Response to Referee 1

General comments

The publication "Towards accurate methane point-source quantification from high-resolution 2D plume imagery" by Jongaramrungrang et al. deals with the important aspect of inverting atmospheric concentration gradients to fluxes or emission rates of not well-constraint CH4 point sources. In order to invert these observations, wind information in the measured area is needed and equally important as the concentration measurements themselves. However, as outlined in the introduction of the manuscript, acquiring wind information, preferably, simultaneously and at an adequate spatial and temporal resolution can be a challenging task. Therefore, the authors propose a new method, which solely relies on spatially resolved imaging data from airborne remote sensing instruments and high resolution large eddy simulations (LES)to estimate the prevailing wind speed during the time of the overflight. The wind speed is then derived from the shape of the observed plume and used during the inversion process to compute a flux of the investigated sources. The descripted method is a novel and promising approach to quantify CH4 point source emissions from aircraft but also potentially from space without having to rely on real wind measurements. The manuscript fits well in the scope of AMT and I recommend publication after some modifications along the line of the comments below. In general, the manuscript is well written. The method is described in a comprehensible way, however, some additional information concerning the figures would improve their readability (see also specific comments). Additionally, the authors should add some more information regarding the stated errors and their propagation to the predicted fluxes(see also specific comments). In my opinion, the manuscript could be strengthened by adding more extensive comparisons and applications to real data. So far, most parts of the approach were developed based on (theoretical) model (LES) studies, whereas only few real observations were used to support the novel approach. Therefore, I would recommend to expand on the already given examples in the manuscript:(1) controlled release experiment and(2) analyses of overflights shown in Figure 1 (see also specific comments).

We thank the reviewer for the constructive comments and appreciate the thoughtful review.

Specific comments

P2, L12:Consider to also add publications regarding the HyTES instrument(e.g., Hulley et al., 2016) or other imaging instruments, which also have CH4 point sources successfully detected, e.g., MAKO (Tratt et al., 2014).

We added Hulley et al. 2016 and Tratt et al. 2014 accordingly to cite publications for HyTES and MAKO instruments.

P2, L24f:I would suggest to either only focus on remote sensing studies (by satellite and aircraft)and remove Conley et al., 2016,or to better distinguish between remote sensing and in-situ studies. If in-situ studies are included I would also recommend to add, e.g., Cambaliza et al., 2015,Gordon et al., 2015, and Lavoieet al., 2015, which have also performed extensive analyses regarding airborne in-situ observations and resulting fluxes.

We would like to mention other studies done by an airborne in-situ approach using a mass balance calculation based on the enhancement downwind of the source. We added the citations from Conley et al., 2016; Jacob et al., 2016, Cambaliza et al., 2015, Gordon et al., 2015, and Lavoieet al., 2015.

P3, L6:"... under various background wind speeds and surface heat fluxes.": Later in the manuscript (P6, L14), it is stated that only one value for the heat fluxes was used("The surface sensible and latent heat fluxes are 400 and 40 W/m².").

We have conducted sensitivity analysis for other values of latent and surface heat fluxes and added an additional small section on this to show that the changes in sensible and latent heat fluxes do not significantly impact the results and are less crucial than wind speed. We added an additional section (6.4) into the text.

P3, L11:"... and presence of ancillary information on the actual wind speed(Section 5.3).": Based on this statement, I would expect to see a comparison between the derived wind speed based on the new method and actual wind observations or reanalysis data in Section 5.3., however, I was not able to find a paragraph referring to actual wind speed observations or reanalysis data.

We added the result of the predicted wind compared to the value from controlled release experiment to section 6.3 P11 L5. The geostrophic wind speed is predicted to be 3.3 +- 1.2 m/s, compared to the surface sonic wind at the source measured at 1.9 m/s. This is consistent given that geostrophic wind is typically higher than the surface wind speed.

P4, L1:Why not also showing a real example observation of HyTES. Maybe, there is one available for the same scene as shown in Figure 1. If this is the wrong place, because in Figure 1, the authors intend to show the high variability of the plume structure during multiple overflights, I would recommend, if available, to add a comparison of an AVIRIS-NG and HyTES observation after Figure 5, where simulated plumes observed by the two instruments are compared.

We added a scene from HyTES at the same location within approximately the same time for this comparison. However, this will be restricted to Clutter Matched Filter retrievals, which are similar but not identical to the Optimal Estimation based retrieval for which the averaging kernels were computed.

P4, L1ff:This would also be a good place to add some more information regarding the applied retrieval algorithms. As Frankenberg et al., 2016, are already cited multiple times and the plume shown in Figure 1 (bottom right) appears to be similar to the one in Figure S1 in Frankenberg et al., 2016, I assume that either the matched filter technique or the IMAP-DOAS method, described in that publication, has been used to retrieve the columns shown in Figure 1 or the ones from the controlled release experiment at the end of Section 5.3 used for a flux inversion. Similar for the HyTES algorithm if real observations are added.

For AVIRIS-NG scenes illustrated in Figure 1 the linearized matched filter technique was used. For HyTES, Clutter Matched Filter Approach (CMF) was used, as explained in the earlier comment.

P4, L26:What is the basis of the chosen threshold of 500 ppm-m? As stated in (P3, L30), it is connected to the measurement precision of the AVIRIS-NG instrument and is thus a property of the instrument (Why does it then differ from the value of 200 ppm-m applied in Frankenberg et al., 2016, Section 'IME' in 'Materials and Methods'?). Furthermore, what is the reasoning in using the same threshold also for HyTES simulations, e.g., as shown in Figure 5?

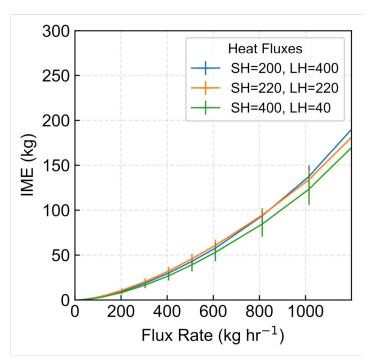

The 500 ppm-m has been chosen as a somewhat conservative threshold, close to what we expect as single-measurement noise for typical scenes. In Frankenberg et al, a lower threshold was used but data were also smoothed and plume segmentation algorithms applied. As for HyTES, we used the same threshold just to exemplify the differences due to averaging kernels only, as opposed to thresholds. We will make this clear in the revised version. For now, we don't have a unique quantitative detection threshold for HyTES, which would strongly depend on surface temperature and other variables. Thus, it is mostly for illustration at the moment.

P5, L5:Please add some explanation for the 'sum' and the parameter 'm' in Equation 2 to the text.

In the Gaussian plume model, we assume equilibrium to find the concentration of plume in 3-dimensional space. For the vertical direction, when we assume an inversion height at Z_i , the model can assume reflective boundary condition. The parameter m multiplied by Z_i indicates the height that the reflection occurs and the summation over this parameter m shows the total concentration at each height within 0 to Z_i . We added this explanation to the text.

P6, L10-15: What is a reasonable range of the proposed values (initial inversion height, potential temperature, specific humidity, surface sensible and latent heat flux) for initializing the LES model? Are these educated guesses or are they based on actual field or reanalysis data? Given these ranges, the authors could also verify their assumption "... our method ... should not be significantly impacted ..." in the conclusions (P12, L6) by performing various LES runs using different initial values. I would agree with the authors that the column-integrated enhancements are not significantly influenced by the surface heat fluxes if the threshold were 0 ppm-m. However, I am curious if and how Figure 6 and 7 might change under various initial conditions, or whether they are well within the error bars.

These values are based on typical field campaign data. To show how the result from our method applies to the field of different conditions, we have added additional LES runs with different combination of sensible and latent heat fluxes (SH and LH) in two more cases: SH = LH, LH > SH to compared with the typical condition we use in this paper (SH > LH)

We found that the relationship between observed IME, flux rate and wind speed under new conditions (orange and blue lines) lie within 1-SD error from our original condition (green line). This shows that the uncertainties associated with the change in these conditions will not significantly impact our method and are captured well with the range of errors we have analysed.

Based on these results, we added a small section on this discussion.

P8, L27:Do the authors only mean Frankenberg et al., 2016, by "... has been ignored in previous studies." or are there further ones?

Previous studies in this case refer to both Frankenberg et al., 2016 and Varon et al,. 2018 both of which assume flux is linearly proportional to IME as mentioned in the introduction.

P9, L33:Could the authors add the fitted polynomial also to Figure 10? Why do the authors use a fifth-degree polynomial? Is there a physical relationship, which relates wind speed and plume angular width by a fifth-degree polynomial or is it just the 'best' fit? Could the relationship in Figure 10 also be explained by an exponential curve? Assumption: The relation in Figure 10 is determined by averaging over an ensemble of LES realizations. If this is done, I expect the resulting plume to be approximately Gaussian as seen in Figure 4, e-f. We added the fitted curve to Figure 10 and its caption. We performed additional experiments and found that exponential fit provide a good fit to the curve without overfitting.

