## 10 **Abstract**

11 Frequently, passive dry deposition collectors are used to sample atmospheric dust deposition. However,  
12 there exists a multitude of different instruments with different, usually not well-characterized sampling  
13 efficiencies. As a result, the acquired data might be considerably biased with respect to their size  
14 representativity, and as consequence, also composition. In this study, individual particle analysis by  
15 automated scanning electron microscopy coupled with energy-dispersive X-ray was used to characterize  
16 different, commonly used passive samplers with respect to their size-resolved deposition rate and  
17 concentration. This study focuses on the microphysical properties, i.e. the aerosol concentration and  
18 deposition rates as well as the particle size distributions. In addition, computational fluid dynamics  
19 modeling was used in parallel to achieve deposition velocities from a theoretical point of view.

20 SEM calculated deposition rate measurements made using different passive samplers show a  
21 disagreement among the samplers. Modified Wilson and Cooke (MWAC) and Big Spring Number Eight  
22 (BSNE) - both horizontal flux samplers - collect considerably more material than Flat plate and the  
23 Sigma-2, which are vertical flux samplers. The collection efficiency of MWAC increases for large  
24 particles in comparison to Sigma-2 with increasing wind speed, while such an increase is less observed  
25 in the case of BSNE. A positive correlation is found between deposition rate and PM<sub>10</sub> concentration  
26 measurements by an optical particle spectrometer. The results indicate that a BSNE and Sigma-2 can be  
27 good options for PM<sub>10</sub> measurement, whereas MWAC and Flat plate samplers are not a suitable choice.  
28 A negative correlation was observed in between dust deposition rate and wind speed. Deposition  
29 velocities calculated from different classical deposition models do not agree with deposition velocities  
30 estimated using computational fluid dynamics simulations (CFD). The deposition velocity estimated

31 from CFD was often higher than the values derived from classical deposition velocity models. Moreover,  
32 the modeled deposition velocity ratios between different samplers do not agree with the observations.

34 fluid dynamics

## 35 1 Introduction

36 Mineral dust aerosol in the climate system has received considerable scientific attention mainly due to  
37 its direct effect on the radiative budget and indirect one on cloud microphysical properties (Arimoto,  
38 2001; Huang et al., 2010). Mineral dust particles also play a key part with respect to gas phase chemistry  
39 by providing a reaction surface e.g. ozone depletion (Nicolas et al., 2009; Prospero et al., 1995).  
40 Moreover, dust aerosol also plays an important role in biogeochemical cycles by supplying important  
41 and limiting nutrients to Ocean surfaces (Jickells et al., 2005). Mineral dust is emitted mainly from the  
42 arid and semi-arid regions of the world and believed to have a global source strength ranging from 1000-  
43 3000 Tgyr<sup>-1</sup> (Andreae, 1995). They form the single largest component of global atmospheric aerosol mass  
44 budget, contributing about one third of the total natural aerosol mass annually (Penner et al., 2001).

45 Deposition measurement data of mineral dust are useful to validate numerical simulation models and to  
46 improve our understanding of deposition processes. However, the scarcity and the limited  
47 representativity of the deposition measurement data for validation pose a major challenge to assess dust  
48 deposition at regional and global scales (Schulz et al., 2012; WMO, 2011). This is in part linked to the  
49 uncertainties evolving from the use of different and non-standardized measurement techniques.

50 Commonly, deposition is measured by passive techniques, which provide an acceptor area for the  
51 depositing atmospheric particles. The advantage of these passive samplers is that they operate passively,  
52 resulting in simple and thus cheaper instruments, so that many locations can be sampled at a reasonable  
53 cost (Goossens and Buck, 2012). The usual lack of a power supply allows also for unattended remote  
54 setups. However, the most important disadvantage is that collection efficiency and deposition velocity is  
55 determined by the environmental conditions not under operator control, and in remote setups also  
56 frequently also unknown. That implies, in addition, that the sampler shape can have a strong and variable  
57 impact of the collection properties.

58 While there is previous work describing and modeling single samplers (Einstein et al., 2012; Wagner and  
59 Leith, 2001a, b; Yamamoto et al., 2006) and a few comparison studies (Goossens and Buck, 2012;  
60 Mendez et al., 2016), most previous studies (Goossens and Buck, 2012; López-García et al., 2013) only

61 compare total mass, thereby neglecting size dependence and potential comparison biases. Also, a  
62 systematic assessment of the impact of wind conditions is not commonly carried out, but for example  
63 Mendez et al. (2016) showed that the efficiency of the BSNE and MWAC samplers for collecting PM<sub>10</sub>  
64 varies with wind speed, and Goossens and Buck (2012) found that PM<sub>10</sub> concentrations from BSNE and  
65 DustTrak samplers have comparable values for wind speeds from 2–7 m/s.

66 The purpose of this study is to assess the particle collection properties of different deposition and other  
67 passive samplers based on single particle measurements, and to assess their agreement with theory. From  
68 the available data, also relations of the collected particle microphysics and composition homogeneity  
69 between the samplers will be presented, which can be used as estimators for the comparability of previous  
70 literature data based on the different techniques. To the best of our knowledge, this is the first study to  
71 analyze dry deposition measurements collected using passive samplers by means of a single-particle  
72 SEM-EDX Analysis approach (particularly in the size fraction larger than 10 μm).

## 73 2 Material and methods

### 74 2.1 Sampling location and time

75 Sahara and Sahel provide large quantities of soil dust, resulting in a westward flow of mineral dust  
76 particles over the North Atlantic Ocean accounting for up to 50% of global dust budget (Goudie and  
77 Middleton, 2001). Owing to proximity to the African continent, the Canary Islands are influenced by dust  
78 particles transported from Sahara and Sahel regions. Therefore, Tenerife is one of the best locations to  
79 study relevant dust aerosol in a natural environment.

80 For this study, we conducted a two month (July to August 2017) aerosol collection and dry deposition  
81 sampling campaign at Izaña Global Atmospheric Watch observatory (Bergamaschi et al., 2000;  
82 Rodríguez et al., 2015) (28.3085°N, 16.4995°W). Sampling inlet were placed at a height of 2 m above  
83 ground, on top of a measurement installation. The installation was made on a 160 m<sup>2</sup> flat concrete  
84 platform. The trade wind inversion, which is a typical meteorological feature of the station, shields most  
85 of the time the observatory from local island emissions (García et al., 2016). Therefore, the Izaña Global  
86 Atmospheric Watch observatory is an ideal choice for in-situ measurements under “free troposphere”  
87 conditions (Bergamaschi et al., 2000; García et al., 2016).

## 88 2.2 Wind measurements

89 An ultra-sonic anemometer (Young model 81000, R. M. Young Company, Traverse City, MI, USA) was  
90 installed at approximately 2 m height above the ground to obtain the 3-D wind velocity and direction. It  
91 was operated with a time resolution of 10 Hz to get basic information on turbulence structure.

## 92 2.3 Particle sampling

93 Samples were collected from different, commonly used samplers, namely Big Spring Number Eight  
94 (BSNE) (Fryrear, 1986), Modified Wilson and Cooke (MWAC) (Wilson and Cook, 1980), Sigma-2  
95 (VDI2119, 2013) and Flat plate (UNC-derived) (Ott and Peters, 2008). In addition, the free-wing  
96 impactor (FWI) (Kandler et al., 2018) was used to collect coarser particles. The BSNE, MWAC, FWI  
97 and Filter Sampler were mounted on wind vanes to align them to the ambient wind direction. Samples  
98 were collected continuously, and substrates were exchanged at intervals of 24 hours. The sampling  
99 duration for FWI (12 mm Al-stub) was 30 min only to avoid overloading. The sampling duration for filter  
100 sampler was set to be one hour. It has to be noted that the  $PM_{10}$  from optical measurements for this  
101 particular 0.5 or 1 hour only deviates by 2 % and 0.2 % respectively from the 24-h-average.

### 102 2.3.1 Dust deposition samplers

#### 103 2.3.1.1 Flat plate sampler

104 The Flat plate sampler used in this work was taken from the original Flat plate geometry used in Ott and  
105 Peters (2008). Briefly, the geometry contains two round brass plates (top plate diameter 203 mm, bottom  
106 plate 127 mm, thickness 1 mm each) mounted in a distance of 16 mm. Unlike the original design, the  
107 geometry of the current work has a cylindrical dip in the lower plate, which recedes the sampling substrate  
108 – a SEM stub with a thickness of 3.2 mm – from the airflow, thereby reducing the flow disturbance. A  
109 preliminary study with the modified and original setup side-by-side in a rural environment had shown  
110 that this recession approximately doubles the collection efficiency for large particles. In this design, larger  
111 droplets ( $> 1$  mm) are prevented by this setup from reaching the SEM stub surface at the local wind  
112 speeds Ott and Peters (2008). As described in Wagner and Leith (2001a); (Wagner and Leith, 2001b),  
113 the main triggers for particle deposition on the substrates for this sampler are diffusion, gravity settling,  
114 and turbulent inertial forces, of which only the latter two are relevant in our study.

#### 115 2.3.1.2 Upward-downward deposition rate sampler

116 It is important to compare the upward and downward rates to understand the turbulent and the  
117 gravitational share in aerosol deposition rate measurement. Following an approach by Noll and Fang  
118 (1989), it was assumed that turbulent transport is the main mechanism for upward-directed deposition  
119 rate while turbulent transport and sedimentation are the mechanism of for the downward one. Therefore,

120 a sampler with an upward- and a downward-facing substrate in analogy to the Flat plate sampler was  
121 designed. Air is flowing between two circular steel plates thick 1 mm with a diameter of 127 mm. In the  
122 centers of the plates, two substrates are mounted opposite to each other. The substrate holders are  
123 recessed, so that their adhesive collection surface is in plane with the steel surface. The construction is  
124 mounted into a frame with a distance of 16 mm between the plates / substrates.

#### 125 2.3.1.3 Sigma-2 sampler

126 The Sigma-2 sampling device is described in Dietze et al. (2006); (Schultz, 1989; VDI2119, 2013).  
127 Briefly, the geometry consists of a cylindrical sedimentation tube with a height of about 27 cm made of  
128 antistatic plastic, which is topped by a protective cap with diameter of 158 mm. At its top, the cap has  
129 four rectangular inlet windows (measuring 40 mm x 77 mm, all at the same height) at its side providing  
130 away for passive entrance of particles to the collection surface. Once entered the tube, particles are  
131 assumed settle down to the collection surface due to gravitation (Stokes' law) (VDI2119, 2013). The  
132 samplers designed in a way that it protects the sample from direct radiation, wind and precipitation.

