The Geostationary Environment Monitoring Spectrometer (GEMS) is scheduled to be launched in 2019 on board the GEO-KOMPSAT (GEOstationary KOrea Multi-Purpose SATellite)-2B, contributing as the Asian partner of the global geostationary constellation of air quality monitoring. To support this air quality satellite mission, we perform a cross-evaluation of simulated GEMS ozone profile retrievals from OMI (Ozone Monitoring Instrument) data based on the Optimal Estimation and ozonesonde measurements within the GEMS domain, covering from 5°S (Indonesia) to 45°N (south of the Russian border) and from 75°E to 145°E. The comparison between ozonesonde and GEMS shows a significant dependence on ozonesonde types. Ozonesonde data measured by Modified Brewer-Master (MBM) at Trivandrum and New Delhi show inconsistent seasonal variabilities in tropospheric ozone compared to Carbon Iodine (CI) and Electrochemical Condensation Cell (ECC) ozonesondes at other stations in a similar latitude regime. CI ozonesonde measurements are negatively biased relative to ECC measurements by 2-4 DU; better agreement is achieved when simulated GEMS ozone retrievals are compared to ECC measurements. ECC ozone data at Hanoi, Kuala Lumpur, and Singapore show abnormally worse agreements with simulated GEMS retrievals than other ECC measurements. Therefore, ECC ozonesonde measurements at Hong Kong, Pohang, Naha, Sapporo, and Tsukuba are finally identified as an optimal reference dataset. The accuracy of simulated GEMS retrievals is estimated to be ~ 5.0 % for both tropospheric and stratospheric column ozone with the precision of 15 % and 5 %, which meets the GEMS ozone requirements.

## 37 1. Introduction

38

39 The development of geostationary ultraviolet (UV)/visible (VIS) spectrometers is a new paradigm  
40 in the field of the space-based air quality monitoring. It builds on the polar-orbiting instrument heritage  
41 for the last 40 years, which were initiated with the launch of a series of Total Ozone Mapping  
42 Spectrometer (TOMS) instruments starting in 1978 (Bhartia et al., 1996) and consolidated by the Global  
43 Ozone Monitoring Experiment (GOME) (ESA, 1995), the SCanning Imaging Absorption spectroMeter  
44 for Atmospheric CHartography (SCIAMACHY) (Bovensmann et al., 1999), the Ozone Monitoring  
45 Instrument (OMI) (Levelt et al, 2006), GOME-2 (EUMETSAT, 2006), the Ozone Mapping and Profiler  
46 Suite (OMPS) (Flynn et al., 2014), and the TROPOspheric Monitoring Instrument (TROPOMI)  
47 (Veefkind et al., 2012). Three geostationary air quality monitoring missions, including the  
48 Geostationary Environmental Monitoring Spectrometer (GEMS) (Bak et al., 2013a) over East Asia,  
49 Tropospheric Emissions: Monitoring of Pollution (TEMPO) (Chance et al, 2013; Zoogman et al., 2017)  
50 over North America, and Sentinel-4 (Ingmann et al., 2012) over Europe, are in progress to launch in the  
51 2019-2022 time frame, to provide unprecedented hourly measurements of aerosols and chemical  
52 pollutants at sub-urban scale spatial resolution (~ 10-50 km<sup>2</sup>). These missions will constitute the global  
53 geostationary constellation of air quality monitoring.

54 GEMS will be launched in late 2019 or early 2020 on board the GeoKOMPSAT-2B (Geostationary  
55 Korea Multi-Purpose Satellite) to measure O<sub>3</sub>, NO<sub>2</sub>, SO<sub>2</sub>, H<sub>2</sub>CO, CHOCHO, and aerosols in East Asia  
56 (Bak et al., 2013a). Tropospheric ozone is a key species to be monitored due to its critical role in  
57 controlling air-quality as a primary component of photochemical smog, its self-cleansing capacity as a  
58 precursor of the hydroxyl radical, and in controlling the Earth's radiative balance as a greenhouse gas.