P10, L5-13:Basically, in this paragraph the authors summarize their developed method. I have some questions/comments to the used example.a) The error bars (shaded area) shown in Figure 11:Are they related to the errors shown in Figure 6 or to Figure 10? b) Have the flux rates, shown in Figure11, been corrected for the missing IME (as indicated in Figure 7)? c) How is the error (1-SD of the plume angular width) shown in Figure 10 related/translated to the wind speed error, which then linearly propagates to the estimated flux?

- a) The error bars from Figure 11 are directly related to Figure 6. For a given IME, we found the possible range of fluxes for a given value of wind speed from the relationship from Figure 6. b) Yes, the flux rate in Figure 11 is based on the relationship from Figure 6, in which the IME is the IME that is observed on the scene after applying the threshold.
- c) Based on Figure 10, at a given angular width measured from the plume, we can predict the wind speed from the fitted line. The associated uncertainties of the wind speed are approximated by the possible range within 1-SD area. We assume that by projecting a value of plume width onto the corresponding range of wind within 1-SD shading area, we obtain uncertainties for predicted wind speed that approximately represent 1-SD error for the wind speed as well.

We modified the text in this paragraph accordingly in the manuscript.

P10, L14-17: Could the authors be more precise in terms of the given "average percentage error" of 30%? I assume it is the mean value of the vertical error bars shown in Figure 12.However, as in reality not only entire fields/regions of CH4 sources (as then investigated in P10, L18-25)are investigated but also single plumes, which are typically observed only once, an interesting measure would also be the average of the absolute differences (also in percent) of the predicted flux rates and the corresponding prescribed flux rates. This would give an idea of the magnitude of the bias one can expect from the method. I assume that the observed bias in the flux for the controlled release experiment of ~32% lies within this computed theoretical value.

The average percentage error here is meant to be the average of the percentage differences between the predicted value and the actual value in Figure 12. Each point in Figure 12 is showing prediction for a single plume measurement, not for the entire field. To make this clearer, we have accordingly revised the sentence to be "The average of the percentage differences (in absolute terms) between the predicted value and the actual value for single point source predictions is approximately 30%,..."

P10, L25: What do the authors exactly mean by "mean percentage of error"? Is that the average of all differences between actual and predicted flux OR is it a similar error as computed for Figure 12 in P10, L14-17? If the authors refer to the latter one, I would suggest to also compute the average of all differences between actual and predicted flux (not the average of the absolute differences as in the previous comment). For example, a positive or negative value would then quantify an over-or underestimation caused by the method on average. The same exercise can be done for Figure 12 because it appears (as for Figure 13) that more predicted fluxes lie above the 1-to-1 line then below especially for larger fluxes.

We computed both the mean of absolute differences from all these aggregates which is 5.1% with a standard deviation of 3.9%, and the average of all differences (negative and positive) which results in 2.9% with the standard deviation of 5.9%. We added this result to this section.

P10, L26ff: The possibility to compare the novel approach, which is mostly based on 'theoretical' models, to real data is a huge strength of the publication. Therefore, I would recommend to expand this part of the publication. Some starting points are already given. First of all, the authors could add some more information regarding the already analyzed controlled release experiment allowing for a better judgement by the reader. Useful information would be (a) a figure showing the overflight and the retrieved plume and CH4 column enhancements (similar to Figure 1), (b) the fitted wind speed, which is then used to invert the IME to a flux, and (c) as the observation is based on a controlled release experiment, do the authors have access to real wind observations on-site or at least to meteorological reanalysis data, which can then be compared to the fitted wind to test its plausibility? Additionally, the authors nicely show multiple overflights of one source within ~25 minutes by the AVIRIS-NG instrument in Figure 1. It would be an interesting opportunity to apply the developed method to the four overflights shown in that figure and discuss the resulting fitted winds and inverted fluxes.

We added more information regarding the controlled release experiment. The information included are

- (1) a figure (Fig.15) showing the actual overflight AVIRIS-NG scene
- (2) the deduced wind speed that was then applied to calculate the flux rate

(3) comparison between the deduced background wind speed and the available observation at 10-m during the controlled release experiment flight.

We also applied our method to the observed AVIRIS-NG scenes from Fig.1.

P10, L29:I assume the given estimated emission of 118 kg/hr is already corrected by the potentially missed IME as indicated in Figure 7, right? Additionally, could the authors elaborate on what error sources are included in the error estimate (of 30kg/hr) of the predict flux. Yes, it has been corrected. In our method, we apply the observed IME to the relationship in Figure 6 which has the relationship between observed IME, wind speed and flux rates. The geostrophic wind speed is predicted to be 3.3 +- 1.2 m/s. The error from the predicted wind speed results on the error of 30 kg/hr. We have added this details in this section.

P15, Figure 2:Please clarify whether altitude on z-axis is given in meters above sea level or above ground level. Additionally, please harmonize the minimum altitudes of the computed averaging kernels, either to 0 m or to a specific surface elevation. Consider also adding the aircraft altitude(s) which the examples CAKs are valid / have been computed for. The altitude on z-axis is given above ground level. We harmonized the minimum altitude on the plot. In the Thermal case (HyTES) the flight altitude is an important factor for the CAK. In Figure 2, the CAK of HyTES was computed for an altitude of about 3 km. For the shortwave range, however, the CAK of AVIRIS-NG is not impacted significantly by flight altitude. In this paper, we focus our analysis on the results from AVIRIS-NG scenario. We added this info to the caption of Fig.2.

P16, Figure 3:Consider adding the true IME (idealized threshold of 0 ppm-m) to the caption. Additionally, consider adding labels for the stability classes to the caption so that the reader sees immediately their meaning without looking up the relevant information in the cited publications, e.g., A = very unstable; B = moderately unstable; ...

The idealized IME when threshold is 0 ppm-m has been added accordingly. Without any threshold, the IME actually depends on the box size as enhancements approach the domain boundaries. In this case, we calculated the IME that would have been observed within the box as shown in the figure if the threshold were to be 0. We have added the meaning for each label as A=very unstable, B=unstable, C=slightly unstable. We have added this description to the caption of Figure 3 for more clarity.

P17, Figure 4:Consider adding the true IME (idealized threshold of 0 ppm-m) to the caption (as suggested for Figure 3), and the variance of IME(of the 60 individual snapshots) to each plot in the right column for the three cases of wind speed so that the reader can assess the statement from (P7, L10f).

Based on the values of IME across snapshots, we computed the variance of IME, and have added these values to the right column panels. We have also added the idealized IME similar to what was described above in "P16, Figure 3."

P18, Figure 5:Consider adding the true IME (idealized threshold of 0 ppm-m) to the caption (as suggested for Figure 3)

We have also added the idealized IME similar to what was described above in P16, Figure 3.

Figure 3-5:For clarification: The wind shown in Figure 3 (Gaussian plume model) is not directly comparable to the wind shown in Figure 4 and 5 because the latter one is the geostrophic wind, whereas the former one is the wind at plume level(s), correct?

Yes, that is correct. We added this clarification to the Figure captions.

P19, Figure 6: Which threshold was used for Figure 6, 500 ppm-m? Consider adding this information to the caption.

Yes, we have used the threshold of 500 ppm-m in the analysis of Figure 6. We have added this information to the caption of Figure 6.

P20, Figure 9:Please add meaning of vertical bars to caption.

The vertical bars represent the standard deviation of the normalized IME at a given angle across all snapshots. We added this detail to the caption of Figure 9.

P21, Figure 10:Please add meaning of shaded area also to caption.

The shaded area represents one standard deviation from the mean plume angular width for each wind speed. The standard deviation is computed across different values of flux rates and snapshots. We have added the meaning of the shaded area to the caption of Figure 10.

P21, Figure 11:Please add meaning of shaded area also to caption.

The shaded area represents one standard deviation for the flux rate at a particular value of IME for each wind speed. The 1-SD for the flux rate is approximated by the possible range of flux rates resulted from an observed IME and wind speed in Figure 6. I added the meaning of the shaded area to the caption of Figure 11.

P22, Figure 13:Consider using a density plot for better visualization of the data cloud. Because we would like to illustrate the comparison between predicted and actual values at each point, showing the data cloud could be more helpful in our case.

Response to Referee 2

The manuscript "Towards accurate methane point-source quantification from high-resolution 2D plume imagery" by S. Jongaramrungruang et al. introduces a procedure to quantify the methane flux of a point source from a high resolution 2D imagery of the plume. Large Eddy Simulations are used to deduce the method. The flux inversion is described in detail and an error estimate for the method is given. The procedure is then applied to one case of a controlled release experiment, where it could reproduce the flux rate within the assumed error estimate.

