial temperature gradients. However, these measurements
475 showed that the only manner to achieve an even thermal profile would be a static cell.

476 A permanently seated thermocouple was placed perpendicularly to the flow, close to the
477 sampling region, measurements from this thermocouple were then compared with temperature
478 assignments from the reaction of OH and methane using the temperature dependence assigned by
479 Dunlop and Tully (1993). This was performed over a range of heater settings and flows to allow
480 for temperature assignment. This method was also applied to a standard low-pressure cell where
481 the flows can be reduced to slow enough flows that thermocouple measurements could accurately
482 define the temperature to verify the method. Additionally, the well-determined OH + ethylene
483 adduct formation equilibrium was measured over a range of temperatures to provide an additional
484 verification of the temperature assignment.

485 The method to assign a temperature from the reaction of OH and methane used the pseudo-
486 first order rate coefficients ($k'_{\text{OH,1st}}$) measured at the first detection axis over a range of added
487 methane flows. An estimate of the temperature was made from the thermocouple measurement,
488 this estimated temperature was used, along with the pressure in the reactor, to calculate the added
489 methane concentration. Comparing the predicted pseudo-first-order rate coefficient that this

490 estimated concentration provided using the literature value of $k_{\text{OH}+\text{CH}_4}$ (Dunlop and Tully, 1993) to
491 the measured rate coefficient produced a difference for each point. The estimated temperature was
492 then iteratively changed to minimize the difference between estimated and measured rate
493 coefficients. For this minimum value, the difference between thermocouple measurement and
494 actual temperature was tabulated against the voltage setting for the heater. A parameterization of
495 voltage versus temperature difference was used to estimate the temperature of the reactor for
496 experiments where no OH and methane measurements were performed and has been shown to
497 reliably predict the temperature of the reactor within 7 K when measurements have been made
498 subsequently.

499
500 **Figure 8.** Bimolecular plot for the reaction of OH and methane at 680 K, 1760 Torr using 193 nm
501 photolysis of water as an OH precursor. Here the inset shows that even at removal rates $< 1000 \text{ s}^{-1}$
502 the plot is still linear, indicating that within the measured experimental timescales there is little
503 deviation in temperature.

504

505 To assess the axial temperature gradients in the gas sampled through the pinhole over the
506 timescales of reactions measured, OH and methane rate coefficients were measured using
507 photolysis of water at 193 nm as a source of OH. Using water photolysis allowed for low removal
508 rates of OH by precursor and assignment of OH and methane over a range of pseudo-first-order
509 rate coefficients ($k'_{\text{OH,1st}}$) 100 – 40000 s⁻¹ as shown in Figure 8. This was performed at two
510 temperatures (505, 680 K), and the slope of observed OH removal rate coefficients against
511 concentration of methane appeared linear over the full range for both temperatures, thus verifying
512 that over the distances sampled within experimental timeframes there is a minimal temperature
513 gradient.

514

515 **4 Determination of Site Specific Rate Coefficients for the Reaction of OH with n-butanol**

516 The branching ratios for the sites of OH attack on n-butanol, as presented in Scheme 2, are of
517 significance to the modelling of the ignition delay times for n-butanol (Agbro et al., 2017).
518 Abstractions at the α and OH positions are chain terminating reactions at low temperatures due to
519 the formation of the relatively inert HO₂ radical, and abstraction at the β site leads to chain
520 propagation, through OH recycling. The new instrument permitted determination of the attack at
521 the α and β sites; attack at the α site leads to prompt HO₂ formation in the presence of O₂; at
522 elevated temperatures biexponential fits to non-single exponential OH loss traces in the absence
523 of O₂ (due to decomposition of the β hydroxy radical to OH and iso-butene) allowed for attack at
524 the β site to be measured.