#### 133 2.3.1.4 The Modified Wilson and Cooke (MWAC) sampler

134 The MWAC sampler is based on an original design developed by Wilson and Cook (1980). The sampler  
135 consists of a closed polyethylene bottle, serving as settling chamber, to which an inlet tube and an outlet  
136 tube have been added. The MWAC sampling bottles are 95 mm long with a diameter of 48 mm. The two  
137 inlet and outlet plastic tubes with inner and outer diameter 8 and 10 mm respectively, pass air through  
138 the cap into the bottle and then out again. The large volume of the bottle relative to the inlet diameter  
139 makes the dust particles entering the bottle to be deposited in the bottle due to the flow deceleration the  
140 total bottle area, and due to impaction below the exit of the inlet tube. The air then discharges from the  
141 bottle via the outlet tube. MWAC is one of the most commonly used samplers (Goossens and Offer,  
142 2000) and has a high sampling efficiency for large particles (Mendez et al., 2016).

#### 143 2.3.1.5 The Big Spring Number Eight (BSNE) sampler

144 The BSNE sampler, originally designed by Fryrear (1986), is intended to collect airborne dust particles  
145 from the horizontal flux (Goossens and Offer, 2000). Briefly, the particle laden air passes through a  
146 rectangular inlet (21 mm wide and 11 mm high, with total area of 231 mm<sup>2</sup>). Once inside the sampler,  
147 air speed is reduced by continuous cross section increase (angular walls) and the particles settle out on a  
148 collection surface. Air discharges through a mesh screen.

### 149 2.3.2 Free-wing impactor (FWI)

150 A free rotating wing impactor (Jaenicke and Junge, 1967; Kandler et al., 2018; Kandler et al., 2009) was  
151 used to collect particles larger than approximately 5  $\mu\text{m}$ . A FWI has a sticky impaction surface attached  
152 to a rotating arm that moves through air; particles deposit on the moving plate due to their inertia. The  
153 rotating arm is moved at constant speed by a stepper motor, which is fixed on a wind vane, aligning the  
154 FWI to wind direction. The particle size cut-off is defined by the impaction parameter, i.e. by rotation  
155 speed, wind speed and sample substrate geometry. Details of working principle of FWI can be obtained  
156 from Kandler et al. (2018)

### 157 2.3.3 Filter sampler

158 A filter sampler with Nucleopore filters (Whatman® Nucleopore™ Track-Etched Membranes diam. 25  
159 mm, pore size 0.4  $\mu\text{m}$ , polycarbonate) mounted on a wind vane was used for iso-axial particle collection.  
160 An inlet nozzle of 6 mm was used to achieve pseudo-isokinetic conditions. Sample flow (0.75  $\text{m}^3/\text{h}$   
161 volumetric at ambient conditions) was measured by a mass flow meter (MASS-STREAM, M+W  
162 instruments, Leonhardsbuch, Germany). The filter sampler was operated at least two times a day.

## 163 2.4 Ancillary Aerosol Data

164 Additional information regarding the aerosol particle size distributions has been obtained by using an  
165 optical particle counter (OPC, GRIMM, Ainring, Germany), which is operationally available at the Izaña  
166 Global Atmospheric Watch observatory (Bergamaschi et al., 2000; Rodríguez et al., 2015).

## 167 2.5 SEM-Analysis

168 All aerosol samples (except the filter sampler) were collected on pure carbon adhesive substrates (Spectro  
169 Tabs, Plano GmbH, Wetzlar, Germany) mounted to standard SEM aluminum stubs. The filter samples  
170 were stored in standard 'Petrislides' (Merck KGaA, Darmstadt, Germany). All adhesive samples were  
171 stored in standard SEM storage boxes (Ted Pella Inc, Redding, CA, USA) in dry conditions at room  
172 temperature. Individual particle analysis by automated scanning electron microscopy (SEM; FEI ESEM  
173 Quanta 400 FEG, FEI, Eindhoven, The Netherlands; operated at 12.5 kV, lateral beam extension 3 nm  
174 approx., spatial resolution 160 nm) was used to characterize particles for size and composition. A total  
175 of 316,000 particles from six samplers was analyzed. 26 samples from BSNE (53,000 particles), 23  
176 samples from MWAC (49,000), 23 samples from SIGMA-2 (39,000), 18 samples from Flat plate (12  
177 mm) (24,000), 22 samples from Flat plate (25 mm) (21,000), 13 samples from Filter (80,000) and 12  
178 samples from FWI-12 mm (50,000) were analyzed. Each sample was characterized at areas selected by  
179 a random generator, until a total of 3,000 particles with projected area diameters greater than 1  $\mu\text{m}$  was

180 reached. For particle identification, the backscattered electron image (BSE-image) has been used, as dust  
181 particles contain elements with higher atomic number than carbon and therefore appear as detectable  
182 bright spots in the BSE-image.

183 Chemistry information was derived by energy-dispersive X-ray analysis (EDX; Oxford X-Max 120,  
184 Oxford Instruments, Abingdon, United Kingdom). The internal ZAF-correction of the detector / software  
185 system – based on inter-peak background radiation absorption measurements for correction – was used  
186 for obtaining quantitative results.

## 187 **2.6 Particle size determination**

188 The image analysis integrated into the SEM-EDX software determines the size of particles as a projected  
189 area diameter.

$$190 \quad \mathbf{d}_g = \sqrt{\frac{4B}{\pi}} \quad (1)$$

191 Where  $\mathbf{B}$  and  $\mathbf{d}_g$  are the area covered by the particle on the sample substrate and the projected area  
192 diameter respectively.

193 Following Ott et al. (2008), the volumetric shape factor,  $\mathbf{S}_v$  is determined from the count data as:

$$194 \quad \mathbf{S}_v = \frac{P^2}{4\pi A} \quad (2)$$

195 Where P and A are the perimeter and the projected area of the particle respectively.

196 The volume-equivalent diameter (sphere with the same volume as the irregular shaped particle) is then,  
197 calculated from the projected area diameter via the volumetric shape factor (Ott et al., 2008) and is  
198 expressed by particle projected area and perimeter as

$$199 \quad \mathbf{d}_v = \frac{4\pi B}{P^2} \mathbf{d}_g = \frac{1}{P^2} \sqrt{64\pi B^3} \quad (3)$$

200 The aerodynamic diameter ( $\mathbf{d}_a$ ) is calculated from projected area diameter through the use of a volumetric  
201 shape factor and aerodynamic shape factor (Wagner and Leith, 2001b)

$$202 \quad \mathbf{d}_a = \sqrt{[\mathbf{d}_v (\rho_p / \rho_0) \mathbf{1} / \mathbf{S}_d]} \quad (4)$$

203 With  $\mathbf{S}_d$  the aerodynamic shape factor;  $\rho_p$  and  $\rho_0$  are particle density and unit density respectively. For  
204 this work, a value of  $\mathbf{S}_d = 1.41$  was used (Davies, 1979). Cunningham's slip correction was neglected in  
205 this study, as all particles considered were super-micron size.

## 206 **2.7 Mass and number deposition rate calculation**

207 The mass deposition rate (MDR) and number deposition rate (NDR) are calculated from deposited  
208 particle numbers per area, individual particle size and, in case of MDR, density. The particle density was  
209 assumed to be equal the bulk material density of the dominating identified compound for each particle  
210 (Kandler et al., 2007). A window correction (Kandler et al., 2009) was applied to the particle deposition  
211 rate as:

$$212 \quad C_w = \frac{w_x w_y}{(w_x - d_p)(w_y - d_p)} \quad (5)$$

213 Where  $w_x$  and  $w_y$  are the dimensions of the analysis rectangle.

214 The MDR of the samples is then determined as

$$215 \quad MDR = \frac{1}{Ati} \sum_k \rho d_p^3 C_w(d_p, k) \quad (6)$$

216 Similarly, The NDR of the samples is determined as

$$217 \quad NDR = \frac{1}{Ati} \sum_k C_w(d_p, k) \quad (7)$$

218 With  $A$  is the total analyzed area,  $t$  is the sample collection time,  $\rho$  particle density and  $k$  is index of the  
219 particle.

220 Size distributions for all properties were calculated for the logarithmic-equidistant intervals of 1-2  $\mu\text{m}$ ,  
221 2-4  $\mu\text{m}$ , 4-8  $\mu\text{m}$ , 8-16  $\mu\text{m}$ , 16-32  $\mu\text{m}$ , and 32-64  $\mu\text{m}$ .

## 222 **2.8 Modeling atmospheric concentrations and size distributions from flux measurements**

223 Concentrations are calculated from the deposition rate using different deposition velocity models for  
224 different samples, namely the models of Stokes and Piskunov (Piskunov, 2009). The basic relationship  
225 between concentration and deposition rate was already given by Junge (1963), as the ratio of deposition  
226 rate to concentration:

$$227 \quad V_d = F/C \quad (8)$$

228 With  $F$  is deposition rate and  $C$  is concentration. Note that the formulation is independent of the type of  
229 concentration, i.e. it can be equally applied to number or mass concentrations.

230 All different approaches now give different formulations for the deposition velocity, based on a set of  
231 assumptions and neglects.

232

233 2.8.1 Stokes settling

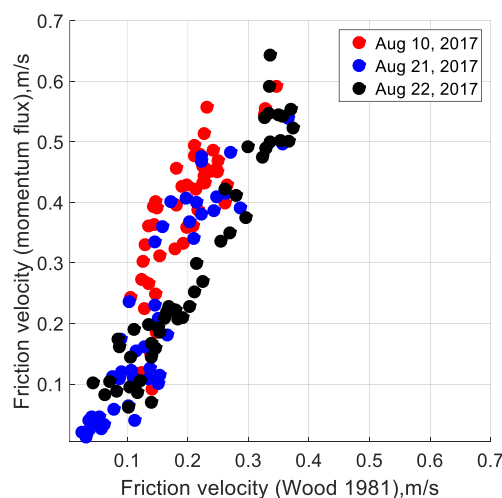

234 Terminal settling velocity ( $V_{ts}$ ) is calculated according to Stokes' law.

235 
$$V_{ts} = \frac{d_p^2 g (\rho_p - \rho_a)}{18\mu} \quad (9)$$

236 Where  $d_p$  is the particle size,  $g$  is the gravitational acceleration ( $9.81 \text{ m/s}^2$ );  $\rho_p$  the density of particle;  $\rho_a$   
 237 the air density;  $\mu$  is the dynamic viscosity of air ( $1.8 \cdot 10^{-5} \text{ kg/(ms)}$ ).