The method seems useful, especially as it does not need the wind speed as an addi-tional input variable. All required values are only extracted from the 2D scene of the(vertically integrated) plume. This makes this method useful for optical measurements, and also for future satellite missions aiming at high resolution methane retrievals.

The method is novel and clearly outlined, the paper fits well into the scope of AMT. The manuscript is well structured, however, sometimes (long) sentence structures made it hard for me to follow. It would be nice, if the authors invest some time for rephrasing, giving the reader a more fluent reading experience.

The authors should use SI units in the preferred inverse notation throughout the manuscript (as stated in AMT manuscript guidelines), several times ppm-m is used (in the text and figure labels), which may be ppm m in SI units (?).

For better understanding, the authors should avoid synonyms (e.g. synthetic measure-ments vs. pseudo measurement vs. synthetic observation).

Generally, many of the figure legends, axis labels, and other labels might be to small for a good reproduction in the final publication.

Please, do not forget to add the necessary sections: "Data and code availability", "Author contributions", "Conflict of interest".

I recommend publication in AMT, subject to some improvements.

We thank the reviewer for the constructive comments and appreciate the thoughtful review. Please find a point by point response below:

Specific comments

p. 3, ll. 6ff.:The inclusion of retrieval noise in the simulation of synthetic measure-ments is mentioned, but I have not found anything about this topic in Sec. 4.1 or Sec.5, which describe more details. Is additional noise used (and if, which) in preparing the synthetic measurements? Is this affecting the estimated errors (and how)? Maybe more details can be included in Section 4.2.

We performed experiments to add noise to the scenes using random Gaussian noise and found that the IME only changes by 7%, well within the 1-SD error from snapshot average. So we did not include the retrieval noise in our figures (but will consider this in the future when we will focus more on real data for which proper treatment of noise and plume segmentation will become increasingly important).

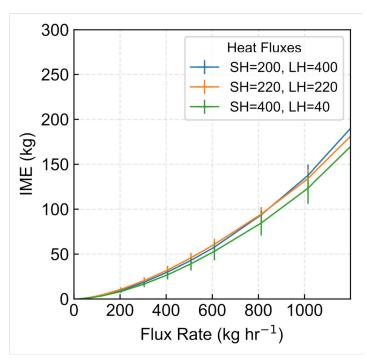

p. 3, 1. 26: A 15 minute revisit time is mentioned, sub-figures of Fig. 1 show instrument overpasses in time intervals of 7 to 9 minutes (as also stated in the figure caption). The revisit time is indeed 7-9 minutes apart. We have corrected the details in the figure caption to match with this.

p. 6: I recommend to restructure Section 4, as Section 4 itself is empty. It could rather be: "4 Large Eddy Simulation" and "5 Synthetic measurement", following Sections change accordingly. The section on synthetic measurement could be extended by some details on the additional noise added. Maybe the applied detection thresholds could also be included here, instead of in Section 2

Based on the reviewer's suggestion, we adjusted the structure of the paper accordingly, and changed the number in the texts that mention to these sections.

p.6, l. 14: In this study latent and sensible surface heat fluxes are kept constant. Was the method tested with other settings (except of the controlled release exper-iment)? What would happen if these fluxes are varied? How would the plume be affected? Would this impact the method? If the method is still applicable with the derived correlations, would the error estimates change? Some of these questions are answered in "Discussion and conclusion" and answers may not fit in "LES setup". The authors should consider a reference to the discussion section and a strengthening of the corresponding paragraph there, or an additional section on limitations.

These values are based on typical field campaign data in the Four Corners area. To show how the result from our method applies to the field of different conditions, we have added additional LES runs with different combination of sensible and latent heat fluxes (SH and LH) in two more cases: SH = LH, LH > SH to compared with the typical condition we use in this paper (SH > LH)

We found that the relationship between observed IME, flux rate and wind speed under new conditions (orange and blue lines) lie within 1-SD error from our original condition (green line). This shows that the uncertainties associated with the change in these conditions will not significantly impacted our method and are captured well with the range of errors we have analysed.

We added a small section to show the relatively small impact in the discussion.

p.8, ll. 4ff.:If I understand it right, the instantaneous value for U-10 is written out from the LES simulation every minute. When the plume structure is – as stated in line 7 – influenced by the wind during this minute, the LES model (integration)time-step should be smaller. The model time-step should be somewhere around few seconds, taking into account the high resolution of 5 m. However, I found no value for the model time-step, maybe you could include it in the Section about the LESsetup. Maybe a rephrasing of the sentence in ll. 4f. could help to understand that instantaneous wind values are written out from the model simulation. Also, using the term "timestep" for one instance of the model output may be a bit misleading, as output does not coincide with every model time-step, maybe you could use "snapshot".

You are right, the model time-step is much shorter, namely one second. We added "The model computational time-step is one second." to the LES Set Up section. We paraphrased and adjusted the world "time-step" to "snapshots" accordingly.

p.9, ll. 17ff.:For the method to work, has the plume origin to be known for the angular mass binning? For LES simulation and field campaigns this should be no problem (when measuring unknown flux rates from a known point source). Also, for flux inversions of known sources from future high resolution satellite imagery, e.g, foremission monitoring, the method will be useful. In other situations, it might be more challenging. Limitations of the method should be addressed in the discussion section,or an additional section on limitations. (e.g., more than one point source or parts of a second plume included in a scene ...)

For large enough plumes, the plume origin can be easily found from the imagery itself. In fact, we will work on image classification schemes to automate this procedure in the future. However, in the current study we don't consider the plume origin to be a major factor. For HyTES data it might be as the origin cannot be readily inferred but with total column data in the short-wave infrared, the error in the origin is rather small.

p.10, ll. 16f.:The paragraph about error estimates could be strengthened. Please do not just give the value of χ 2 without interpreting this result. Maybe additional description how the "average percentage error" is calculated, and how the error propagates through all steps of the method could be added.

We clarified that the average percentage error is the average of the percentage differences (in absolute terms) between the predicted value and the actual value for single point source predictions. It is approximately 30%. The reduced chi-2 value is 3.84 which suggests that the error variance may tend to be slightly underestimated for this individual point source prediction. However, when calculating the aggregate prediction, the predicted value is different to the actual value within only less than 10%. We added additional information on this section in the paper. We have added additional explanations for how the errors propagation is calculated from Figure 6, 10 and 11.

p.10, ll. 26ff.:Additional information about the controlled release experiment would be nice. Maybe, include a figure of the scene, or a figure of the angular distribution (comparable to Fig. 8)...

We have added the scene observed by AVIRIS-NG in the controlled release experiment and more information on date, time, and location to the scene.

p. 12, ll. 3ff.:This paragraph addresses the limitations arising from using constant sensible and latent surface heat fluxes. The authors should consider to present the limitations in a separate section. The last sentence of the paragraph should be moved closer to the discussion of the constant surface fluxes. All limitations should be named and discussed.

We added more analysis for the runs with two additional cases. One being the sensible heat flux (SH) and latent heat flux (LH) are equal to 220 W/m2. Another case is when SH is 200 and LH is 400 W/m2. This is two different cases in contrast to the typical condition of SH being higher than LH (400 W/m2 and 40 W/ms respectively in our method). Our result shows that the relationship between IME, flux rate and wind speed is not significantly impacted by the large change in heat fluxes, as described in the response to p.6, l. 14 above.

p. 20, Fig. 8:The figure contains two black lines, which are not explained, I as-sume they denote something like the main axis of the plume. If the plume is already rotated, why is the maximum of the normalized angular IME distribution not at 0?

The two black lines denote an angular bin of 0.5 degree that sweeps through the 2D plume to construct the angular distribution. It is just for illustrative purposes. We have added the meaning of the two black lines to the caption of Figure 8. The plume is rotated based on an axis that is defined by an angle that separates plumes into 50/50 ratio, which can be slightly different from the angle of maximum density.

Technical corrections

We have adjusted our text according to the suggested technical corrections.

Towards accurate methane point-source quantification from highresolution 2D plume imagery

Abstract. Methane is the second most important anthropogenic greenhouse gas in the Earth climate system but emission quantification of localized point sources has been proven challenging, resulting in ambiguous regional budgets and source categories distributions. Although recent advancements in airborne remote sensing instruments enable retrievals of methane 15 enhancements at unprecedented resolution of 1-5 m at regional scales, emission quantification of individual sources can be limited by the lack of knowledge of local wind speed. Here, we developed an algorithm that can estimate flux rates solely from mapped methane plumes, avoiding the need for ancillary information on wind speed. The algorithm was trained on synthetic measurements using Large Eddy Simulations under a range of background wind speeds of 1-10 m s⁻¹ and source emission rates ranging from 10 to 1000 kg, h., The surrogate measurements mimic plume mapping performed by the next generation Airborne Visible/Infrared Imaging Spectrometer (AVIRIS-NG) and provide an ensemble of 2-D snapshots of column methane enhancements at 5 m, spatial resolution. We make use of the integrated total methane enhancement in each plume, denoted as Integrated Methane Enhancement (IME), and investigate how this IME relates to the actual methane flux rate. Our analysis shows that the IME corresponds to the flux rate non-linearly and is strongly dependent on the background wind speed over the plume. We demonstrate that the plume width, defined based on the plume angular distribution around its main axis, provides 25 information on the associated background wind speed. This allows us to invert source flux rate based solely on the IME and the plume shape itself. On average, the error estimate based on randomly generated plumes is approximately 30% for an individual estimate and less than 10% for an aggregation of 30 plumes. A validation against a natural gas controlled-release experiment agree to within 32%, supporting the basis for the applicability of this technique to quantifying point sources over large geographical areas in airborne field campaigns and future space-based observations.