59 To support the development of the GEMS ozone profile algorithm, Bak et al. (2013a) demonstrated  
60 that the GEMS spectral coverage of 300-500 nm minimizes the loss in the sensitivity to tropospheric  
61 ozone despite the lack of most Hartley ozone absorption wavelengths shorter than 300 nm. They further  
62 indicated the acceptable quality of the simulated stratospheric ozone retrievals from 212 hPa to 3 hPa  
63 (40 km) through comparisons using Microwave Limb Sounder (MLS) measurements. As a consecutive  
64 work, this study evaluates simulated GEMS tropospheric ozone retrievals against ozonesonde  
65 observations. GEMS ozone retrievals are simulated using an Optimal Estimation (OE) based fitting  
66 algorithm with OMI radiances in the spectral range 300-330 nm in the same way as Bak et al. (2013a).  
67 The validation effort is essential to ensuring the quality of GEMS ozone profile retrievals and to  
68 verifying the newly implemented ozone profile retrieval scheme. In-situ ozonesonde soundings have  
69 been considered to be the best reference, but should be carefully used due to the spatial and temporal

70 irregularities in instrument types, manufacturers, operating procedures, and correction strategies  
71 (Deshler et al., 2017). Compared to TEMPO and Sentinel-4, the GEMS validation activity is expected  
72 to be more challenging for the ozone profile product because of the much sparser distribution of stations  
73 and more irregular characteristics of ozonesonde measurements over the GEMS domain. Continuous  
74 balloon-borne observations of ozone are only available at the Pohang (129.23°E, 36.02°N) site in South  
75 Korea, but this site has not been thoroughly validated. Therefore the quality assessment of its  
76 ozonesonde data is required before we use this data for GEMS validation. Compared to ozonesondes,  
77 satellite ozone data are less accurate and have much coarser vertical resolution, but more homogenous  
78 due to single data processing for the measurements from a single instrument. Therefore, abnormal  
79 deviations in satellite-ozonesonde differences from neighboring stations might indicate problems at  
80 individual stations (Fioletov et al. 2008). For example, Bak et al. (2015) identified 27 homogenous  
81 stations among 35 global Brewer stations available from the World Ozone and Ultraviolet Radiation  
82 Data Centre (WOUDC) network through comparisons with coincident OMI total ozone data. This study  
83 adopts this approach to select a consistent ozonesonde dataset among 10 stations available over the  
84 GEMS domain based on comparisons of the tropospheric ozone columns (TOC) between simulated  
85 GEMS retrievals and ozonesonde measurements, that is, simulated GEMS retrievals using OMI data  
86 are used to verify the ozonesonde observations. The simulated GEMS retrievals are ultimately evaluated  
87 against the ozonesonde dataset identified as a true reference to demonstrate the reliability of our future  
88 GEMS ozone product. The simulated GEMS retrievals and ozonesonde dataset are described in Sect.  
89 2.1 and 2.2 with the comparison methodology in Sect. 2.3. Our results are discussed in Sect. 3 and  
90 summarized in Sect. 4.

91

## 92 **2. Data and Methodology**

93

### 94 **2.1 Ozone Profile Retrievals**

95

96 The development of the GEMS ozone profile algorithm builds on the heritage of the Smithsonian  
97 Astrophysical Observatory (SAO) ozone profile algorithm which was originally developed for GOME  
98 (Liu et al., 2005), continuously adapted for its successors including OMI (Liu et al., 2010a), GOME-2  
99 (Cai et al., 2012), and OMPS (Bak et al., 2017). In addition, the SAO algorithm will be implemented to  
100 retrieve TEMPO ozone profiles (Chance et al., 2013; Zoogman et al., 2017). In this algorithm, the well-  
101 known optimal estimation (OE) based iterative inversion is applied to estimate the best ozone  
102 concentrations from simultaneously minimizing between measured and simulated backscattered UV