238 2.8.2 Turbulent deposition and more complex deposition models

239 To calculate the turbulent impaction velocity, which depends of the wind speed, the friction velocity is  
 240 needed. Friction velocity ( $u_*$ ), which is a measure of wind generated turbulence is one most important  
 241 variables affecting deposition velocity (Arya, 1977). Mainly two different approaches have been used to  
 242 estimate  $u_*$ . On one hand the momentum flux or the eddy covariance (EC) approach (Ettling, 1996),  
 243 which directly estimates  $u_*$  from the correlations between the measured horizontal and vertical wind  
 244 velocity fluctuation, and on the other the law of the wall (LoW) approach (Shao et al., 2011), which  
 245 estimates  $u_*$  from the wind profile. The latter can be approximated from free-stream velocity and  
 246 roughness assumptions (Wood, 1981), where the flow inside the sampler is assumed to be in the  
 247 hydraulically smooth regime (Schlichting, 1968). **Figure 1** shows correlations between  $u_*$  estimated  
 248 using Wood (1981) and Ettling (1996) approaches. Obviously, the approaches lead to different results,  
 249 for which no clear explanation is available (Dupont et al., 2018) .

250

251 **Figure 1:** Comparison of the friction velocities obtained from the momentum flux and the Wood 1981  
252 approaches for different days with different wind speeds (average wind speed =2.9 m/s, 2.1 m/s, 3.1  
253 m/s for Aug 10, Aug 21, and Aug 22, 2017, respectively).

254 For the current work, the friction velocity is calculation is based on Wood (1981) approach:

$$255 \quad u_* = (u/\sqrt{2}) [(2\log_{10}(Re) - 0.65)^{-1.15}] \quad (10)$$

256 Where  $Re$  is the flow Reynolds number at the sampling stub location and is given as

$$257 \quad Re = uX/V \quad (11)$$

258  $X$  is the distance from the lower plate edge to the center of the sampling stub (6.3 cm) and  $V$  is kinematic  
259 viscosity.

260 The reason why we opted to use the Wood (1981) over the Ettling (1996) approach is a) its simplicity, as  
261 it requires only average wind speeds instead of 3D high resolution ones, and therefore will be more  
262 commonly applicable; and b) the fact that the momentum approach yields sometimes uninterpretable  
263 data, in particular in case of buoyancy-driven flow. For some case studies, both approaches are compared  
264 below.

265 There are a variety of models estimating the particles deposition speed (Aluko and Noll, 2006; Noll and  
266 Fang, 1989; Noll et al., 2001; Piskunov, 2009; Slinn and Slinn, 1980; Wagner and Leith, 2001a) (see  
267 **Figure 2**). And these different deposition velocity models yield different results, which could be due to  
268 negligence of unaccounted forces (Lai and Nazaroff, 2005) or due to the way how friction velocity is  
269 determined or can be related to suppositions by different models (Kandler et al., 2018). Unless otherwise  
270 stated, the particle density used in deposition velocity calculation is  $2600 \text{ kg/m}^3$ .

271 It can be noted that a particular deposition model therefore may not be suitable in different cases for  
272 describing the deposition velocity precisely, so as a result concentrations derived from deposition rate  
273 measurements are likely to be biased (Giardina and Buffa, 2018; Kandler et al., 2018).

274  
 275 **Figure 2:** Deposition velocities for single particles to a smooth surface (Flat plate sampler) calculated  
 276 by using set of different classical deposition models for Tenerife samples (Aug 9, 2017; average wind  
 277 speed =3.0 m/s).

278 2.8.3 Deposition models applied to the samplers

279 **Table 1** shows the different deposition velocity models applied to the various samplers. The Piskunov  
 280 deposition velocity model is made for flat surfaces, and therefore it is applied to BSNE and Flat plate,  
 281 where deposition occurs to such surfaces. For the Sigma-2 sampler, it is assumed that each particle settles  
 282 with the terminal settling velocity (Tian et al., 2017), and therefore Stokes' velocity was used for  
 283 calculation of concentrations. In the case of MWAC, a different approach was required due to its  
 284 geometry. It is internally in principle an impactor design with the incoming tube pointing at the substrate,  
 285 but is operating at very low flow speed and therefore Reynolds numbers. As a result, it cannot be  
 286 described by the impactor theory only. Therefore, we assumed that the deposition velocity can't become  
 287 smaller than the one prescribed by the Piskunov model. As a result, we derived a velocity model based  
 288 on wind speed (or a reduced wind speed) and calculated the collection efficiency assuming the MWAC  
 289 to act as impactor for particles in the range of the cut-off diameter and larger. For smaller particles, we  
 290 assumed that flow is like a flow over a smooth surface, so the Piskunov deposition velocity model was  
 291 applied (e.g., as soon as the deposition velocity from impactor considerations becomes smaller than the  
 292 Piskunov one, the latter was used).

294

**Table 1:** A summary of different deposition velocity models applied to the samplers

<b>Sampler</b>	<b>Deposition velocity model</b>
Sigma-2	Stokes' velocity
Flat plate	Piskunov
BSNE	Piskunov
MWAC	Combination of Piskunov and Impaction curve

295

296 **2.9 Determining the size distributions for mass concentration from the free-wing impactor**  
297 **measurements**

298 Considering the windows correction and the collection efficiency dependence on the impaction speed  
299 and geometry, the overall collection efficiency E is calculated according to Kandler et al. (2018). After  
300 calculating the collection efficiency, the atmospheric concentration is calculated from deposition rate and  
301 deposition velocity as

302 
$$C = \frac{M}{V_d} = \frac{M}{E V_{imp}} \tag{12}$$

303 With E being the collection efficiency and v\_imp the impaction velocity, calculated from ambient wind  
304 speed and rotation speed.

305 **2.10 Determining the size distributions for mass concentration from the filter sampler**  
306 **measurements**

307 Apparent number concentrations are determined from the particle deposition rate and the volumetric flow  
308 rate calculated from the mass flow for ambient conditions. The inlet efficiency ( $Eff_{in}$ ) – accounting for  
309 the sampling biased caused by the difference in wind speed and inlet velocity – is calculated (Belyaev  
310 and Levin, 1974). The ambient concentration  $N_{out}$  is calculated by dividing the measured number  
311 concentration by the inlet efficiency. The effect for the regarded particles size, however, is small in  
312 comparison to the differences between the samplers.

313 **2.11 Statistical uncertainty**

314 Owing to the discrete nature of the particle size measurement, the uncertainty coming from counting can  
315 pose a significant contribution to the uncertainty of mass deposition rate measurement (Kandler et al.,  
316 2018). It is, therefore, important to assess the uncertainties in our mass deposition rate measurements,  
317 which is done in accordance to the previous work (Kandler et al., 2018). For the mass deposition rate,  
318 the statistical uncertainty is assessed by a bootstrap simulation approach using Monte Carlo

319 approximation (Efron, 1979). In this work, the bootstrap simulations and the two-sided 95 % confidence  
320 intervals calculation were performed by using Matlab's bootstrap function (MATLAB R2016a  
321 (MathWorks, Inc). Here, MATLAB function uses a non-parametric bootstrap algorithm (Neto, 2015) to  
322 compute the 95% bootstrap confidence interval.

### 323 3 Computational fluid dynamics (CFD) simulation

324 Computational fluid dynamics (CFD) simulations were conducted to predict the deposition of particles  
325 on to different passive samplers (MWAC, Sigma-2 and Flat plate). A discrete phase model without  
326 interaction with continuous phase was used to calculate the trajectories of the particles. The CFD software  
327 ANSYS-FLUENT 18.2 was used for performing the numerical simulations.

#### 328 3.1 Evaluating the mean flow field

329 In a first step the geometry of samplers was created using ANSYS DesignModeler. In a second step, an  
330 enclosure around the geometry was generated. To ensure that there are no large gradients normal to the  
331 boundaries at the domain boundary, the domain was created depending on the width, the height and the  
332 length of the geometries. The space in front of the geometry is two times the height of the sampler, the  
333 space behind the sampler is ten times the height, the space left and right of the geometry is five times the  
334 width of the geometry and the space below and above the sampler is five times the height.

335 Afterwards a mesh was created using the ANSYS Meshing program. For the enhanced wall treatment  
336 the first near-wall node should be placed at the dimensionless wall distance of  $y^+ \approx 1$ . The dimensionless  
337 wall distance is given by

$$338 \quad y^+ = \frac{u_* y}{\nu} \quad (13)$$

339 With  $y$  the distance to the wall,  $\nu$  the kinematic viscosity of the fluid and  $u_*$  the friction velocity which  
340 is defined for this purpose by

$$341 \quad u_* = \sqrt{\tau_w / \rho} \quad (14)$$

342 With  $\tau_w$  the wall, shear stress and  $\rho$  the fluid density at the wall. The wall is then subdivided into a  
343 viscosity-affected region and a fully turbulent region depending on the turbulent Reynolds number  $Re_y$

$$344 \quad Re_y = \frac{\rho y \sqrt{k}}{\mu} \quad (15)$$

345 With  $y$  the wall-normal distance from the wall to the cell centers,  $k$  the turbulence kinetic energy and  $\mu$   
 346 the dynamic viscosity of the fluid. If  $Re_y > 200$  the k-epsilon model is used.  $Re_y < 200$  the one-equation  
 347 of Wolfstein is employed (Chmielewski and Gieras, 2013; Fluent, 2015). The flow field was calculated  
 348 by solving the Reynolds Averaged Navier Stokes's equations with the software ANSYS Fluent. Standard  
 349 k-epsilon model was used to calculate the Reynolds-stresses. The boundary conditions at the sides of the  
 350 domain were set to symmetric. The inlet boundary condition was set to 2, 4 or 8 m/s with air as fluid  
 351 (Density: 1.225 kg/m<sup>3</sup>, viscosity: 1.7849\*10<sup>-5</sup> kg/(ms)). The outlet boundary condition was set to pressure  
 352 outlet.