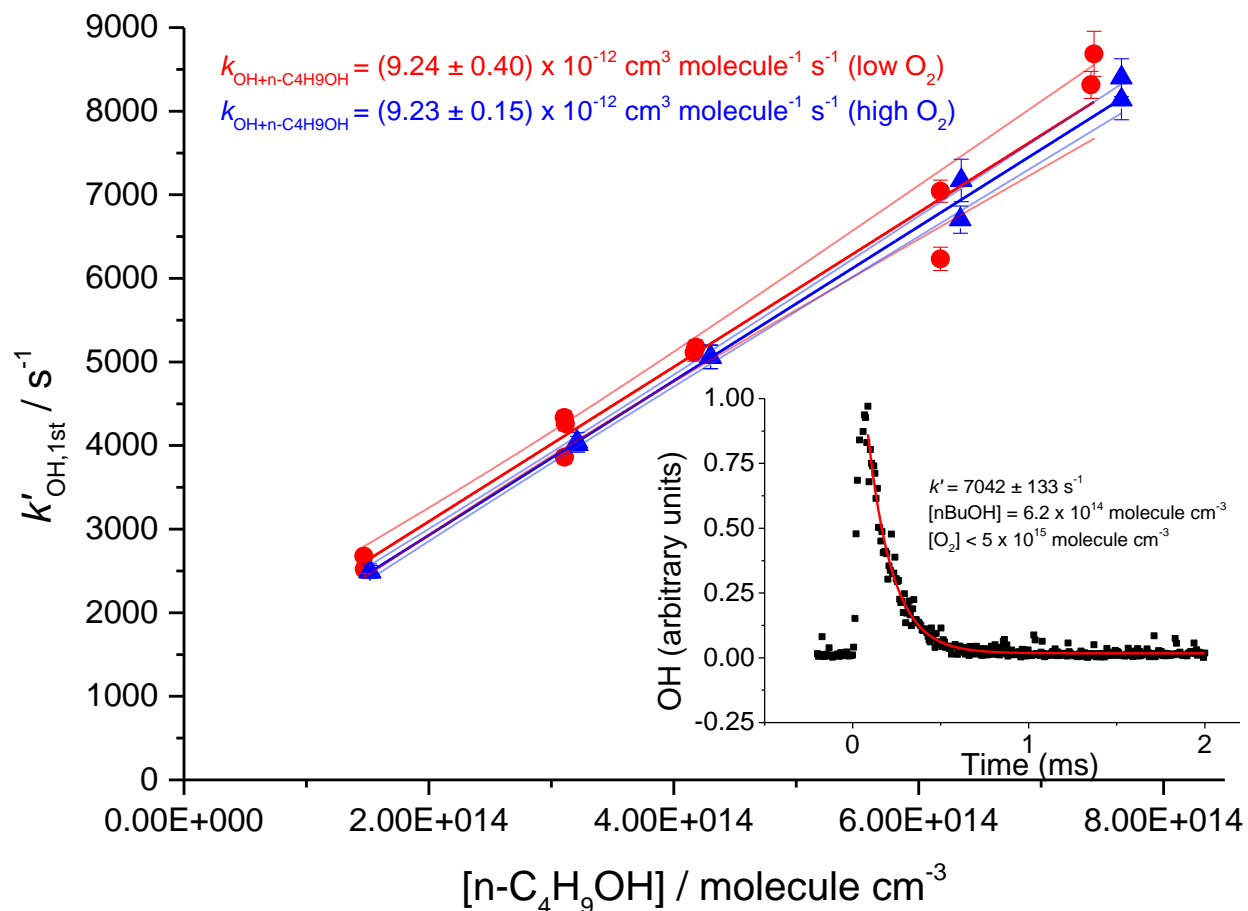

525

526 **4.1 Room temperature OH kinetics**

527 At room temperature under pseudo-first-order conditions ($[\text{OH}] < 3 \times 10^{12}$ molecule cm⁻³, [n-
528 butanol] $> 1.5 \times 10^{14}$ molecule cm⁻³), the OH loss traces recovered from the first detection axis
529 from the jet expanded gas corresponded closely with single exponential decays. These decays
530 relate to the overall loss process for the reaction of OH with n-butanol:

532 The resulting rate coefficients were plotted against the concentration of butanol, in the presence of
 533 both low and high oxygen, as shown in Figure 9 (low oxygen $< 5 \times 10^{15}$ molecule cm^{-3} , high
 534 oxygen 1.2×10^{19} molecule cm^{-3}), where $k_{\text{obs}} = k_1 \times [\text{butanol}]$, giving a resultant bimolecular
 535 removal rate of $k_1 = (9.24 \pm 0.40) \times 10^{-12}$ cm^3 molecule $^{-1}$ s $^{-1}$ under low oxygen conditions, and k_1
 536 $= (9.23 \pm 0.15) \times 10^{-12}$ cm^3 molecule $^{-1}$ s $^{-1}$ under high oxygen conditions.

537
 538 **Figure 9.** Plots $k'_{\text{OH},1\text{st}}$ against the concentration of butanol, at two oxygen concentrations, $< 5 \times$
 539 10^{15} molecule cm^{-3} and 1.2×10^{19} molecule cm^{-3} . Bimolecular rate coefficients were taken from
 540 the slopes as $(9.24 \pm 0.40) \times 10^{-12}$ cm^3 molecule $^{-1}$ s $^{-1}$ under low oxygen conditions (red circles with
 541 95 % confidence limits), and $(9.23 \pm 0.15) \times 10^{-12}$ cm^3 molecule $^{-1}$ s $^{-1}$ under high oxygen conditions
 542 (blue triangles with 95 % confidence limits). The inset shows a typical OH temporal profile at the
 543 first detection axis.

544
 545 The good agreement between the measured rate coefficients with varying $[\text{O}_2]$ verifies that,
 546 as expected under our experimental conditions at room temperature, the R radical formed from the
 547 β abstraction does not undergo fragmentation to OH and but-1-ene. The resultant combined data
 548 gives an overall 293 K bimolecular rate coefficient for OH and n-butanol of $k_1 = (9.24 \pm 0.21) \times$

549 $10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$, which is in excellent agreement with the recent work of McGillen et al.
550 (2013) of $k_{1,296} = (9.68 \pm 0.75) \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$.

551

552 **4.2 Room temperature HO₂ results**

553 Experiments were carried out in high oxygen conditions ($3 \times 10^{17} - 1.2 \times 10^{18} \text{ molecule cm}^{-3}$), at
554 296 – 303 K, and high pressures (1800 – 2000 Torr) of N₂ bath gas using photolysis of hydrogen
555 peroxide at two different wavelengths (248 nm and 266 nm), and the resulting HO₂ yields are
556 shown in Table 2. The resulting HO₂ yield was determined to be $(58 \pm 7) \%$ at 266 nm, and $(55 \pm$
557 $12) \%$ at 248 nm. As there is no significant variation in the yield with laser wavelength or power,
558 we can treat the data in Table 2 as 12 independent estimates of the yield, giving an averaged HO₂
559 yield of 57% with a standard error (95%) of 6%. Therefore under the experimental conditions
560 (pressure >1800 Torr, [O₂] > $3 \times 10^{17} \text{ molecule cm}^{-3}$), the HO₂ yield, which originates from OH
561 attack at the α abstraction site, was $(57 \pm 6) \%$, with a minor contribution from abstraction from
562 the hydroxyl group. The yield assigned is in good agreement with McGillen et al. (2013) 57%, and
563 Cavalli et al. (2002) $52 \pm 7 \%$.

564

565 **Table 2.** HO₂ yields from experiments carried out at room temperature (293 – 298 K) with reaction
566 initiated by photolysis of H₂O₂ at 248 nm and 266 nm.