103 measurements constrained by the measurement covariance matrix, and between retrieved values and its  
 104 climatological a priori values constrained by an a priori covariance matrix (Rodgers, 2000). The impact  
 105 of a priori information on retrievals becomes important when measurement information is reduced due  
 106 to instrumental errors, instrument design sensitivity (e.g. stray light, dark current, and read-out smear),  
 107 and physically insufficient sensitivities under certain geophysical conditions (e.g. the reduced  
 108 penetration of incoming UV radiation into the lower troposphere at high solar zenith angles or blocked  
 109 photon penetration below thick clouds). The described OE-fitting solution  $\hat{X}_{i+1}$  can be written,  
 110 together with cost function  $\chi^2$ :

111

$$112 \quad \hat{X}_{i+1} = \hat{X}_i + (K_i^T S_y^{-1} K_i + S_a^{-1})^{-1} \{K_i^T S_y^{-1} [Y - R(\hat{X}_i)] - S_a^{-1} (\hat{X}_i - X_a)\} \quad (1)$$

113

$$114 \quad \chi^2 = \left\| S_y^{-\frac{1}{2}} K_i (\hat{X}_{i+1} - \hat{X}_i) - [Y - R(\hat{X}_i)] \right\|_2^2 + \left\| S_a^{-\frac{1}{2}} (\hat{X}_{i+1} - X_a) \right\|_2^2, \quad (2)$$

115

116 where  $\hat{X}_{i+1}$  and  $\hat{X}_i$  are current and previous state vectors with a priori vector,  $X_a$  and its covariance  
 117 error matrix,  $S_a$ .  $Y$  and  $R(X)$  are measured and simulated radiance vectors, with measurement error  
 118 covariance matrix,  $S_y$ .  $K$  is the weighting function matrix  $(\frac{dR(x)}{dx})$ , describing the sensitivity of the  
 119 forward model to small perturbations of the state vector.

120 The ozone fitting window was determined to maximize the retrieval sensitivity to ozone and  
 121 minimize it to measurement error: 289–307 nm and 326–339 nm for GOME, 270–309 nm and 312–330  
 122 nm for OMI, 289–307 nm and 325–340 nm for GOME-2, and 302.5–340 nm for OMPS. For OMI,  
 123 GOME and GOME-2, partial ozone columns are typically retrieved in 24 layers from the surface to ~  
 124 60 km. However, GEMS (300–500 nm) and OMPS (300–380 nm) do not cover much of the Hartley  
 125 ozone absorption wavelengths and hence the reliable profile information of ozone is limited to below ~  
 126 40 km (Bak et al., 2013a).

127 Fig. 1 is a schematic diagram of the ozone profile algorithm. With the input of satellite  
 128 measurements, the slit function is parameterized through cross-correlation between satellite irradiance  
 129 and a high-resolution solar reference spectrum to be used for wavelength calibration and for high -  
 130 resolution cross section convolution (Sun et al., 2017; Bak et al., 2017); a normalized Gaussian  
 131 distribution is assumed to derive analytic slit functions for OMI. To remove the systematic errors  
 132 between measured and calculated radiances, “soft-calibration” is applied to measured radiances and  
 133 then the logarithms of sun-normalized radiances are calculated as measurement vectors (Liu et al.,