353 The turbulence intensity  $T_i$  was calculated as

$$354 \quad T_i = \frac{\left(\frac{2}{3}k\right)^{1/2}}{v} \quad (16)$$

355 With  $k$  the turbulence intensity and  $v$  the velocity at the inlet of the domain.

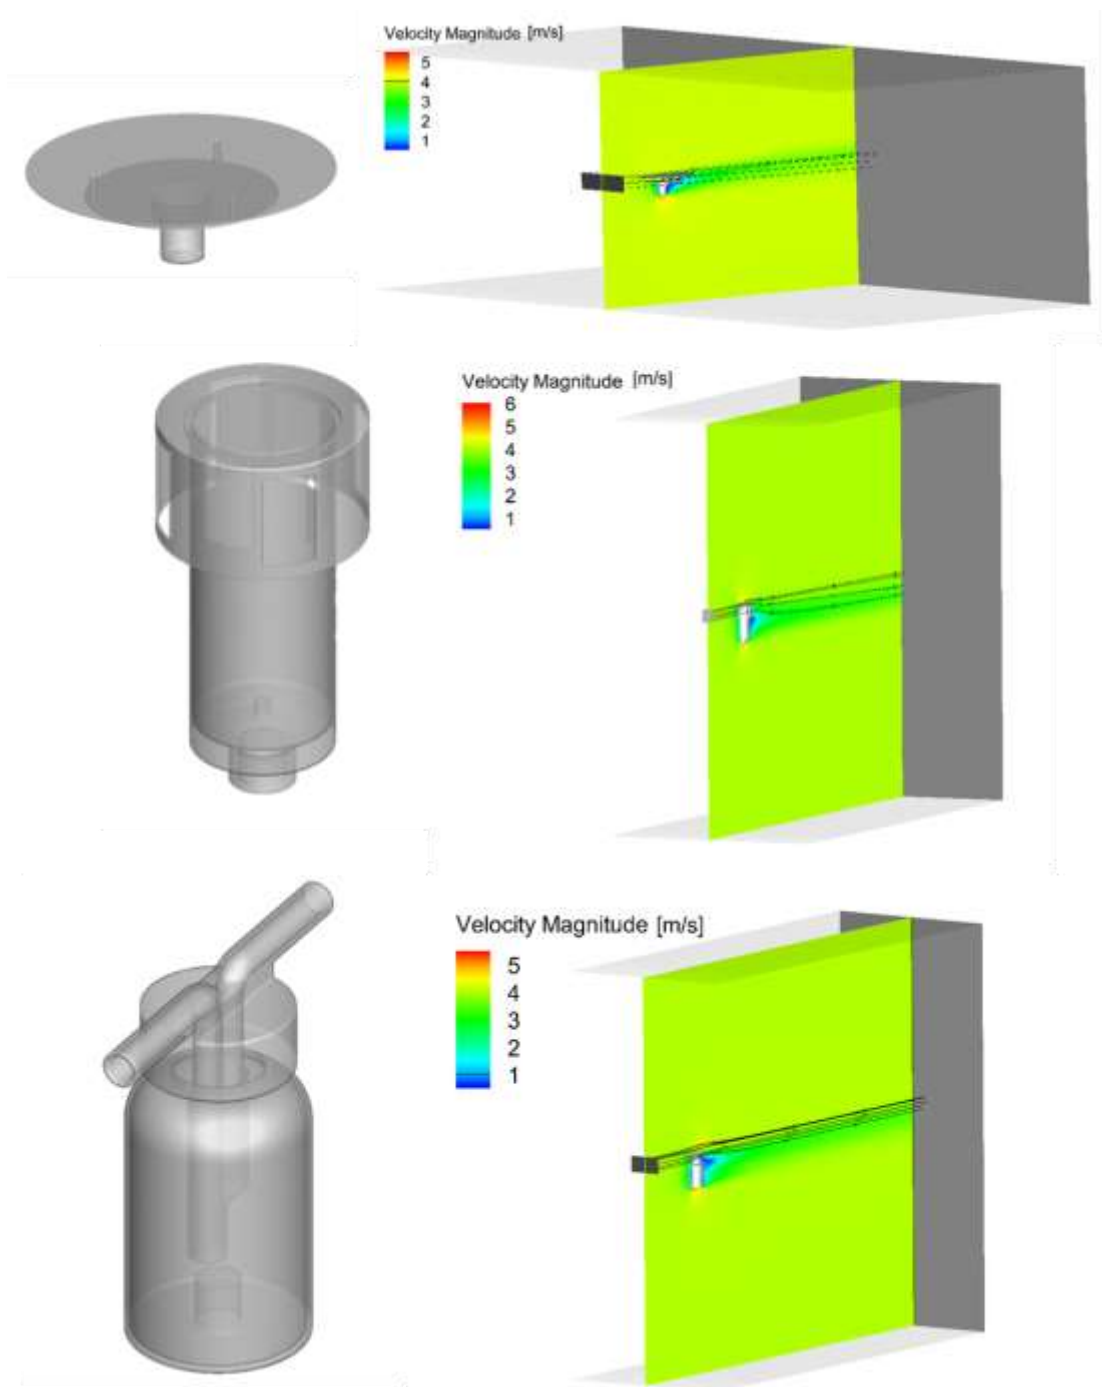

356 Detail of the sampler construction and geometry are found in the electronic supplement (see **Figure S**  
 357 **24, S 25** and **S 26**). Different cases were calculated for the Flat plate sampler (deposition area of 12 and  
 358 25 mm), for the Sigma-2 and for the MWAC (**Figure 3**). For the Flat plate, a mesh with 3,920,000 cells  
 359 was generated, for the Sigma-2 one with 7,600,000 cells and for the MWAC one with 4,620,000. After  
 360 the meshing, the flow fields were calculated. **Figure 3** shows as example the velocity magnitude in the  
 361 middle of the domain for a velocity of 4 m/s at the inlet.

362 In the last step, particles were injected into the velocity field and their trajectories computed. For all  
 363 samplers, the deposition area boundary condition was set to "trap" and the walls were defined as  
 364 reflecting boundaries. Different particle sizes (1, 2.5, 5, 10, 20 and 50  $\mu$ m, Stokes' diameter) for three  
 365 different wind speeds (2, 4, 8 m/s) were investigated. The particles density was set to a value of 2600  
 366 kg/m<sup>3</sup> to match an approximate dust bulk density. The particle concentration was 4\*10<sup>8</sup> /m<sup>2</sup> in all cases,  
 367 while the injection area was adjusted to the geometries (**Figure 3**).

368 The number of particles trapped in the deposition area was determined. The deposition velocity  $V_d$  was  
 369 calculated by

$$370 \quad V_d = \frac{N_{pt}v}{A_d C_p} \quad (17)$$

371 with  $N_{pt}$  the number of trapped particle at the deposition area,  $v$  the velocity of the air at the inlet  
 372 boundary of the domain,  $A_d$  the deposition area and  $C_p$  the particle concentration at the particle injection  
 373 area (Sajjadi et al., 2016).

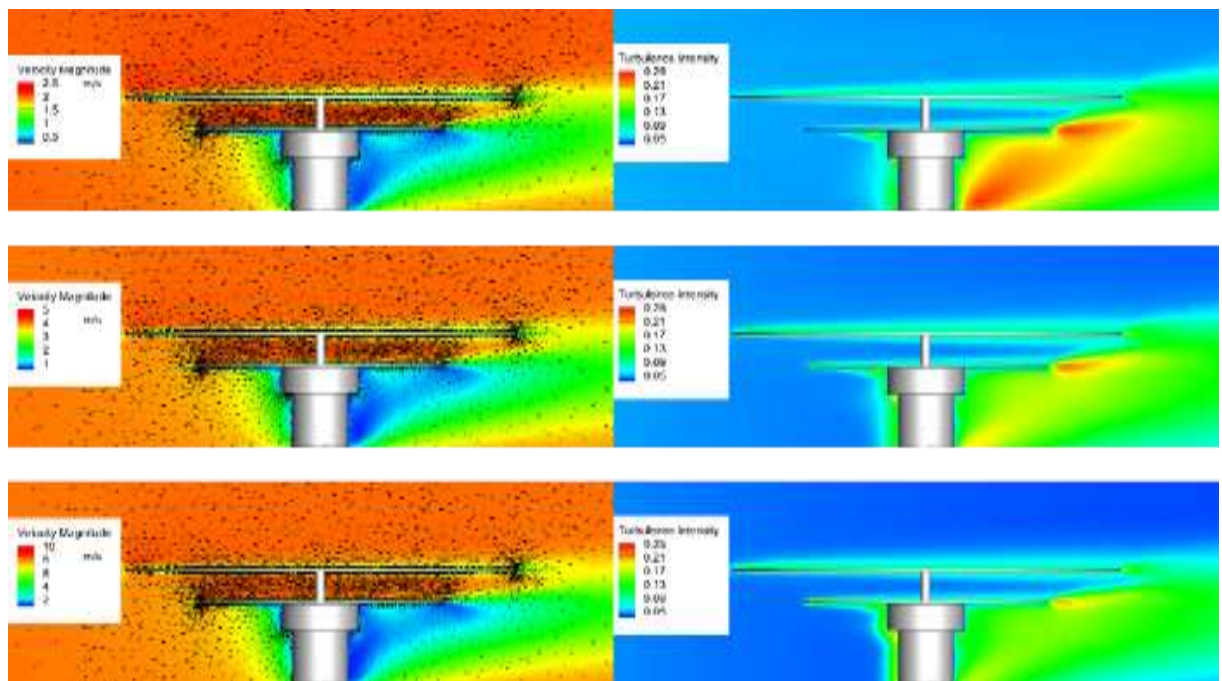

375

376 **Figure 3:** Geometries of Flat plate sampler (top), Sigma-2 sampler (middle), MWAC sampler (bottom).  
 377 CFD modeling domain and velocity magnitude, inlet velocity: 4 m/s (right); in addition, the injection  
 378 area is shown in black (Flat plate sampler: width 0.2 m, height 0.05 m; Sigma-2-sampler: width 0.2 m,  
 379 height 0.1 m; Bottle sampler: width 0.1 m, height 0.05 m) along with exemplary streamtraces.

### 380 3.2 Velocity contours and vectors for the samplers

381 For the Flat plate sampler, stream velocities and turbulence intensities are shown in **Figure 4**. The  
382 formation of the boundary layer at the wall of the sampler is clearly visible at all velocities. At the central  
383 sampling location, the flow between the plates has the same velocity as the free stream, so for the  
384 analytical deposition models, the lower plate can be treated as single surface. The highest velocity is  
385 found at the sharp edge at the bottom of the sampler. Due to the high velocity gradients in this part there  
386 is also the highest turbulence intensity in the domain. As expected, the turbulent wake becomes smaller  
387 with increasing wind speed.

388  
389 **Figure 4:** Flat plate Sampler: Velocity magnitude and turbulence intensity at wind speed 2 m/s (top),  
390 Flat plate Sampler: Velocity magnitude and turbulence intensity at wind speed 4 m/s (middle), Flat  
391 plate Sampler: Velocity magnitude and turbulence intensity at wind speed 8 m/s (bottom).