1 Introduction

Methane is the second most important anthropogenic greenhouse gas in Earth's atmosphere, with additional indirect impacts as it affects both tropospheric ozone and stratospheric water vapor. Despite its significance, our understanding of global and regional CH4 budgets has remained inadequate due to the fact that the strength and distribution of CH4 emissions from various source types are not well-constrained (Houweling et al., 2017; Turner et al., 2017). Estimates of CH4 emissions from point sources (e.g. at facility scale) are particularly uncertain, since space-based observations lack sufficiently fine spatial resolutions while in situ measurements are too sparse and mostly representative of large-scale background concentrations. Improved estimates of the CH4 emissions at this point-source scale are critical in guiding emission mitigation efforts.

Recent developments in airborne imaging spectroscopy techniques to quantify CH₄ plumes have opened the way for 10 CH₄ measurements at sufficiently high spatial resolution needed to differentiate various local sources within regional scales (Frankenberg et al., 2016; Hulley et al., 2016; Thompson et al., 2015; Thorpe et al., 2016a, 2017; Tratt et al., 2014), A recent airborne campaign in the Four Corners region retrieved column methane enhancements at a resolution of 3 m (Frankenberg et al., 2016), enabling the observation of the plume shape in direct vicinity of the point source. During the campaign, many plumes of various sizes ranging from a few tens of meters to hundreds of meters were detected across the region, with the 15 majority of their source emission rates between 10 and 1000 kg(CH₄) h⁻¹ (Frankenberg et al., 2016). This allows for an effective way to remotely identify and locate CH4 emissions from point sources such as pipeline leaks or oil and gas facilities. The retrievals provide the quantification of a column enhancement (e.g. in molecule, cm², above background), which can be integrated across the entire methane plume to derive the total amount of methane within the plume, denoted as Integrated Methane Enhancement (IME, either in molecule or mass units, Frankenberg et al., 2016). In addition, the instrument observes 20 the fine structure of the plume at an unprecedented spatial resolution. However, the flux inversion from the observed plumes to the actual emission rate at the source remains complicated due to the dependence on tropospheric boundary layer conditions such as wind speed and atmospheric stability during the overpass. To interpret the relationship between the observed plumes and flux rates, previous studies have relied on Gaussian plume inversion models (Krings et al., 2011, 2013; Rayner et al., 2014; Nassar et al., 2017; Schwandner et al., 2017) or an airborne in-situ approach using a mass balance calculation based on the 25 enhancement downwind of the source (Cambaliza et al., 2015; Conley et al., 2016; Gordon et al., 2015; Jacob et al., 2016; Lavoie et al., 2015), Frankenberg et al. (2016) used a simple linear scaling between IME and flux rate, which allowed for a straightforward derivation of fluxes from the observed IME given an averaged wind speed across a large region for the campaign over several days. Varon et al., 2018 estimated flux rate as IME divided by the residence time of methane in the plume calculated based on the effective length of the plume from its area and the effective wind speed inferred from 10 m wind speed by in situ measurement or meteorological reanalysis data. All of these methods rely on knowledge of local wind speed, which is acquired through either in situ wind measurements or the estimation from meteorological forecast or reanalysis data. The former can be costly and time consuming without prior knowledge of source locations, while the latter can be

Formatted: Font: 10 pt

inaccurate due to the rapid changes of a local plume over a much shorter temporal and spatial scale (minutes, hundreds of meters) than the typical atmospheric reanalysis products (a-few-hourly average, tens of kilometers).

In this work, we aim to improve our understanding of how the inferred emission rates change under different atmospheric conditions, e.g. the errors due to a lack of accurate wind measurements. To investigate this relationship and associated errors, we used Large Eddy Simulations (LES, Matheou and Bowman, 2016) to simulate the plume dynamics at high spatial resolution (5 m) with prescribed source rates under various background wind speeds and typical surface latent and sensible heat fluxes. Using 3D LES model output for each snapshot, we simulated synthetic 2D airborne measurements by applying the respective averaging kernels. Based on these synthetic measurements, we developed an algorithm to deduce the wind speed from the plume's spatial distribution and investigate the degree to which the flux rate can be inverted from only the remotely-sensed CH4 retrievals. This allowed us to perform an end-to-end test of errors in inverted methane fluxes in both the absence and presence of ancillary information on the actual wind speed (Section 4.3).

This work was inspired by the use of IME to quantify methane single-point sources from field campaigns using airborne instruments. These plumes generally are of small-to-medium sizes (<2 kilometers). The concept, nevertheless, can be applicable to larger sources as well as toward measurement of localized sources from space in the coming decade for satellite retrievals at a much finer spatial resolution (Thorpe et al., 2016b).

Section 2 illustrates the plume observations and the instrument specifications. Section 3 will give a brief overview of Gaussian plume modelling. The setup of the LES and application of instrument operators to simulate airborne measurements are described in Section 4 and Section 5 respectively. Section 6 shows simulated plumes under different atmospheric scenarios and the relationship between observed IME and actual emission rates. The error analysis of flux inversion based on the IME method is also provided. The final section provides a discussion and conclusion.

2 Plume Observations and Instrument Specifications

Spectrometer (AVIRIS-NG) and the Hyperspectral Thermal Emission Spectrometer (HyTES) during the Four Corners flight
campaign (Frankenberg et al., 2016). The Iterative Maximum a Posteriori Differential Optical Absorption Spectroscopy
(IMAP-DOAS) method (Thompson et al., 2015) and Clutter Matched Filter (CMF) were used to retrieve the scenes from
AVIRIS-NG and HyTES respectively. In this case, the aircraft repeatedly flew over a coal mine venting shaft, with
approximately 10 minute revisit time. Evidently, the plume is changing in time and exhibits fine-scaled features due to
atmospheric turbulence. Quantifying the source rate from detected plumes using atmospheric simulations to understand their
behavior and variations in space and time is the main subject of this work. In order to compare our simulations with actual
observations, we need to take the measurement characteristics of the remote sensing instrument into account. This relates to
both measurement precision, which determines detection thresholds which marks and defines the detected plume, as well as
vertical sensitivity, which affects what parts of the plume structure can actually be observed. Depending on the techniques
being used, both can vary widely.

The Jeft column in Fig. 1 shows scenes that are retrieved from the AVIRIS-NG instrument, which measures reflected solar radiation between 0.35 μ m and 2.5 μ m at 5 μ m at 5 μ m resolution and sampling (Hamlin et al., 2011; Thompson et al., 2015). To first order, it has a uniform vertical sensitivity (averaging kernel) of J at each height (see Fig. 2). Another instrument that was used in the Four Corners campaign is HyTES, which enables the detection of CH4 plumes due to its absorptions in the thermal infrared around 7.65 μ m (Hulley et al., 2016). Its varying sensitivity, in the vertical can be calculated as the derivative of the retrieved total column amount with respect to the change in a particular layer. These vertical sensitivities are formally called column averaging kernels. They inform us how well methane deviations from the prior at each height can be measured, which determines whether they will be visible in retrieved column enhancements. Mathematically, we can express this relationship as.

$$E(i,j) = \sum_{k} (\Delta x \Delta y \Delta h) * C(i,j,k) * CAK(k)$$
(1)

where $E(i,j)_k$ is the observed total column enhancement (mass or molecules) at the horizontal grid cell $(i,j)_k \Delta x, \Delta y$ and Δh are grid sizes in \hat{L} , and \hat{K} respectively, C is the concentration (mass or molecules per volume), CAK(k) denotes the column averaging kernel evaluated at level k. Technically, the CAK can also be a function of location $(i,j)_k$ but for the purpose of producing synthetic measurements from our simulations in this work, we apply the CAK only as a function of height.