2010a; Cai et al., 2012; Bak et al., 2017). Measurement covariance matrices are constructed as diagonal matrices with components taken from the square of the measurement errors as measurement errors are assumed to be uncorrelated among wavelengths. In the OMI algorithm, a noise floor of 0.4 % (UV1) and 0.2 % (UV2) is used because OMI measurement errors underestimate other kinds of random noise errors caused by stray light, dark current, geophysical pseudo-random noise errors due to sub-pixel variability, motion when taking a measurement, forward model parameter error (random part), and other unknown errors into account (Huang et al., 2017). GEMS is expected to have similar retrieval sensitivity to tropospheric ozone, and have at least comparable radiometric/wavelength accuracy (4% including light source uncertainty/0.01 nm) as OMI. It is designed to provide hyperspectral radiances at a spectral resolution of 0.6 nm and spectral intervals of 0.2 nm, which are also similar to OMI (spectral resolution: 0.42-0.63 nm, sampling rate: 0.14-0.33 nm/pixel). A priori ozone information is taken from the tropopause-based (TB) ozone profile climatology which was developed for improving ozone profile retrievals in the upper troposphere and lower stratosphere (Bak et al., 2013b). The Vector Linearized Discrete Ordinate Radiative Transfer (VLIDORT) model (Spurr, 2006; 2008) is used to calculate normalized radiances and weighting function matrices for the atmosphere, with Rayleigh scattering and trace-gas absorption and with Lambertian reflection for both surface and cloud (Liu et al., 2010a). The ozone algorithm iteratively estimates the best ozone profiles within the retrieval converges (typically 2-3 iterations), together with other geophysical and calibration parameters (e.g., cloud fraction, albedo, BrO, wavelength shift, Ring parameter, mean fitting scaling parameter) for a better fitting accuracy even though some of the additional fitting parameters can reduce the degrees of freedom for signal of ozone. We should note here that GEMS data processing is expected to be different from OMI mainly in two ways: 1) OMI uses a depolarizer to scramble the polarization of light. However, GEMS has polarization sensitivity (required to be less than 2%) and performs polarization correction using an RTM-based look-up table of atmospheric polarization state and pre-flight characterization of instrument polarization sensitivity in the level 0 to 1b data processing. The GEMS polarization correction is less accurate and hence additional fitting process might be required in the level 2 data processing, especially for ozone profiles that are more sensitive to the polarization error compared to other trace-gases. 2) GEMS has a capability to perform diurnal observations and hence diurnal meteorological input data are required to account for the temperature dependent Huggins band ozone absorption. Hence, the numerical weather prediction (NWP) model analysis data will be transferred to the GEMS Science Data Processing Center (SDPC).

165

## 166 **2.2 Ozonesonde measurements**

167

168 Ozonesondes are small, lightweight, and compact balloon-borne instruments capable of measuring  
169 profiles of ozone, pressure, temperature and humidity from the surface to balloon burst, usually near 35  
170 km (4 hPa); ozone measurements are typically reported in units of partial pressure (mPa) with vertical  
171 resolution of ~ 100-150 m (WMO, 2014). Ozone soundings have been taken for more than 50 years,  
172 since the 1960s. The accuracy of ozonesonde measurements has been reported as 5-10 % with precision  
173 of 3-5%, depending on the sensor type, manufacturer, solution concentrations, and operational  
174 procedure (Smit et al., 2007; Thompson et al., 2007; 2017; Witte et al., 2017; 2018). Three types of  
175 instruments have been carried on balloons, i.e., the modified Brewer-Master (MBM), the carbon iodine  
176 cell (CI), and the electrochemical concentration cell (ECC). Each sounding is disposably operated and  
177 hence weekly launched for long-term operation.

178 Fig. 2 displays the locations of 10 ozonesonde sites focused on this study within the GEMS domain  
179 bordering from 5°S (Indonesia) to 45°N (south of the Russian border) and from 75°E to 145°E. A  
180 summary of each ozonesonde site is presented in Table 1. Most of measurements are collected from the  
181 WOUDC network, except that Pohang soundings are provided from the Korea Meteorological  
182 Administration (KMA) and Kuala Lumpur and Hanoi measurements are from the Southern Hemisphere  
183 Additional OZonesondes (SHADOZ) network. In South Korea, ECC sondes have been launched every  
184 Wednesday since 1995 at Pohang, without significant time gaps. There are three Japanese stations (Naha,  
185 Tsukuba, and Sapporo) where the CI-type sensor was used before switching to the ECC-type sensor as  
186 of early 2009, and two Indian stations at New Delhi and Trivandrum using the modified BM (MBM)  
187 sensor. The rest of stations (Hanoi, Hong Kong, Kuala Lumpur and Singapore) use only ECC. Most  
188 stations employ ECC sensors, but inhomogeneities in ECC ozonesondes are strongly correlated to  
189 preparation and correction procedures. There are two ECC sensor manufactures: the Science Pump  
190 Corporation (Model type: SPC-6A) and the Environmental Science Corporation (Model type: EN-SCI-  
191 Z/1Z/2Z). Since 2011 EN-SCI has been taken over by Droplet Measurement Technologies (DMT) Inc.  
192 The the recommend recipes of the Standard Sensing Solution (SSI) are 1.0 % potassium iodide (KI)/full  
193 buffer (SST1.0) and 2.0 % KI/no buffer (SST0.5) for the SPC and EN-SCI sondes, respectively by the  
194 ASOPOS (Assessment for Standards on Operation Procedures for Ozone Sondes) (Smit et al., 2012).  
195 Among ECC stations, Pohang, Hong Kong, and the Japanese stations have applied the standard sensing  
196 solution to all ECC sensors manufactured by one company. In Singapore, the ozonesonde manufacture  
197 was changed in late 2015 from EN-SCI to SPC, while SST 0.5 was switched to SST1.0 as of 2018. Two  
198 SHADOZ stations (Kuala Lumpur, Hanoi) have applied the standard sensing solution just since 2015.  
199 Hanoi changed sensing solution 4 times with two different ozonesonde manufactures; Kuala Lumpur