#### 392 3.2.1 Sigma 2 Sampler

393 The cross section of the velocities for the Sigma-2 are shown for the 4 m/s case in **Figure S 27**.  
394 Apparently the velocity magnitude inside the sampler is much smaller than outside. In the vertical settling  
395 tube, the turbulence intensity is low, justifying the idea of Stokes settling inside. Owing to the open, but  
396 bulky geometry, there is a flow into the interior at the back. The highest velocities and turbulence  
397 intensities are found at the sharp edges at the top and bottom of the sampler.

398 **Figure S 28** shows the cross section of the velocities for the MWAC in the 4 m/s case. Furthermore, the  
399 velocity field and the velocity vectors in the cross sections across and along the inlet tube are shown in

400 **Figure S 29.** In the tubes the typical pipe flow is formed. In the figures showing the cross sections along  
401 the inlet tube a symmetrical flow over the pipe cross section is visible. Finally, **Figure S 30** shows the  
402 mean flow velocity in the MWAC tube is shown as a function of the outside velocity for the three cases.  
403 The fitting curve shows that the mean velocity in the pipe increases linearly with the external velocity.

## 404 4 Results and Discussion

### 405 4.1 Methodical aspects (Field Measurements)

#### 406 4.1.1 Mass deposition rate comparison

407 Mineral dust was the dominating particle type during this campaign, consisting of different silicates,  
408 quartz, calcite, dolomite, gypsum, similar to previous findings for this location (Kandler et al., 2007).  
409 Therefore, hygroscopicity was not taken into account, as due to the mostly non-hygroscopic compounds  
410 and the moderate humidities their impact was rated low. Details on the composition will be reported in a  
411 companion paper.

412 The mass and number deposition rates (given per unit time and sample surface area) along with daily  
413 average temperature and wind speed are presented as daily values. Details for all days and all samplers  
414 can be found in the electronic supplement (see **Table S 1, S 2, S 3** and **S 4**). All data shown in this section  
415 are calculated from SEM measurements. Particle sizes are reported as aerodynamic diameter, if not  
416 otherwise stated. It is also worth mentioning the plots shown in the paper are a few examples of a  
417 comparison while the bulk of the data is presented in the electronic supplement.

418 **Figure 5** shows as example mass deposition rates for different samplers during a dust event and a non-  
419 dust event day. For all samplers, the mass deposition rate size distributions peaked in the 8-16  $\mu\text{m}$   
420 diameter interval. This result is in support of the conclusion that atmospheric dry deposition is dominated  
421 by coarse particles owing to their high deposition velocities (Davidson et al., 1985; Holsen et al., 1991).  
422 There is a considerable difference among different samplers affecting mainly the size range with the  
423 highest mass deposition rates, whereas the difference is small for smaller particles. MWAC and BSNE –  
424 both horizontal flux samplers – collect coarser material than the Flat plate and Sigma-2 samplers, which  
425 in contrary measure the vertical flux. In particular, the MWAC sampler exhibits considerably higher  
426 coarse particle mass deposition rates, probably owing to its impactor-like design.

427

428

429

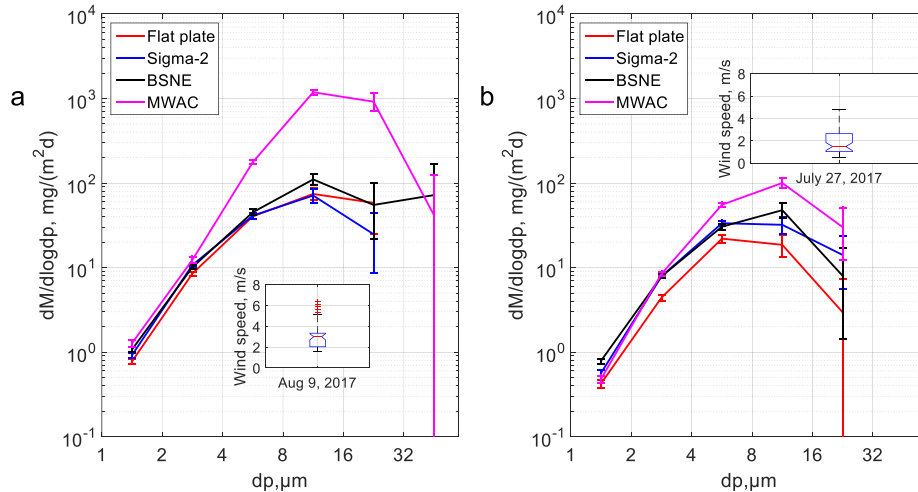

430

431 **Table 2:** The campaign maximum and minimum and median mass deposition rates measured by the  
432 samplers

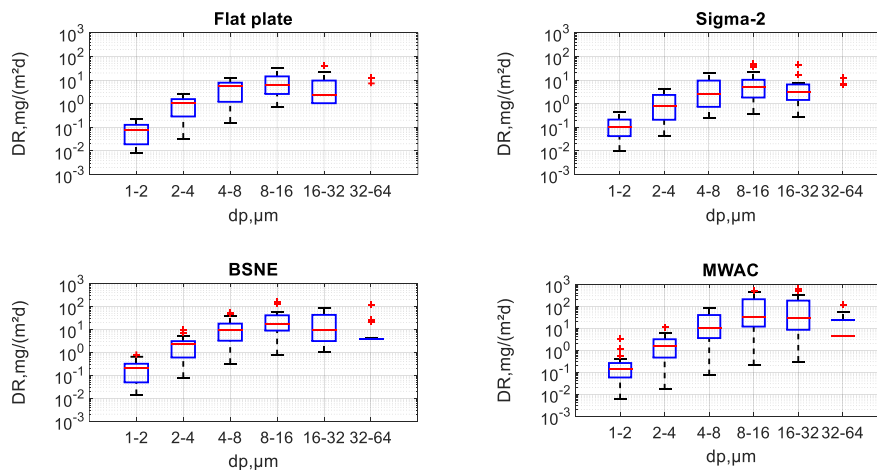

Sampler	Maximum deposition rate (mg/ (m <sup>2</sup> d))	Minimum deposition rate (mg/ (m <sup>2</sup> d))	Median deposition rate (mg/ (m <sup>2</sup> d))
MWAC	1240	0.6	4.8
BSNE	310	0.2	3.1
Flat plate	80	2.0	1.1
Sigma-2	117	1.9	1.1

433

434 As consequence the vertical flux instruments collect much less material than the horizontal flux ones  
435 (**Table 2**), which is in accordance with previous findings (Goossens, 2008). In the present study,  
436 horizontal to vertical flux mass ratio is approximately between 2.8 and 4.4 (with single size intervals  
437 ranging between 2 and 50), while Goossens (2008) reported it to be in between 50 and 160. This  
438 difference in the ratio might come from the different approaches. Goossens (2008) used water as a  
439 deposition surface while in our study we used a SEM sampling substrate. Furthermore, from **Figure 5**,  
440 we can clearly see that that there is a strong variation in mass deposition rates between dust event days  
441 and non-dust event days (full dataset is shown in **Figure 6**). Generally, the temporal variation is higher  
442 than the difference between the samplers so a strict comparison between this and the previous study can't  
443 be done.

444  
 445 **Figure 5:** Size resolved mass deposition rate measured by different passive samplers: a) dust event day;  
 446 b) non-dust event day. Data are derived from SEM measurements. The bars show the central 95%  
 447 confidence interval of the daily variation. The inserts show box plots for the wind speed distribution  
 448 based on 30-min intervals.

449  
 450 **Figure 6:** Box-plots of size resolved deposition rate (campaign data; Flat plate, Sigma-2, MWAC and  
 451 BSNE samplers). On each blue box, the central mark is the median, the edges of the box are the 25th  
 452 and 75th percentiles. The red vertical lines show the standard deviation. The median, percentiles and  
 453 standard deviations shown there correspond to the variability of the whole campaign for each

454 instrument and bin. From the structure of the deposition models, a wind speed dependency for the  
455 deposition velocity should be expected. The average wind speed during the campaign was about 3.5  
456 m/s with the lowest daily median around 1.5 m/s and the highest 7 m/s. A daily box-plot of 30-min  
457 averaged wind speed at Izaña is shown in **Figure S 1**.

458 **Figure 7** shows the mass deposition rate ratio of MWAC, BSNE and Flat plate to Sigma-2 as function  
459 of wind speed. The Sigma-2 sampler was chosen for comparison, as due to its settling tube design, it is  
460 expected to have the least wind sensitivity. The results show highly scattered values. The collection  
461 efficiency of MWAC for large particles has an increasing tendency in comparison to Sigma-2 slightly  
462 with increasing wind speed, while there is barely a trend visible for the BSNE. Both – being horizontal  
463 flux samplers – collect considerably more material than the Sigma-2. For the Flat plate, the deposition  
464 velocity in relation to the Sigma-2 has a weak decreasing trend for higher wind speeds, but generally, the  
465 deposition speed is similar. Overall, the relation of Sigma-2 to BSNE shows the closest agreement, while  
466 the scatter is higher for the other combinations. More information on the relation between the other  
467 instruments is shown in **Figure S 2, S 3, S 4, S 5, S 6, S 7, S 8, S 9** and **S 10**.

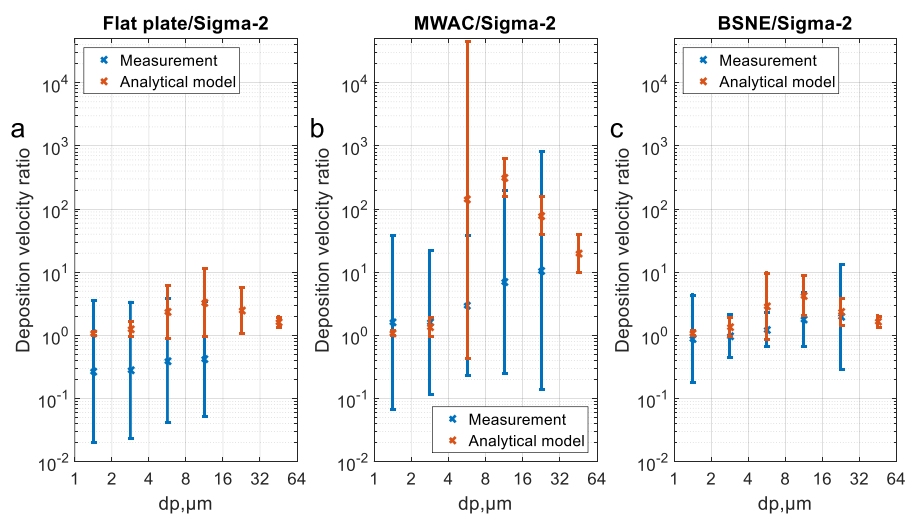

468  
469 **Figure 7:** Deposition rate ratio as function of wind speed for different days (MWAC/ Sigma-2 (a),  
470 BSNE/Sigma-2 (b) and BSNE/ Sigma-2 (c)). Different colors represent deposition rate measured in  
471 different size intervals (black: 1-2  $\mu\text{m}$ ; blue: 2-4  $\mu\text{m}$ ; yellow: 4-8  $\mu\text{m}$ ; red: 8-16  $\mu\text{m}$ ; green: 16-32  $\mu\text{m}$ ;  
472 cyan: 32-64  $\mu\text{m}$ ).