Fig. 2 illustrates the difference between the column averaging kernels that we use to model AVIRIS-NG and HyTES synthetic measurements. The distinct column averaging kernels of both instruments hold significant importance, each with its advantages and disadvantages. The column averaging kernel of AVIRIS-NG is approximately uniform across all vertical levels, which implies that the retrieved column enhancement accurately reflects the actual column enhancement. On the other hand, the sensitivity of HyTES is almost zero near the surface but increases with height, becoming even larger than 1 at a certain height. This means that the instrument is almost blind to methane near the ground, but amplified the actual methane amount at certain heights in the column. This distinction is evident in Fig. 1 where the observed methane plume remains more

consistent from AVIRIS-NG scenes, whereas more variations appear in the HyTES scenes potentially due to changes in plume vertical structures. It should also be noted that the HyTES averaging kernel strongly depends on the temperature profile as well as the surface temperature, which can vary within and between scenes. In contrast, averaging kernels using short-wave reflected light are less variable.

25 3 Gaussian Plume Modelling and Its Limitations

The simplest way to simulate plumes is Gaussian plume modelling, which assumes a steady and uniform wind U along the x-axis and orthogonal spreading of the plume in crosswind (y-axis) and vertical (z-axis) directions. The spreading of the plume depends on the dispersion functions $g_{yy}(x)$ and $g_{x}(x)$. The dispersion functions depend on the atmospheric stability Pasquill, 1961). For instance, convective conditions favor vertical dispersion, whereas in a stable atmosphere the plume primarily disperses in the horizontal directions (Briggs, 1973; Matheou and Bowman, 2016; Sutton, 1931), The three-dimensional Gaussian plume equation is given by Matheou and Bowman, 2016)

4

$$C\left(x,y,z\right) = \frac{1}{2\pi\sigma_{y}(x)\sigma_{z}(x)} \cdot \frac{Q}{U} \cdot \exp\left[\frac{-y^{2}}{2\sigma_{y}^{2}(x)}\right] \sum_{m=0}^{\infty} \left(\exp\left[-\frac{(z-2mz_{i})^{2}}{2\sigma_{z}^{2}(x)}\right] + \exp\left[-\frac{(z+2mz_{i})^{2}}{2\sigma_{z}^{2}(x)}\right]\right) \tag{2}$$

where C(x, y, z) is the (equilibrium) concentration at each point in the 3-dimensional space within the atmospheric boundary layer with inversion height Z_{loc} . The model assumes a reflective boundary condition where the parameter m multiplied by z_t indicates the height that the reflection occurs and the summation over this parameter m represents the equivalent

concentration within 0 to $z_{l.}Q$ is the source flux rate at the origin. The variances $g_{y_l}(x)$ and $g_{z_l}(x)$ are given by empirical relations based on atmospheric stability following the Pasquill classification (Matheou and Bowman, 2016; Pasquill, 1961).

By integrating Eq. 2 in z-direction, the methane column enhancement can be modelled in analytical form as

$$\bar{C}(x,y) = \frac{1}{\sqrt{2\pi}\sigma_{y}(x)} \cdot \frac{Q}{U} \cdot \exp\left[\frac{-y^{2}}{2\sigma_{y}^{2}(x)}\right]$$
(3)

Based on this model, we can vary source rate, wind speed, and stability category to simulate the 2D integrated concentration field. We then apply a device detection threshold to illustrate how the synthetic Gaussian plume column enhancement may change under distinct atmospheric conditions. Examples of the simulated Gaussian plumes with a flux rate of 300 kg, h⁻¹, are shown in Fig. 3. The left column of Fig. 3 shows the Gaussian plumes under different wind speeds for a fixed stability category, while the right column demonstrates those under a fixed wind speed at 4 m, s⁻¹, but different stability regimes.

The wind speed *U* influences the column enhancement, which, based on Eq. 1, is proportional to the ratio *Q/U*. Thus, the Gaussian plume model suggests a strong dependence of the IME on wind speed, which in turn does not explicitly affect the shape of the plume. One way of quantifying a plume shape is using an aspect ratio in the x-y plane. In the Gaussian plume model, the aspect ratio of the plume only changes when the stability switches from one category to another. Thus, the wind speed is only implicitly linked to the shape of the plumes by affecting the stability categories and changing the crosswind variances (as can be seen in Eq. 3).

The stability categories in this model, nonetheless, are based on empirical formulae. In reality, the wind speed can influence the shape and distribution of the plumes more directly through advection of the tracer along the flow. The actual plume observations from the Four Corners campaign (Fig. 1) demonstrate that the plumes are of turbulent nature - at times being discontinuous - and cannot be modelled as Gaussian when only one plume snapshot in time is recorded. Therefore, we utilize an LES model, which yields realistic realization of the turbulent flow and the methane plume, to quantify the effect of wind speed on the plume structure.

4 Large Eddy Simulation setup

20

Realistic modeling of CH₄ plumes is a prerequisite for this study. We use <u>LES</u> to model the time-resolved 3-dimensional CH₄ distribution in the boundary layer under different atmospheric conditions at resolutions currently available

from aircraft measurements (1-5 m). The LES model setup for the simulation of plumes emanating from point sources is as described in Matheou and Bowman (2016). Further details of the model formulation, including the turbulence parameterization, are in Matheou and Chung (2014). A methane surface point source with a specific emission rate in a cloud-free convective atmospheric boundary layer is simulated. The buoyancy of methane is currently being ignored – a good approximation for the present methane concentrations away from the source.

The atmospheric boundary layer is initialized with a mixed layer inversion free troposphere with an initial inversion height $z_i = 800$ m. The initial potential temperature and specific humidity in the mixed layer are $\theta = 298$ K and $q_{x,z} = 6.6$ g kg⁻¹. The Japse rate is $\Delta\theta/\Delta z = 0.12$ K m⁻¹. The flow in the boundary layer is driven by a constant geostrophic wind in the *x*-direction, u_{g_x} Different values of the geostrophic wind from 1 to 10 m s^{\perp}} are used. The surface sensible and latent heat fluxes are 400 and 40 W m⁻². These values are based on typical field campaign data. Additional simulations with other sensible and latent heat fluxes are also performed later in Section 6.4. Surface momentum fluxes are estimated using Monin–Obukhov

The model domain is $10.24 \times 2.56 \times 1.5 \text{ km}^2$ in the x, y, and z direction and the grid resolution is uniform and isotropic $\Delta x = \Delta y = \Delta h = 5 \text{ m}$. The model computational time-step is one second. Following one hour of model "spin up", where fully-developed three-dimensional turbulence is established in the boundary layer, the three-dimensional concentration at each location at one-minute intervals (snapshots are written out at every minute) is used to construct the synthetic observations. Furthermore, the 10 m and 2 m wind speeds are extracted from the model output to compare with the large-scale geostrophic wind value in each run.

20 5 Synthetic Measurement

similarity theory (MOST)

With the output from the LES simulations, we can create synthetic measurement of a plume instance that would enable simulation of observations from any instrument. The procedure is that we apply vertical integration as described by Eq. 1 to the 3-D concentration at a given time step, using the column averaging kernel of the instrument of interest. We apply the column averaging kernel of AVIRIS-NG as well as that of HyTES to produce synthetic measurements for these instruments.

25 The detection thresholds of AVIRIS-NG and HyTES instruments can potentially be dependent on the surface properties such as surface reflectance and surface temperature respectively. However, given the typical scale of the plumes of our interest, we assume an average uniform detection threshold across the scene. Here, we use a constant threshold of 500 ppm-m (or about 1.34 10¹⁸ molecules cm⁻²), which is a common value for AVIRIS-NG. As for HyTES, we used the same threshold to exemplify the differences due to averaging kernels only, as opposed to thresholds. This allows us to understand to what extent each instrument can detect CH₄ plumes under various wind speeds.

6 Results

The output from the LES run provides a more realistic simulation, compared to the Gaussian model, of the plume dynamics as shown in Fig. 4 for AVIRIS-NG synthetic measurements. The left column of Fig. 4 shows single snapshots of the plume, while the right column shows the time-averaged plume snapshots over 60 timesteps, spanning a duration of 60 sequential minutes in total, under distinct background wind speeds but with a constant flux rate. Based on this simulation, we see that the plume varies rapidly in shape and orientation from snapshot to snapshot due to turbulence. The temporal averages in the right column also still exhibit some structure as we only averaged 60 individual snapshots. Overall, the simulated plumes from the LES closely resemble actual plumes from remotely-sensed observation as shown in Fig. 1. The instantaneous plumes exhibit non-Gaussian behavior; sometimes the plume can even be discontinuous as eddies can rupture the plume structure. However, we found that the total enhancement across the scene (the IME) remains rather constant over time for a given wind speed and flux rate, making it a reliable variable for performing the flux inversion of the source. In addition, we also found that the plumes have distinct features in both magnitude and spatial characteristics for different wind speeds, which are evident in the plume snapshots as well as their ensemble means shown in Fig. 4.

plume for three different wind speed conditions. Because the column averaging kernel of the HyTES is close to zero near the ground, the synthetic measurements for HyTES miss parts of the plume near the surface, and detect only the parts of the plume that have risen high enough. This is consistent with the averaging kernels shown in Fig. 2. This is especially apparent for the case of high wind speed where the majority of the CH4 is advected horizontally resulting in a plume remaining near the ground. The result in Fig. 5 is in accord with the comparison between the observed AVIRIS-NG and HyTES scenes in Fig.1 during the first overpass. This potentially indicates that the plume at this time remains mostly near the ground, which may not always happen in the same way for the coal mine venting shaft, which is emitting above the ground surface. The insensitivity of HyTES near the ground makes it complicated to locate the source accurately and there are additional uncertainties in the methane retrievals associated with averaging kernels that vary with environmental conditions (Kuai et al., 2016). The advantage of the HyTES instrument, on the other hand, is the fact that in principle it can operate at night when there is no sunlight, which is a prerequisite for AVIRIS-NG instrument. For AVIRIS-NG, the total column CH4 enhancement in each pixel is also better constrained given the averaging kernel is approximately one throughout the column. For these reasons, we proceed to focus only on AVIRIS-NG results in the current study, while we will study the information content of joint measurements in the future.