Laser wavelength/nm	HO ₂ Yield (%)							Average HO ₂ Yield (%)
	Expt 1	Expt 2	Expt 3	Expt 4	Expt 5	Expt 6	Expt 7	
266	61 ± 7	54 ± 4	46 ± 5	56 ± 7	54 ± 7	67 ± 10	66 ± 6	58 ± 7
248	63 ± 2	68 ± 2	48 ± 5	52 ± 5	49 ± 5			55 ± 12

567

568 Experiments were carried out with photolysis at 266 nm and at a variety of laser energies at 248
569 nm, the yields remained consistent with photolysis wavelength and power. Varying the laser power
570 did alter the profiles of the HO₂ traces recovered; the growth rates remained unaffected but the
571 tails changed; decreasing laser power slowed the removal rate of HO₂ (from greater than 100 s^{-1}
572 to under 10 s^{-1}) showing that radical-radical processes are the main source of HO₂ loss from the

573 system. If radical-radical reactions were an important source of any observed HO₂ yield changing
574 laser power would have altered the HO₂ yield and additionally the HO₂ growth kinetics.

575

576 4.3 Higher temperature – HO₂ yield and OH recycling

577 The R radical formed from abstraction at the β site (CH₃CH₂CHCH₂OH) can regenerate OH and
578 form butene, Scheme 2, in the absence of added oxygen. This process was not observed at ambient
579 temperatures (293 – 305 K) but at elevated temperatures, 616 K – 657 K, the OH loss observed at
580 the first detection axis was no longer well described by a single exponential loss process, Figure
581 10. The non-exponential decays formed were due to OH being returned following decomposition
582 of the β R radical. Biexponential fits to the recycling traces gave the fraction of OH returned
583 (Medeiros et al. 2018), with an average β branching fraction of (23 ± 4)%, Table 3.

584

585 **Table 3.** OH recycling and HO₂ yields from experiments carried out under elevated temperatures
586 (> 600 K) all experiments were carried out with photolysis at 248 nm.

Temperature (K)	Fraction of OH returned (%)	Observed HO ₂ Yield (%)
616	24.2 ± 4.1	54 ± 4 ⁵⁸⁸
622	24.4 ± 4.9	
636	25.7 ± 5.6	⁵⁸⁹
657	18.1 ± 4.0	590

591 The HO₂ yield measured at an elevated temperature (616 K), where OH recycling was also
592 observed, was 54 ± 4 % (Table 3) which is within error of the value (57 ± 6 %) measured at room
593 temperature (293 K), although it is not possible to partition the HO₂ yield between α and OH
594 abstraction. Over the temperature range tested the branching ratio for OH attack at the α position
595 is therefore also likely to remain unchanged. With the sum of the α and β sites contributing (78 ±
596 4)%, at 616 K, the remainder of the abstraction (~22%) occurs at the δ and γ sites. These results
597 are in excellent agreement of the product study of Cavalli et al. (2002) which found (52 ± 7)% α
598 from the butanal product yield and (23 ± 4) % β from the propanal yield using FTIR detection and
599 the site specific analysis by McGillen et al. (57 % α and 26% β). The product study of Hurley et
600 al. (2009) found 44 ± 4 % α and 19 ± 2 % β values which are lower than our experimental values

601 but are within the combined error ranges. However, it should be noted that the β branching fraction
602 of 23 ± 4 % measured in this study was obtained at elevated temperatures, 616 – 657 K.

603
604 **Figure 10.** An example of the OH signal collected at the first detection axis for the reaction of OH
605 with n-butanol ($[n\text{BuOH}] \approx 1.4 \times 10^{15}$ molecule cm^{-3} , at 616 K, black, red and green points were
606 three consecutive decays collected with differing timescales. The black line represents the least
607 squares fits to an exponential decay ($k'_{1,1st} = (6780 \pm 380) \text{ s}^{-1}$), with the blue line representing a bi-
608 exponential fit ($k_{1,\text{biexp},1st} = (8190 \pm 180) \text{ s}^{-1}$). Both lines are global fits to the three experiments.