473 While without a true reference technique the absolute deposition velocities can't be determined, their  
474 ratio between different instruments can be compared theoretically and by measurement. The deposition

475 velocity ratios for a pair of different samplers are identical to the deposition rate ratios obtained from the  
 476 corresponding measurements (eq. (7)), as long as the sampling time and the aerosol concentration are the  
 477 same; the latter condition is achieved by the close and parallel sampling. Therefore, the experimentally  
 478 determined ratios can now be compared to the deposition velocity ratios derived from the theoretical  
 479 considerations. **Figure 8** shows the according comparison. Note that this consideration allows for the  
 480 assessment of relative model performance and sampler efficiency, but lacking a ‘true’ reference, it does  
 481 not allow for determining the most accurate sampler.

482 While for BSNE and Sigma-2 observation and model fit comparatively well, the deposition velocity is  
 483 misestimated for the Flat plate/Sigma-2 pairing for all particle sizes (overestimate for Flat plate  
 484 deposition velocity or/and underestimate for Sigma-2). For MWAC/Sigma-2, there is a clear size  
 485 dependency, indicating that probably the impactor model overestimates the deposition velocity; the latter  
 486 might be due to unaccounted particle losses (e.g., inlet efficiency). MWAC, BSNE and Sigma-2 agree  
 487 with respect to deposition velocity better based on the measurement data than predicted by the theory. It  
 488 may be connected to the non-stationarity of the atmosphere, which is not accounted for by the models,  
 489 i.e. the permanent wind speed fluctuations smoothing out detail differences of a stationary flow. The Flat  
 490 plate sampler, however, has a lower-than-predicted deposition velocity.

491  
 492 **Figure 8:** Comparison of geometric mean ratio of deposition velocities for different sampler pairs  
 493 derived from measured deposition rates (blue) and from corresponding deposition models (orange).

494 (a) Flat plate/Sigma-2; (b) MWAC/Sigma-2; (c) BSNE/Sigma-2. Error bars show geometric standard  
 495 deviations. The bars show the central 95% confidence interval of the daily variation. According  
 496 deposition models are listed in **Table 1**.

497 4.1.2 Dependence of PM<sub>10</sub> dust deposition on atmospheric concentration and wind speed

498 **Figure S 22** and **Table 3** display for the approximate PM<sub>10</sub> size range the correlation between number  
 499 deposition rates, atmospheric particle number concentrations measured by OPC and the wind speed for  
 500 different samples. For this consideration, only the overlapping size range – 1-10 µm aerodynamic  
 501 diameter – was used. As expected, there is in all cases a positive correlation between concentrations and  
 502 number deposition rates (see **Figure S 22a**). In particular, for the BSNE and the Simga-2, robust  
 503 correlations with a trend to underestimation at higher concentrations exist. While the models predict a  
 504 positive correlation of wind speed and deposition rate, this is not observed in the measurements. E.g., the  
 505 table does not show a linear correlation since the  $r^2$  values are not close to 1 for the first two samplers  
 506 (particularly the MWAC). Instead, a non-significant anti-correlation can be observed, if at all (e.g., for  
 507 Flat plate;  $r^2$ : 0.319, p-value = 0.070, slope=-0.261) (see **Figure S 22b**), indicating a cross-influence of  
 508 wind speed and concentration. E.g. higher concentrations of dust aerosol particles might be  
 509 meteorologically linked to lower wind speeds due to a different transport situation. Such a general  
 510 behavior was observed previously for example by different techniques for a dust transport region  
 511 (Kandler et al., 2011). An ambiguous wind-dependency has been reported for other places (Xu et al.,  
 512 2016). In this study, the main driver of the deposition rate during is obviously the dust concentration.

513 **Table 3:** Summary of the regression analysis for the correlations between the dust deposition rate and  
 514 the atmospheric concentrations (**PM<sub>10</sub>** size range; measured by the OPC), and for the correlations  
 515 between the dust deposition rates and the wind speeds. Significant relationships are shown in bold.

	Deposition rate vs concentration			Deposition rate vs wind speed		
	$r^2$	p-value	slope (m/d)	$r^2$	p-value	Slope ( $1.16 \cdot 10^5$ /(m <sup>3</sup> ))
Flat plate	0.600	0.0052	0.492	0.319	0.070	-0.261
MWAC	0.155	0.335	0.146	0.308	0.153	-0.157
BSNE	<b>0.937</b>	<b>1.00*10<sup>-6</sup></b>	<b>0.832</b>	0.017	0.706	-0.052
Sigma-2	<b>0.925</b>	<b>3.39*10<sup>-5</sup></b>	<b>0.725</b>	0.0125	0.775	-0.069

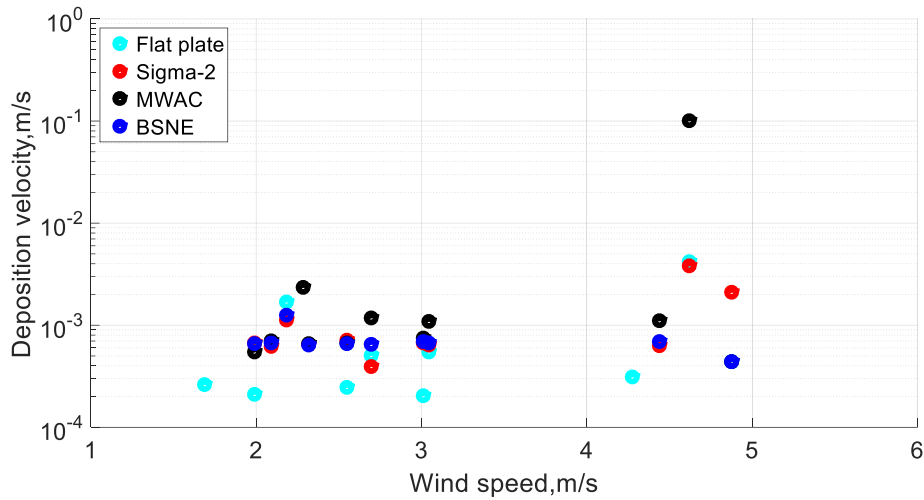

516

517 In a second step is was tested, whether the application of each sampler's assigned deposition model can  
518 increase the correlation between the measurements by the deposition samplers and the OPC observations,  
519 i.e. whether the meteorological parameters accounted for in the models can decrease the deviation.  
520 Therefore, in analogy to the previous correlation, the concentrations modeled from each sampler's SEM  
521 data were correlated with the OPC data for the size range between 1 and 10  $\mu\text{m}$  in particle diameter (see  
522 **Table S 7**). However, no increase in correlation quality is observed, indicating that – like already  
523 observed from the varying ratio calculations above – the deposition models fail to describe the deposition  
524 behavior in detail.

525 From the correlation relations in **Table 3**, it can be learned that MWAC is least suitable for estimating  
526  $\text{PM}_{10}$ , which fully agrees well with previous studies (Mendez et al., 2016). However, the correlation  
527 analysis here shows that BSNE is actually a suitable instrument for a  $\text{PM}_{10}$  estimation, which is in contrast  
528 to the wind-tunnel observation of Mendez et al. (2016). This discrepancy might be owed to the different  
529 approaches. While in the previous work the loss of concentration from the passing aerosol was measured,  
530 in this study a gain of deposition was investigated. As result, for lower deposition velocities (discussed  
531 below), the former approach will yield high uncertainties. Similar to BSNE, Flat plate and Sigma-2  
532 appear good estimators for  $\text{PM}_{10}$ , which is in accordance with previous studies (Dietze et al., 2006).

#### 533 4.1.2.1 Size-resolved apparent deposition velocity in the $\text{PM}_{10}$ size range

534 **Figure 9** displays the apparent deposition velocity (calculated as the ratio of the number deposition rate  
535 to the concentration of the OPC) as function of the wind speed. Obviously, also here there is not clear  
536 trend. The apparent deposition velocities range between  $2 \cdot 10^{-4}$ - $10^{-1}$  m/s. As can be clearly seen from the  
537 plot, the effect of wind speed on deposition velocity is negligible, as indicated already in **Table 3**. While  
538 this is in contradiction to the models, one has to keep in mind that the (a) the observed wind speeds are  
539 comparatively low here, and (b) the considered size range is not the one most affected by the wind speed.  
540 An effect of the wind speed might therefore be much stronger at higher wind speeds and for larger  
541 particles.

542  
 543 **Figure 9:** Apparent deposition velocity: ratio of number deposition rate determined from SEM  
 544 measurements to the number concentration observed by the OPC as function of wind speed. For the  
 545 consideration, only the overlapping size range (approximately 1-10  $\mu\text{m}$ ) was used.

546 4.1.3 Atmospheric mass concentrations derived from deposition rates

547 4.1.3.1 Consistency between samplers and corresponding models

548 **Figure 10** compares a mass deposition rate size distribution with the according concentrations derived  
 549 by the modeled deposition velocities. Calculating the mass concentrations from different passive  
 550 samplers with different models leads in most cases to a better agreement between the measurements,  
 551 taking into account the statistical uncertainties (see **Figure S 11**). This indicates that the deposition  
 552 velocity models selected for the samplers are generally suitable, despite the deviations in single cases.

553

554

555 **Figure 10:** Comparing different samplers with respect to (a, c) dust mass deposition rates and (b, d)  
 556 dust mass concentrations calculated from application of the corresponding model as function of particle  
 557 size. Different colors indicate different samplers (red: Flat plate; blue: Sigma-2; black: BSNE and  
 558 magenta: MWAC). The bars show the central 95% confidence interval of the daily variation. According  
 559 deposition models for concentration calculation are given in the **Table 1**.