Multiple LES runs from a combination of typical point-source flux rates and wind speeds enable us to quantify the
relationship between the actual source rate and the resulting IME for a given wind speed. This gives us the first step to invert
the flux rate. Furthermore, we show how different wind speeds affect this relationship for the flux inversion. The output from
the LES gives us not only the IME but also the spatial distribution of the plume snapshots that correspond to a given pair of
flux rate and wind speed. We analyze how the morphology of the plumes is linked with the underlying background wind

speeds. This helps us understand how we can use the remotely-sensed airborne imagery of the plume to predict the wind, and thus ultimately the flux rate, together with its associated errors.

In our analysis, we primarily refer to the wind speed in each scene from our model runs by using the geostrophic wind 5 speed, as opposed to the instantaneous wind at 2 m (U-2) or 10 m (U-10) above ground which is usually used in literature. For reference, the average U-10 across the horizontal domain in our run ranges approximately from 0.4 to 0.7 of the background geostrophic wind speed in the run. The main reason is that our output snapshots from each LES run is written out every minute, thus we only have the information of the U-10 and the plume structure at every minute, which can change rapidly in direction and magnitude. However, the overall structure of the plume at any given instance could be influenced by the average wind 10 cumulatively from the past minute. The constraint on the output that we have makes it ambiguous to choose what values of near surface winds should be applied when making the prediction of the flux rate from the spatial structure of a plume snapshot. We thus resort to using a background wind speed, which, in turn, is one of the key governing drivers for U-10 itself. While using the large-scale background wind speed might not be as accurate as the ideal case of having continuous U-10 output, it provides a robust correlation with the overall pattern of the plume (see Section 6.2). In other words, in the following, we are 15 using the shape of the plume to predict the value of background geostrophic wind speed that underlies the wind that has driven CH₄ from the point source into the detected plume over that geographical location, and use that background wind speed to quantify the source rate.

6.1 Source Flux Rate and the IME

For each wind speed and flux rate, we have 60 snapshots of methane plumes from the LES model output, with a temporal interval of one minute, We can thus directly compute the mean and the standard deviation of the IME across these anapshots. Although the shape of a plume can vary strongly in time, the IME is relatively stable, varying only within approximately 20% among snapshots under the same wind speed and flux rate. This emphasizes the benefit of using the IME to characterize methane in the scene because the total sum of the gas in the scene remains approximately the same regardless of the advection of methane from one pixel to another with time. This can potentially induce less uncertainty compared to 25 other mass balance approaches where the measurements are commonly location-dependent. The mean values corresponding to various background wind speeds and flux rates are plotted in Fig. 6. The uncertainties reflect the standard deviations of the IME within all 60 temporal snapshots.

The plot of the IME and flux rate at different wind speeds reveals two noticeable findings: as expected, there is a significant dependence of the relationship between the IME and flux rate on wind speed but there is also a non-linearity, which 30 has been ignored in previous studies. The non-linearity can be explained from the fact that we impose a detection threshold to mask out the plume. In the absence of a detection threshold, the scaling between flux rate and IME would be perfectly linear, as was assumed in Frankenberg et al., (2016). However, as the fraction of pixels with methane enhancement below the detection threshold varies with flux rate and wind speed, the truncated IME below the threshold can induce a considerable non-linearity.

The stronger the flux rate, the higher the number of pixels above the threshold used to calculate the IME. Fig. 7 illustrates this connection by showing the percentage of the total enhancement that is missed because of specific thresholds. We use three different flux rates (90, 180, 360 kg.h⁻¹) to illustrate the non-linearity. We can see that when the flux rate drops by a factor of 2, the missing amount does not necessarily decrease by the same factor. How the IME is scaled up with the flux rate depends on the spatial distribution of the plume: if the methane is concentrated in a small area, then it is more likely that a stronger flux rate will make the column enhancements exceed the threshold, as opposed to when the plume is more dispersed, in which case some pixel enhancements will be too diluted to be detected even at a strong flux rate. This is the primary reason why the IME varies with the flux rate with different degree of non-linearity at different wind speeds as found in Fig. 6. The background wind speed is the integral component that drives the spatial distribution of the plume and correlates the IME with the flux rate.

This means that in order to achieve a reliable flux inversion, both the IME and the effective wind speed over the scene of the point source must be known.

The key question in our study is can we predict the underlying background wind speed associated with the observed plume by its spatial characteristics rather than relying on ground measurements or reanalysis data. This is investigated in the following section.

15 6.2 Wind Speed and Plume Morphology

As can be seen in Fig. 4, the spatial distribution of the plumes varies under different wind speeds. Visually, the shape of simulated CH4 plumes provides qualitative intuition on the origin, wind direction and relative strength of the background windspeed. At a higher wind speed, plumes tend to be more elongated, whereas at a lower wind speed, plumes tend to be more spread out around the origin. We quantify the characteristics of the plume by first constructing an angular mass distribution for each snapshot: we count the mass within the angular bin size of 0.5° sweeping across the scene with the center at the origin. We then find the angle at which the mass of methane splits into a 50% ratio and define that as the main axis of that plume snapshot. The plume snapshot is then rotated such that its main axis aligns with the x-coordinate. We can then plot the angular distribution across the plume as well as the Cartesian distribution along the plume, as illustrated in Fig. 8, for every single snapshot. This procedure allows us to find the ensemble-averaged plume distributions for a particular wind speed where the ensemble members consist of the rotated snapshots from all available time outputs in the model runs at various flux rates in the range of our interest, 10–1000 kg.h⁻¹.

Fig. 9 shows that the angular distributions of the plume can be distinguishable under different wind speeds. Evidently, the angular distribution of the plume at highest wind speed of 10 m st is narrower than the rest on average, and the angular spreading becomes increasingly wider for lower wind speeds. Motivated by this finding based on the average distribution, we quantified the relationship between the angular spreading of the plume and the wind speed. For each snapshot, we calculated the cone width of the plume defined as the angles between the 10th and the 90th percentiles from its angular mass distribution. The mean and the standard deviation of the cone width corresponding to a given wind speed were then computed from an ensemble of 60 temporal snapshots and various flux rates. The result of this analysis is plotted in Fig. 10 and shows a

monotonically decreasing cone width with respect to wind speed. Our choice of parameterization in Fig. 10 is an exponential fit, which adequately captures the present relationship without overfitting. This result illustrates that the cone width is a metric that can differentiate wind speeds based on using only the spatial distribution of the plume. This finding, together with the variation of IME with flux rate (Fig. 6), can therefore provide flux inversion without the need for ground measurements. The next section describes steps for estimating the flux rates and its associated uncertainties.

Based on the IME and plume morphology of any given scene, we can estimate the flux rate. First, according to Fig.

6.3 Flux Inversion and Error Analysis

6, for a given value of the IME observed in the scene, we can find what are possible range of fluxes for each wind speed from the lower and upper estimate of 1 standard deviation. We can then parameterize this relationship between the flux rate and the wind speed for this particular value of the IME. An example for the case of the observed IME of 50 kg is demonstrated in Fig. 11. Secondly, based on the spatial distribution of the plume in the scene, we can follow the procedure to construct the angular mass distribution. Based on Fig. 10, using an angular width measured from the plume, we can predict the wind speed from the fitted curve. The associated uncertainties of the wind speed are approximated by the lower and upper estimate of 1 standard deviation. We assume that by projecting a value of plume width onto the corresponding range of wind speeds within 1 standard deviation range, we obtain uncertainties for predicted wind speed that approximately represent 1 standard deviation error for the wind speed distribution. The wind speed and its uncertainty can hence be translated into the estimate of the mean flux rate as well as the corresponding uncertainties from the relationship of the flux rate and wind speed, as in Fig. 11.