609
610 **5 Summary**

611 An instrument based on the FAGE technique for monitoring OH radicals and validated via
612 reproduction of the literature kinetics of several OH reactions over a wide range of temperatures

613 and pressures, has been extended to allow for simultaneous HO₂ and OH detection via the chemical
614 titration of HO₂ to OH with NO.

615 As mentioned in the introduction, the instrument has similarities to that presented by Nehr
616 et al. (2011), where a FAGE system for sequential OH and HO₂ is coupled to a lifetime instrument
617 and yields of HO₂ from OH initiated reactions are reported. Although the principles of HOx
618 detection used in both systems is similar, there are some significant differences between the two
619 instruments. Some differences relate to the reaction cell in which the kinetics takes place: 1 atm of
620 air and 298 K for Nehr et al. and 0.5 – 5 atm of any gas and 298 – 800 K for this work. However,
621 in principle, the Nehr et al. FAGE cell could be coupled to a different reaction cell to probe a wider
622 range of conditions. A more substantial difference is the timescale of the chemistry taking place.
623 Typical temporal profiles from Nehr et al. are of the order of a second compared to <10 ms in this
624 work. The enhanced sensitivity of the Nehr et al. instrument means that radical-radical reactions
625 should not interfere, but the technique may be subject to interferences from first order (or pseudo-
626 first order) reactions including heterogeneous processes. Detection of radicals in kinetics or yield
627 experiments is difficult and studying reactions under a range of conditions is important to identify
628 systematic errors, hence both instruments have a role to play.

629 The use of H₂O₂ as an OH precursor has been shown to provide a reliable method of
630 internally characterizing our system for HO₂ yield detection. Interferences that could arise from
631 using this precursor for HO₂ detection have been accounted for, and the presence of water that the
632 H₂O₂ precursor introduces has no effect on the sensitivity of the LIF method, unlike IR absorption
633 methods.

634 It has been demonstrated that this instrument can reliably assign HO₂ yields and
635 simultaneously measure OH kinetics, even under conditions of high temperatures and high oxygen
636 concentrations, which could be challenging for other detection systems. Such conditions are
637 important for exploring key combustion chemistry reactions, and for converting slow
638 atmospherically relevant processes to the microsecond timescales required to minimize secondary
639 or heterogeneous chemistry.

640 By performing reactions under low NO_x and low radical densities ($<1 \times 10^{13}$ molecule
641 cm⁻³), HO₂ yields formed on fast timescales (> 300 s⁻¹) can be assigned to direct HO₂ channels or
642 reactions of alkyl (R) radicals with oxygen. Whilst some time-resolution is lost at the HO₂ detector,

643 sufficient time-resolution is retained in order to separate varying sources of HO₂, for example the
644 two channels leading to HO₂ production in the OH/CH₃OH/O₂ system (Section 3.2) or from
645 unwanted secondary chemistry.

646 For particular reactions, illustrated in this paper by the study of OH with methanol and
647 butanol in the presence of oxygen, the simultaneous measurement of OH kinetics and HO₂ yields
648 can provide important site-specific information. In other systems, the onset of HO₂ formation could
649 allow for the assignment of new channels becoming important within complex mechanism,
650 potentially allowing for verifying the onset of OOQOOH chemistry within OH regeneration
651 processes.

652

653 **6 Acknowledgements**

654 A studentship from NERC through the University of Leeds ‘Spheres’ Doctoral Training
655 Programme for T.H. Speak is gratefully acknowledged. We are grateful to Leanne James for help
656 with some of the measurements.

657

658 **7 Author Contributions**

659 THS undertook most of the experimental measurements and contributed to the first draft of the
660 manuscript. DS provided input into experimental design and analysis of transport effects. MAB
661 and PWS lead the project and completed the manuscript.

662

663 **8 Competing Interests**

664 The authors declare that they have no conflicts of interest.