200 operated only with SPC 6A-SST1.0 combination until 2014, but with four different radiosonde  
201 manufactures. Therefore the SHADOZ datasets were homogenized (Witte et al., 2017) through the  
202 application of transfer functions between sensors and solution types. The post-processing could be  
203 applied by data users to some WOUDC datasets given a correction factor, which is the ratio of integrated  
204 ozonesonde column (appended with an estimated residual ozone column above burst altitude) and total  
205 ozone measurements from co-located ground-based and/or overpassing satellite instruments. The  
206 above-burst column ozone is estimated with a constant ozone mixing ratio (CMR) assumption above  
207 the burst altitude (Japanese sites, Morris et al., 2013) or satellite derived stratospheric ozone climatology  
208 (Indian sites, Rohtash et al., 2016). No post-processing is done for Pohang, Hong Kong, and Singapore.  
209 Most stations made weekly or bi-weekly regular observations, except for Indian stations with irregular  
210 periods of 0-4 per month and for Singapore with monthly observations.

211 In Fig. 3 the seasonal means and standard deviations of ozonesonde measurements are  
212 presented to show the stability and characteristics of ozonesonde measurements at each site.  
213 Instabilities of measurements are observed from New Delhi ozonesondes. High surface ozone  
214 concentrations at Trivandrum in summer are believed to be caused by measurement errors  
215 because low levels of pollutants have been reported at this site under these geolocation and  
216 meteorological effects (Lal et al. 2000). Besides Trivandrum, Naha could be regarded as a  
217 background site according to low surface ozone (Fig. 3) and precursor concentrations (Fig. 2)  
218 compared to neighboring stations, and previous studies (Oltmans et al., 2004; Liu et al., 2002).  
219 In the lower troposphere, high ozone concentrations are captured at Pohang, Tsukuba, and  
220 Sapporo in the summer due to enhanced photochemical production of ozone in daytime,  
221 whereas tropical sites, Naha, Hanoi, and Hong Kong show ozone enhancements in spring,  
222 mainly due to biomass burning in Southeast Asia, with low ozone concentrations in summer  
223 due to the Asian monsoon and in winter due to tropical air intrusion (Liu et al., 2002; Ogino et  
224 al., 2013). Singapore and Kuala Lumpur are supposed to be severely polluted areas, but ozone  
225 pollution is not clearly captured over the seasons. This might be explained by the morning  
226 observation time at these two stations. In addition, instabilities of Singapore measurements are  
227 noticeable, including abnormally large variability and very low ozone concentration in the  
228 stratosphere. The effect of stratospheric intrusions on the ozone profile shape is dominant at  
229 mid-latitudes (Pohang, Tsukuba, and Sapporo) during the spring and winter when the  
230 ozonepause goes down to 300 hPa, with larger ozone variabilities in the lower stratosphere and  
231 upper troposphere, whereas the ozonepause is around 100 hPa with much less variability of

232 ozone in other seasons.