With this approach, we selected 90 random snapshots with random prescribed flux rates and wind speeds. We predict the flux rate from the IME and the spatial distribution of each of plume scene and compare it to its actual prescribed value, as shown in Fig. 12. The average of the percentage differences (in absolute terms) between the predicted value and the actual value for single point source predictions is approximately 30%. The x2 value from the predictions in Fig. 12 is 3.84 suggesting that the error variance may tend to be slightly underestimated for an individual point source prediction.

Nevertheless, the results shown in Fig. 12 demonstrates that this method permits estimation of total emission flux rate. Most importantly, accounting for non-linearities and variable wind speed helps to avoid systematic biases. Thus, the method employed here can minimize systematic errors that could be induced by assumptions on wind speed. To verify this point, we performed an aggregation analysis by bootstrapping 30 plumes out of 500 plumes of various flux rates and wind speeds, with 3000 repetitions. The sample size of 30 is chosen arbitrarily but is large enough to represent a situation for the estimation of total fluxes from a region. The comparison between the predicted and the actual total flux aggregated over 30 plumes is shown in Fig. 13. The predictions lie close to the actual aggregated fluxes, as demonstrated by the concentration of points near the 1-to-1 line in Fig. 13, implying that there are no significant systematic biases in our method. The mean of absolute differences from all these aggregates is 5.1% with a standard deviation of 3.9%, while the average of all differences (negative and positive) results in 2.9% with the standard deviation of 5.9%.

To further demonstrate the validity of this method, we applied it to a controlled release experiment from a natural gas pipeline located at Victorville, CA (34.8°, -117.3°) on October 11th, 2017 with a flux rate of 89 ± 4 kg, h⁻¹. Based on a sample of the actual AVIRIS-NG scene over the source location (Fig. 15), we calculated the IME and constructed the angular distribution of the plume to obtain its width to deduce the wind speed. The geostrophic wind speed is predicted to be 3.3 ± 1.2 m s⁻¹, compared to the surface sonic wind at the source measured at 1.6 m s⁻¹. This is consistent given that geostrophic wind is typically about 1.4 – 2.5 times higher than the surface wind speed in the LES output. We used this deduced wind speed to predict the flux rate, and its associated error as described at the beginning of this section. The value that we predict is 118 ± 30 kg, h⁻¹, consistent with the actual release flux within the error estimate.

Furthermore, we applied our method to multiple overflight AVIRIS-NG scenes from Fig.1. The fitted flux rates are

within a consistent range: 1275, 1033, 1397, and 926 kg h⁻¹ respectively. The mean of these estimates is thus 1158 kg h⁻¹ and the standard deviation is 187 kg h⁻¹.

6.4 Sensitivity Analysis for Different Heat Fluxes

In our LES simulations for this study, we primarily set the sensible and latent heat fluxes to the typical condition during the Four Corner field campaign. Changing the condition of these surface heat fluxes can potentially affect the vertical structure of the simulated plumes and the dynamics of the plumes in time. Nevertheless, our method involves the columnintegrated enhancement and hence is not significantly impacted by the surface heat fluxes. To verify this point, we performed sensitivity analysis by running additional LES experiments with different combination of sensible and latent heat fluxes (SH and LH respectively): (1) SH = LH (220 W m⁻²) and (2) SH (200 W m⁻²) < LH (400 W m⁻²). These two additional scenarios contrast with the typical condition that was previously used i.e. SH (400 W m⁻²) > LH (40 W m⁻²), and cover a common range of surface heat flux conditions. The background wind speed is kept the same as 4 m s⁻¹. The result from our runs are demonstrated in Fig.15, where the relationship between the IME and flux rate is found to be approximately the same, remaining within 1 standard deviation error from the original scenario in the previous analyses. This implies that the uncertainties associated with the change in these conditions will not significantly impact our method and are captured well with the range of errors we have analyzed.

25 7 Discussion and Conclusion

In this study, we showed that Gaussian plume modeling cannot be used for a meaningful comparison with observed methane plumes from a point source. Thus, Large-Eddy Simulations (LES) were used to generate realistic synthetic measurements of methane plumes under different background wind speeds and source flux rates. This allowed a comparison of the performances of two considered instruments, one measuring in the short-wave infrared (AVIRIS-NG) and the other in the thermal infrared (HyTES), resulting in widely different vertical sensitivities towards methane enhancements. The AVIRIS-NG was found to provide an unambiguous identification and quantification of the methane source as it is sensitive to methane throughout the air column. While the HyTES instrument has the potential for night time observations, variations in the

Formatted: Font: 10 pt

integrated methane enhancements depended highly on vertical plume structure, rendering interpretation more challenging. While we attempt to make use of the vertical information in the future, we focus this study on results from the AVIRIS-NG synthetic plume measurements. Using the IME method and a large ensemble, we derived the relationship between the detected IME of a plume and its source flux rate. This relationship is found to be non-linear because of the device detection threshold, which causes a variable fraction of the true IME to fall below the detection limit. In addition, the inversion of IME to an accurate flux rate depends strongly on the wind speeds during the measurements. This finding is expected and confirms the significance of wind speeds on the methane point-source flux estimations from remote sensing data. To study whether we can gain additional information from the plume shape itself, we performed an analysis on a large ensemble of plume snapshots from wide-ranging source flux rates and wind speeds. We found that the angular width of the plume negatively correlates with the wind speed, allowing us to constrain the effective wind-speed from the shape itself. The angular width is defined based on the plume angular distribution around its main axis and is found to be effectively independent of the source rates.

Using the relationship between the IME and the flux rates for different wind speeds together with the connection between plume shape and the wind speed, we can disentangle the source flux rate based on an observed snapshot of the plume which provides both the IME and the spatial distribution. Our error analysis of this method applied on randomly generated snapshots of various flux rates in the range of 10-1000 kg, h⁻¹, showed an error of around 30% on average for an individual point source estimate. Given that point sources are highly uncertain and also fluctuate in time, this single measurement error appears acceptable. More important than single, measurement precision is accuracy for larger ensemble averages, which informs regional emission estimates. Thus, we also performed an error analysis for aggregated flux estimates from 30 plumes. We used bootstrap sampling and found the aggregation error estimate to be in the range of less than 10%. This provides a significant improvement from other pre-existing approaches that rely on wind data, for which reliable meteorological reanalysis data might not be available at high spatial resolution everywhere.

Furthermore, our method is validated by the application of this method on an actual scene from a controlled release experiment from a natural gas pipeline in 2017, which demonstrated an error of 32% from the controlled flux rate of 89 kg hr a notable accuracy given the simplicity of our algorithm that does not require wind speed data. This provides added value in quantifying methane point source emissions especially in locations where atmospheric reanalysis products and surface meteorological observations are not available.

It should be noted that altering the device detection threshold level in our synthetic modelling to higher values does impact the robustness of the correlation between the plume width and the wind speed. In this study, we set the threshold to 500 ppm-m to match the capabilities of the current instrumentations. Future instruments with improved gas sensitivity (Thorpe et al., 2016b), will likely improve our ability to estimate emission rates. Repeat overflights that result in multiple snapshots of the same source can also further reduce uncertainties from transient variations of the plume due to turbulence. Another aspect is that our current LES does not yet model direct emission that could be released at height above the ground. Incorporating this feature into our future analysis may provide even more realistic methane plume simulations. Despite these limitations, this current study is a first step proving the potential of the method.

In this study, we have demonstrated the ability to estimate flux rates of methane point sources based solely on the remotely sensed column methane enhancement without the need for ground measurements or weather reanalysis data. This method could be applied to recent large-scale flight campaigns to improve previous emission rate estimates. This also has immediate implications for future AVIRIS-NG flight campaigns, in particular over parts of the world lacking available wind data. The methodology described in this study could also be applied to anticipated satellites that will provide methane measurements at finer spatial resolutions than currently available. A path towards an improved understanding of the regional methane budget as well as insights into methane source distributions by categories is made possible.

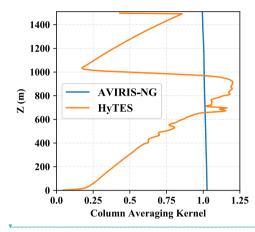

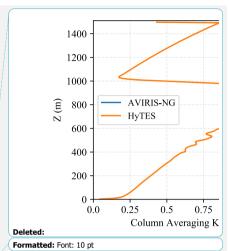

Figure 2: Column averaging kernels for two instruments, AVIRIS-NG (in blue) and HyTES (in orange), as a function of height. The altitude on z-axis is given above ground level. In the Thermal case (HyTES) the flight altitude is an important factor for the CAK. The CAK of HyTES was computed for an altitude of about 3 km. For the shortwave range, however, the CAK of AVIRIS-NG is not impacted significantly by flight altitude.