#### 560 4.1.3.2 Size-resolved comparison with active samplers

561 The calculated number concentrations in the size interval between 1–10  $\mu\text{m}$  are compared with the  
 562 concentrations measured using the OPC. Similarly, the mass concentration size distributions above the  
 563  $\text{PM}_{10}$  size range are validated using the FWI measurements.

564 **Figure 11** (see also **Figure S 14, S 15, S 16** and **S 17**) shows a comparison of number concentration size  
 565 distributions calculated from deposition rate measurements of the Flat plate, Sigma-2, BSNE and MWAC  
 566 samplers with the number size distributions measured by the OPC for different days. Overall, most of the  
 567 times the number concentrations obtained from OPC measurements are slightly higher than the ones from  
 568 the deposition rates for the size range 2-5  $\mu\text{m}$  and for dust days, with the exception of the Sigma-2, when  
 569 considering only Stokes' velocity. This reflects the tendency of a relative underestimation of the  
 570 concentrations by the passive techniques for high concentrations, which was already visible in the  
 571 correlation analysis above. In general, **Figure 11** shows that the deviation of calculated values from OPC  
 572 measured values is significant.

573 In this context, **Figure 11** shows also the low influence of the two techniques used for  $u_*$  estimation.  
 574 While the number concentrations derived using the friction velocity estimated from Wood (1981)

575 formulation are slightly higher and therefore in better agreement with the OPC data, the difference  
 576 appears to be negligible in general, probably owing to the relatively low wind speeds in this study.

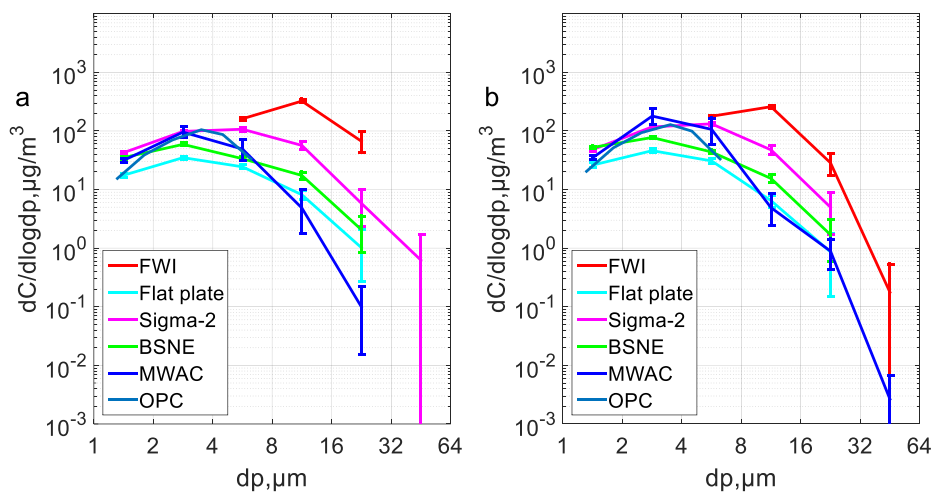

577

578 **Figure 11:** Comparison of the number concentrations calculated from the deposition measurements  
 579 with the number concentrations measured by the OPC. Number size distributions are obtained by  
 580 converting the SEM number deposition rates to number concentrations using the different deposition  
 581 velocity models (**Table 1**), in analogy to the mass size distributions. For the concentrations obtained  
 582 from the number deposition rates, two different approaches for the friction velocity are shown. The  
 583 black curve shows the concentration curve calculated using the momentum flux approach without PM<sub>10</sub>  
 584 inlet correction (i.e. the atmospheric concentration). The red curve shows the concentration curve  
 585 calculated using the Wood approach without PM<sub>10</sub> correction. The dotted blue curve shows the  
 586 concentration curve calculated using the Wood approach with PM<sub>10</sub> inlet correction (simulating the  
 587 concentration the OPC would supposedly measure). The dotted red curve shows the concentration  
 588 curve calculated using the Momentum flux approach with PM<sub>10</sub> inlet correction. In case of the Sigma-2,  
 589 the green curve shows the concentrations calculated using the Stokes velocity and the magenta curve  
 590 the ones using Stokes velocity with the PM<sub>10</sub> inlet correction. The bars show the central 95%  
 591 confidence interval of the daily variation. (a): Flat plate; (b) BSNE; (c): MWAC; (d) Sigma-2. The  
 592 average wind speed on Aug 9, 2017 was 3.0 m/s. Note that panel (d) refers to the second legend.

593 **Figure 12** (see also **Figure S 12**) shows the comparisons for the larger particles between the deposition-  
 594 derived number concentrations and the ones from the FWI. Here, a significant inconsistency occurs  
 595 between the mass size distributions from passive samplers and the ones from FWI. In particular, the size  
 596 range larger than 10  $\mu\text{m}$  seems to be generally underestimated by the passive samplers. While for particles  
 597 around 10  $\mu\text{m}$ , this could be partly to a badly-defined collection efficiency curve of the FWI ((Kandler  
 598 et al., 2018); 50 % cut-off at 11  $\mu\text{m}$ ) and the according correction, this can't be the reason for the particles  
 599 larger than 16  $\mu\text{m}$ , where this efficiency approaches unity. Here, the deposition velocity for the samplers  
 600 is apparently overestimated. A possible explanation would be inlet losses of the passive sampler, but this  
 601 need to be subject of further research. An overview of the OPC measurements comparing the size  
 602 distributions between the long-term (deposition) and short-term (FWI) sampling is shown in **Figure S**  
 603 **13**.

604

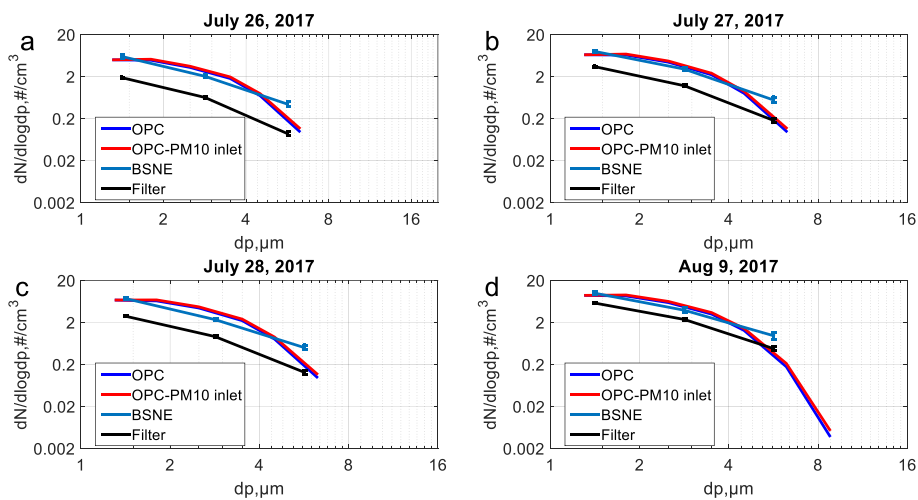

605

606 **Figure 12:** Daily average mass size distributions obtained from the passive sampler techniques in  
 607 comparison to an active sampler (FWI). Mass concentration size distributions were calculated from the  
 608 SEM mass flux measurements using the corresponding deposition velocity models. Samples were  
 609 collected on 26<sup>th</sup> of July (a) and 27<sup>th</sup> of July (b). The mass concentration measurements shown by the  
 610 FWI are daily averages (3 samples per day). The bars show the central 95% confidence interval of the  
 611 daily variation.

612 In a last step, the deposition-derived concentrations are compared to these determined from the iso-axial  
 613 filter sampler. **Figure 13** shows that, while the calculated size distributions are in good agreement with

614 the OPC ones, the filter-derived seem to relatively underestimate the concentrations. A correlation  
 615 analysis (R-squared: 0.681, p-value = 0.0854 and slope = 2.0394) suggests, that there is a weak positive  
 616 correlation between calculated number concentration from filter samples and the OPC measured  
 617 concentration. BSNE has been chosen here for comparison, as its agreement with the OPC measurements  
 618 is generally the closest. The reasons for this weak correlation between the filter sampler and the OPC  
 619 measurements – in particular compared to the stronger correlation between Sigma-2 and BSNE with the  
 620 OPC – are not clear. For sake of completeness, the same comparison for the other samplers is shown in  
 621 **Figure S 18, S 19 and S 20**. While in general here, the disagreement between the Filter sampler and the  
 622 MWAC and Sigma-2 samplers is significant, for the Flat plate sampler less disagreement occurs. In  
 623 addition, an overview of the OPC measurements comparing the size distributions between the long-term  
 624 (deposition) and short-term (filter) sampling is shown in **Figure S 21**.

625

626

627 **Figure 13:** Average size distributions obtained from the SEM analysis of the filter sampler, in  
 628 comparison to BSNE and OPC for different measurement days (a: July 26, 2017; b: July 27, 2017; c:  
 629 July 28, 2017; d: July 29, 2017). Number concentration size distributions from deposition are obtained  
 630 by converting the SEM obtained number deposition rates to number concentration using different  
 631 deposition velocity models. The red curve shows the OPC with PM<sub>10</sub> inlet efficiency correction  
 632 (representing the atmospheric concentration). The number concentration measurements shown for the  
 633 filter sampler are daily averages. The bars show the central 95% confidence interval of the daily  
 634 variation.