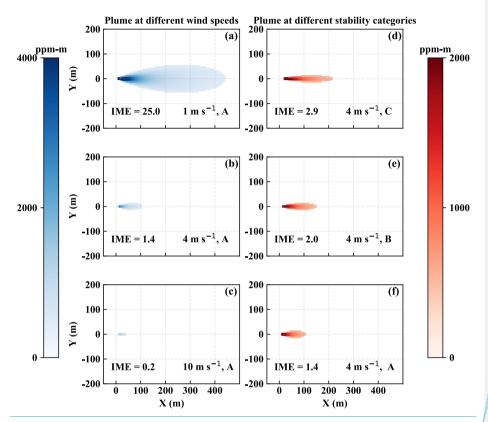

Figure 3: (a) – (c) Gaussian plumes under wind speeds of 1,4, and 10 m_ss¹/₄ respectively, with Pasquil stability type "A= very unstable," (d) – (f) Gaussian plumes under wind speed of 4 m_ss¹/₄ in the stability type "A=very unstable,", "B=unstable,", and "C=slightly unstable," respectively. All cases are with flux rate of 300 kg, h⁻¹/₄ and detection threshold

5 set 10,500 ppm-m. The IME is calculated over the entire scene and is in kg. The wind speed shown in this Gaussian model is at plume levels.

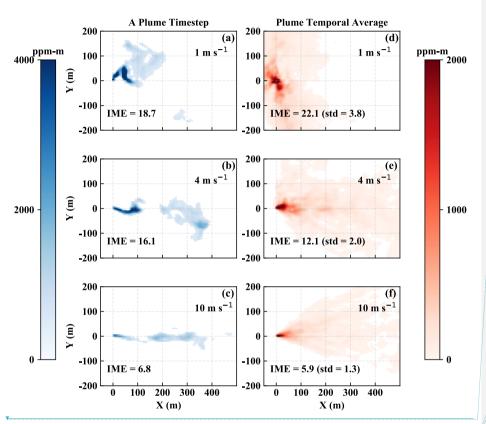

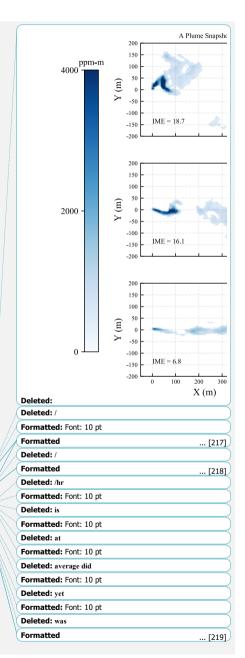

Figure 4: (a) – (c) Snapshots of simulated plumes under wind speeds of 1,4, and 10 m_ss⁻¹ respectively. (d) – (f) time-averaged plumes from 60 timesteps under the geostrophic wind speeds of 1,4, and 10 m_ss⁻¹ respectively. All with flux rate of 300 kg h⁻¹ and detection threshold set to 500 ppm-m. All are based on AVIRIS-NG averaging kernels. The IME is calculated over the entire scene and is in kg. Note that the temporal averages do not reach a true ensemble average as sample size are finite (i.e. the average still exhibit fine structure).

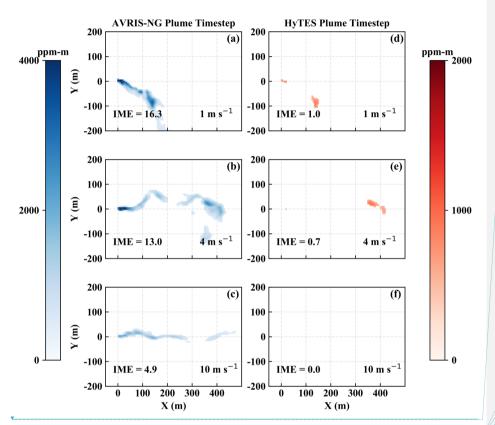

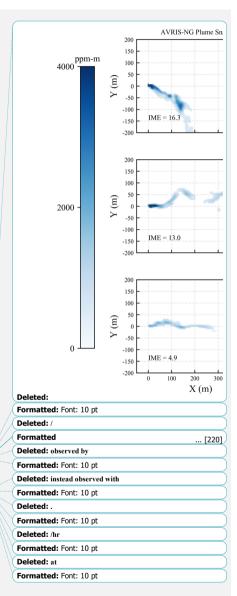

Figure 5: (a)-(c) Snapshots from simulated plumes under 1, 4, and 10 m_ss⁻¹ respectively, when applying the AVIRIS-NG instrument column averaging kernel. (d)-(f) Snapshots from the exact same plumes as in (a)-(c) respectively, but applying the HyTES averaging kernel. The flux rates are all 300 kg, h⁻¹ and the detection threshold is set to 500 ppmm. The IME is in kg.

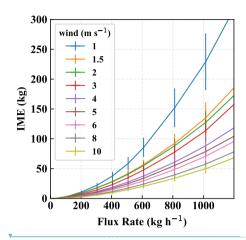

Figure 6: Mean and standard deviation of the IME associated with a range of flux rates under various background wind speeds from 1 to 10 m_es⁻¹. The detection threshold is 500 ppm-m_s

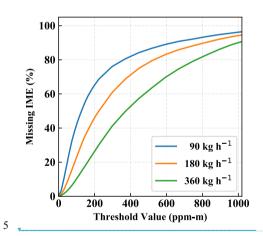

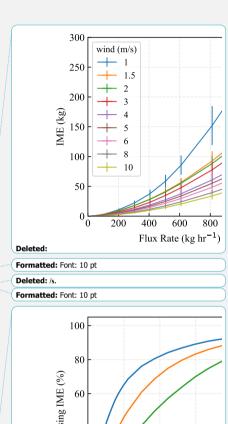

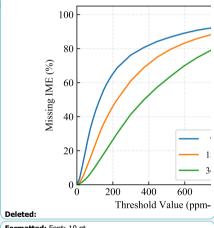

Figure 7: Missing IME, shown as a percentage, for different ppm-m threshold values. Each curve corresponds to a prescribed source flux rate. The flux rates are incremented by a factor of 2.

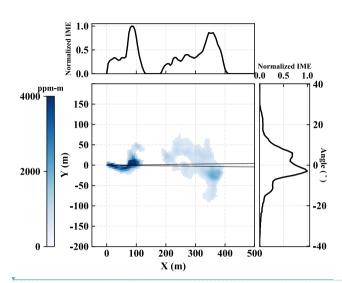

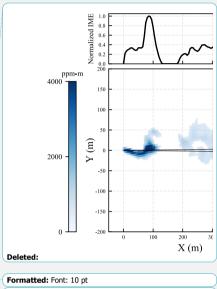

Figure 8: A rotated plume snapshot from a run of 4 m_ss⁻¹ background wind speed and 300 kg, h⁻¹, flux rate with its angular distribution of IME across the plume (right) and its Cartesian distribution of IME along the plume (top). The two black lines denote an angular bin of 0.5 degree that sweeps through the 2D plume to construct the angular distribution,

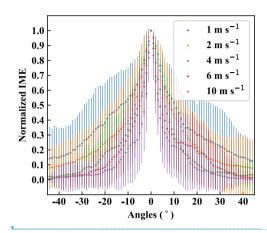

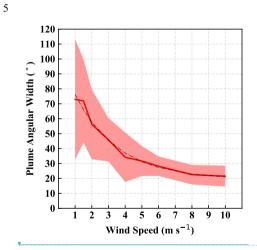

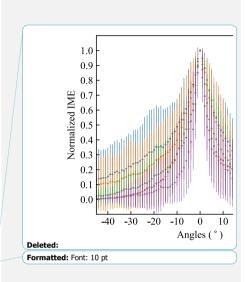

Figure 9: Ensemble-averaged angular distributions of the plume, averaging over all available timesteps at various flux rates. Different colors represent different wind speeds. Each distribution is normalized by its maximum value. The vertical bars represent one standard deviation of the normalized IME at a given angle across all snapshots.

Formatted: Font: 10 pt

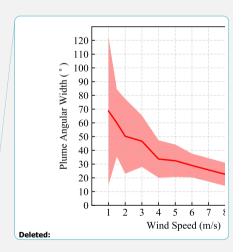

Figure 10: Relationship between the wind speed and the associated cone width averaged over snapshots and flux rates.

The dotted black curve represents the best fit by an exponential function. The shaded area represents one standard deviation from the mean plume angular width for each wind speed.

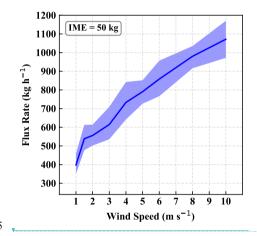

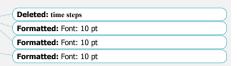

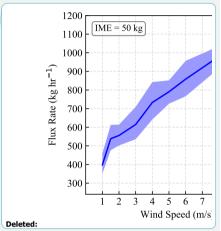

Figure 11: Relationship between flux rate and wind speed for 50 kg IME. The shaded area represents one standard deviation from the mean flux rate at each given wind speed.