635 4.1.4 Estimating the turbulent versus gravitational transport fraction

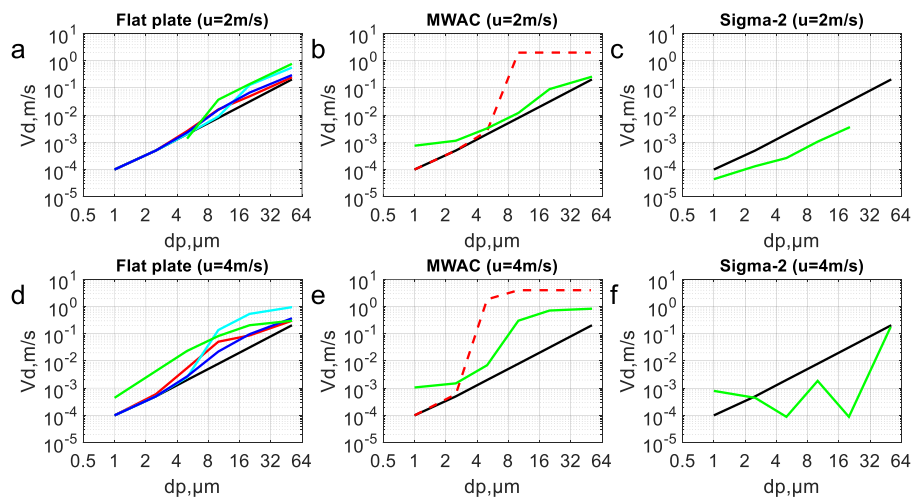

636 The size-resolved upward and downward deposition rates were derived from the upward-/downward  
637 facing deposition sampler by the same type of SEM analyses. Results of the size resolved-mass and  
638 number deposition rate measurements along with daily average temperatures and wind speeds are given  
639 in the electronic supplement (see **table S 5** and **S 6**). The upward deposition rate is always less than the  
640 downward deposition rate. This is expected because the upward facing substrate (i.e. measuring the  
641 downward-directed deposition rate) collects particles deposited by gravitational settling and turbulent  
642 inertial impaction, while the downward facing substrate (for the upward-directed deposition rate) collects  
643 particles only by means of turbulent impaction. **Figure 14** shows the ratio of upward to downward mass  
644 deposition rate as function of particle size. The deviation is greatest for the particle size range around 8  
645  $\mu\text{m}$ , which is strongly affected by turbulence (Noll and Fang, 1989). However, nearly no trend of  
646 increasing ratio with increasing wind speed can be found here (see **Figure S 23**). Besides the wind speed  
647 magnitude, different properties were calculated from the sonic wind data (e.g., turbulent intensity, Monin-  
648 Obukhov length, relative standard deviation of wind speed, average vertical component), but none of  
649 them was able to explain the observed variations in the deposition rate ratio.

650  
651 **Figure 14:** Ratio of upward- to downward-directed mass deposition rate as function of particle size.  
652 The deposition rate is measured using the upward-downward-Flat plate sampler (with 25 mm stub).

653 **4.2 Computational fluid dynamics (CFD) simulation**

654 Using computational fluid dynamics (CFD), deposition velocities of particles for different passive  
 655 samplers were predicted and compared to the analytical deposition velocity models used for the different  
 656 samplers (see **Figure 15** and **Figure S 31**). While for the Flat plate and MWAC sampler the curves agree  
 657 qualitatively (i.e. showing deposition speeds higher than Stokes velocity at particles sizes 4-16  $\mu\text{m}$ , which  
 658 are supposedly strongest affected by turbulence), for the Sigma-2, they are largely contrary except for  
 659 the lowest wind velocity. The latter might be owed to the fact that in a flow model, the non-  
 660 omnidirectional construction of the Sigma-2 might lead to preferred airflows, which are not relevant in a  
 661 more variable and turbulent atmosphere. However, also for the former ones, the deposition velocity  
 662 curves are quantitatively largely different. In this context, **Figure S 32** shows a comparison of the CFD-  
 663 derived particle deposition velocities at different wind speed values for different samplers. For the Flat  
 664 plate and the MWAC samplers, the deposition velocity increases with the wind speed, while for the  
 665 Sigma-2 sampler, such a relation is not observed. Moreover, it can be seen from the figure that in general  
 666 for the Flat plate and the MWAC samplers, Stokes' velocity is considerably lower than the deposition  
 667 velocities calculated at different wind speeds by the other models. Interestingly, however, this is not true  
 668 in the case of Sigma-2 sampler. In general, for the effect of wind speed on the Sigma-2 sampler is not yet  
 669 clear, why there is an effect for some sizes and for others not, so further modeling work is needed.

670  
 671 **Figure 15:** Deposition velocities calculated for different samplers by analytical and CFD approaches.  
 672 The red curve shows the deposition velocity calculated using the Piskunov model, the dotted red curve  
 673 shows the combination of the Piskunov and the impaction curve model, the black curve shows the  
 674 Stokes deposition velocity, the blue curve the Noll and Fang model, the cyan the Zhang model, and the

675 green curve finally the deposition velocity from CFD. Panels **a-c** are calculated for 2 m/s wind speed,  
 676 **d-f** for 4 m/s.

### 677 4.3 Comparison of measured deposition rate ratios to analytically and CFD modeled ones

678 As there is no reference instrument for dry deposition sampling, the separate approaches are compared  
 679 in a relative way. **Figure 16 a-c** show comparisons of the deposition velocity ratios derived from the  
 680 analytical models with the according measured deposition velocity ratios (equalling the according  
 681 deposition rate ratios), **d-f** the respective correlation of the ratios derived from CFD modeling with the  
 682 measurement. As the CFD models could only be calculated for a limited number of flow velocities,  
 683 deposition velocity values were interpolated between the calculated cases. Generally, the agreement is  
 684 very poor. Practically, no variation observed in the measurement data can be explained by model  
 685 variation, independently of the type of model. While this might be explained to a smaller extent by the  
 686 propagating measurement uncertainties for the largest particles with low counting statistics, for the  
 687 smaller ones this systematic deviation must have other reasons.

688 **Figure 16:** Comparison of the observed deposition velocity ratios with modeled ones by the analytical  
 689 deposition models (upper row, a-c) and by the CFD models (lower row, d-f). (a, d) MWAC/Sigma-2;  
 690 (b, e) MWAC/Flat plate; (c, f) Flat plate/Sigma-2. Multiple daily measurements are shown in each plot.  
 691 Different colors represent different size intervals. 1-2  $\mu\text{m}$ : Black, 2-4  $\mu\text{m}$ : Blue, 4-8  $\mu\text{m}$ : Yellow, 8-16  
 692  $\mu\text{m}$ : Red, 16-32  $\mu\text{m}$ : Green, 32-64  $\mu\text{m}$ : Cyan.

## 694 5 Summary and Conclusions

695 Parallel dust aerosol deposition measurements by means of deposition and other passive samplers were  
696 conducted at Izaña Global Atmospheric Watch observatory continuously from 14th of July to 24th of  
697 August 2017. In addition, active aerosol collection was done with a free-wing impactor and an iso-axial  
698 filter sampler. Additional information regarding the aerosol particle size distributions has been obtained  
699 by an OPC. 316,000 single particles from 6 different samplers were analyzed by SEM-EDX, yielding  
700 size resolved deposition rates.

701 As known from previous studies, the total deposition rate was dominated by coarse particles (8-16  $\mu\text{m}$ ).  
702 A high temporal daily variability in total dust deposition rate was observed. The size resolved deposition  
703 rate measurements of different passive samplers varied significantly between the samplers under the same  
704 conditions. This was in principle expected from the different sampler construction. Applying suitable  
705 deposition velocity models, atmospheric concentrations were calculated from different sampler  
706 deposition rates. The resulting concentrations on average are in better agreement between the samplers  
707 than the deposition rates. However, discrepancies beyond the measurement uncertainty remain  
708 unexplained by the deposition models, in particular with respect to dependency on wind speed, which is  
709 predicted by the models, but not observed. The estimation of an appropriate deposition velocity from  
710 different models for calculating atmospheric concentrations remains obviously a challenge. In particular,  
711 when considering the size-resolved deposition velocities and deposition rate ratios, great discrepancies  
712 show up. While for an integrated bulk measurement or the  $\text{PM}_{10}$  size range at least a qualitative agreement  
713 between the samplers can be reached, no model – analytical nor CFD – is able to explain the observed  
714 sampler-specific variations in deposition rate. Clearly, a better physical understanding is needed here.

715 In the  $\text{PM}_{10}$  size range, a good agreement is found between the calculated concentrations for samples  
716 from different passive and the concentrations measured using an OPC. For particle sizes above  $\text{PM}_{10}$ , the  
717 comparison of the deposition-derived size distributions with impactor and filter measurements shows  
718 considerable underestimates of the deposition samplers, which must be interpreted as overestimation of  
719 the large-particle deposition velocities.

720 Deposition velocities from different analytical deposition models are compared to ones calculated using  
721 computational fluid dynamics simulations for different samplers. The comparison shows that two  
722 methods largely disagree. Moreover, all theory-based deposition velocities (analytical as well as CFD  
723 approaches) fail to represent the observed measurement differences between the samplers. This obviously  
724 points to the need of better understanding the physics of dry deposition in general.

725 The correlation analysis between dust deposition rate, dust concentrations and wind speed reveals that  
726 the variation in deposition rate is mainly controlled by changes in concentration; variations in wind speed  
727 play a minor role for wind speeds lower than 6 m/s. However, the situation might be different for higher  
728 wind speeds (Kandler et al., 2018).

729 The correlation analysis between deposition rates and OPC measurements demonstrated that BSNE and  
730 Sigma-2 can be a good option for PM<sub>10</sub> measurement, while the MWAC is not a suitable option. Apart  
731 from that result with respect to the PM<sub>10</sub> size range, no recommendation for a least biased general purpose  
732 deposition sampler can be derived from our study.

733 Moreover, as the results show that the different samplers can't deliver consistent results between the  
734 sampler types, a recommendation must be that if a certain sampler type is chosen for a study, it should  
735 not be modified or replaced by another one for sake of consistency of results, even if it was shown that  
736 the results do not agree well for example with active sampling. The results show, nevertheless, that  
737 passive sampling techniques coupled with an automated single particle analysis provides insights into the  
738 variation of size distribution, deposition rate and concentration of atmospheric particles.

## 739 6 Acknowledgements

740 This project is funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) –  
741 264907654; 264912134; 416816480 (KA 2280). We would like to thank for the financial support by the  
742 DFG in the framework of the Excellence Initiative, Darmstadt Graduate School of Excellence Energy  
743 Science and Engineering (GSC 1070). We thank our colleagues Thomas Dirsch and Conrad  
744 Ballschmiede. We are grateful to all staff members of Izaña Global Atmospheric Watch Observatory for  
745 helping us in maintenance of the sampling equipment. We are especially indebted to Dr Roger Funk from  
746 Leibniz-Centre for Agricultural Landscape Research, Institute of Soil Landscape Research for providing  
747 us some of the passive samplers.

## 748 7 Author contribution

749 A. W. conducted the field measurements and did data evaluation and interpretation. K. S. helped with the  
750 field measurements, carried out the SEM analyses and did data processing. J. M. and B. E. executed the  
751 CFD model setup and calculations. S. R. operated the OPC including the data processing and the  
752 meteorological base measurements. K. K. designed the experiment, designed and prepared the sampling  
753 equipment and did data processing and interpretation. All authors contributed to the data discussion and  
754 manuscript preparation.

755 8 Data availability

756 The data sets used for this publication are available from the Pangaea repository free of charge  
757 (<https://doi.pangaea.de/10.1594/PANGAEA.901413>)