233

### 234 **2.3. Comparison Methodology**

235

236 The GEMS ozone profile algorithm is applied to OMI BUV measurements for 300-330 nm to  
237 simulate GEMS ozone profile retrievals at coincident locations listed in Table 1. The coincidence  
238 criteria between satellite and ozonesondes are:  $\pm 1.0^\circ$  in both longitude and latitude and  $\pm 12$  hours in  
239 time, and then the closest pixel is selected. The Aura satellite carrying OMI crosses the equator always  
240 at  $\sim 1:45$  pm Local Time (LT), thus OMI measurements are collocated within 3 hours to ozonesonde  
241 soundings in the afternoon (1-3 pm). Weekly-based sonde measurements provide 48 ozone profiles at  
242 maximum for a year; the number of collocations is on average 40 from 2004 October to 2008, but  
243 reduced to  $\sim 20$  recently due to the screened OMI measurements affected by the “row anomaly” which  
244 was initially detected at two rows in 2007, and seriously spread to other rows with time since January  
245 2009 (Schenkeveld et al., 2017). From July 2011 the row anomaly extends up to  $\sim 50\%$  of all rows.  
246 Correspondingly, the average collocation distance increases from 57.5 km to 66.6 km before and after  
247 the occurrence of the row anomaly. The impact of spatiotemporal variability on the comparison will be  
248 much reduced for GEMS due to its higher spatiotemporal resolution ( $7\text{ km} \times 8\text{ km}$  @ Seoul, hourly)  
249 against OMI ( $48\text{ km} \times 13\text{ km}$  @ nadir in UV1, daily).

250 To increase the validation accuracy, data screening is implemented for both ozonesonde  
251 observations and satellite retrievals according to Huang et al (2017). For ozonesonde observations, we  
252 screen ozonesondes with balloon-bursting pressures exceeding 200 hPa, gaps greater than 3 km,  
253 abnormally high concentration in the troposphere ( $> 80\text{ DU}$ ), and low concentration in the stratosphere  
254 ( $< 100\text{ DU}$ ). Among WOUDC sites, the Japanese and Indian datasets include a correction factor which  
255 is derived to make better agreement between integrated ozonesonde columns and correlated reference  
256 total ozone measurements as mentioned in Section 2.2; In Fig. 4, Japanese ozonesondes are compared  
257 against GEMS simulations when a correction factor is applied or not to each CI and ECC measurement,  
258 respectively. Morris et al. (2013) recommended restricting the application of this correction factor to  
259 the stratospheric portion of the CI ozonesonde profiles due to errors in the above-burst column ozone.  
260 Our comparison results illustrate that applying the correction factor reduces the vertical fluctuation of  
261 mean biases in ozone profile differences with insignificant impact on their standard deviations.  
262 Therefore we decide to apply this correction factor to the sonde profiles if this factor ranges from 0.85  
263 to 1.15. Because of a lack of retrieval sensitivity to ozone below clouds and lower tropospheric ozone  
264 under extreme viewing condition, GEMS simulations are limited to cloud fraction less than 0.5, SZAs

265 less than  $60^\circ$ , and fitting RMS (i.e., root mean square of fitting residuals relative to measurement errors)  
266 less than 3.

267 Due to the different units of ozone amount between satellites and ozonesondes, we convert  
268 ozonesonde-measured partial pressure ozone values (mPa) to partial column ozone (DU) at the 24  
269 retrieval grids heights of the satellite for the altitude range from surface to the balloon-bursting altitudes.  
270 Ozonesonde measurements are obtained at a rate of a few seconds and then typically averaged into  
271 altitude increments of 100 meters, whereas retrieved ozone profiles from nadir BUUV satellite  
272 measurements have much coarser vertical resolution of 10-14 km in the troposphere and 7-11 km in the  
273 stratosphere, based on OMI retrievals. Consequently, satellite observations capture only the smoothed  
274 structures of ozonesonde soundings, especially near the tropopause, where a sharp vertical transition of  
275 ozone within 1 km is observed, and in the boundary layer due to the insufficient penetration of photons.  
276 Satellite retrievals unavoidably have an error compound due to its limited vertical resolution, called  
277 “smoothing error” in OE-based retrievals (Rodgers, 2000). It could be useful to eliminate the effect of  
278 smoothing errors on differences between satellites and sondes to better characterize other error sources  
279 in comparisons (Liu et al., 2010a). For this reason, satellite data have been compared to ozonesonde  
280 measurements smoothed to the satellite vertical resolution, together with original sonde soundings (Liu  
281 et al., 2010b; Bak et al., 2013b; Huang et al., 2017). The smoothing approach is:

282

$$283 \quad \hat{x}_{sonde} = A \cdot x_{sonde} + (1 - A)x_a \quad (3)$$

284  $x_{sonde}$  : High-resolution ozonesonde profile

285  $\hat{x}_{sonde}$  : Convolved ozonesonde profile into satellite vertical resolution

286 A : Satellite averaging kernel

287  $x_a$  : A priori ozone profile

288

289 In order to define tropospheric columns, both satellite retrievals and ozonesonde measurements  
290 are vertically integrated from the surface to the tropopause taken from daily National Centers for  
291 Environmental Prediction (NCEP) final (FNL) Operational Global analysis data  
292 (<http://rda.ucar.edu/datasets/ds083.2/>). To account for the effect of surface height differences on  
293 comparison, ozone amounts from satellite data below the surface heights of ozonesondes are added to  
294 tropospheric columns of ozonesonde measurements and vice versa.

295

### 296 **3. Results and Discussions**

297

### 298 3.1 Comparison at individual stations

299

300 Witte et al. (2018) recently compared seven SHADOZ station ozonesonde records, including  
301 Hanoi and Kuala Lumpur in the GEMS domain, with total ozone and stratospheric ozone profiles  
302 measured by space-borne nadir and limb viewing instruments, respectively. In this comparison, the  
303 Hanoi station shows comparable or better agreement with the satellite datasets when compared to other  
304 sites. Morris et al. (2013) and Rohtash et al. (2016) thoroughly evaluated ozonesonde datasets over  
305 Japanese and Indian sites, respectively, but they did not address their measurement accuracy with  
306 respect to those at other stations. Validation of GOME TOC by Liu et al. (2006) showed relatively larger  
307 biases at Japanese CI stations and validation of OMI TOC by Huang et al. (2017) showed both larger  
308 biases and standard deviations at the India MBM sites. In South Korea, regular ozonesonde  
309 measurements are taken only from Pohang, but these measurements have been insufficiently evaluated;  
310 only the stratospheric parts of these measurements were quantitatively assessed against satellite solar  
311 occultation measurements by Halogen Occultation Experiment (HALOE) from 1995 to 2004 in Hwang  
312 et al. (2006), but only 26 pairs were compared despite the coarse coincident criteria (48 hours in time,  
313  $\pm 4.5^\circ$  in latitude,  $\pm 9^\circ$  in longitude). Therefore, it is important to perform quality assessment of  
314 ozonesonde measurements to identify a reliable reference dataset for GEMS ozone profile validation

315 For this purpose, we illustrate tropospheric ozone columns (TOC) as a function of time for  
316 individual stations listed in Table 1, measured with three different types of ozonesonde instruments and  
317 retrieved with GEMS simulations (Fig. 5), respectively. The goal of this comparison is to identify any  
318 abnormal deviation of ozonesonde measurements relative to satellite retrievals, so we exclude the  
319 impact of the different vertical resolutions between instruments and satellite retrievals on this  
320 comparison by convolving ozonesonde data with satellite averaging kernels. At mid-latitude sites  
321 (Pohang, Sapporo, and Tsukuba) both ozonesonde and simulated retrievals show the distinct seasonal  
322 TOC variations with values ranging from  $\sim 35$  to  $\sim 40$  DU. Extratropical sites (Naha, Hong Kong, and  
323 Hanoi) show less seasonal variations, 30 to 50 DU, whereas fairly constant concentrations are observed  
324 at Kuala Lumpur and Singapore in the tropics. Both ozonesonde observations and simulated retrievals  
325 illustrate similar seasonal variabilities at these locations. At New Delhi and Trivandrum, on the other  
326 hand, MBM ozonesonde measurements abnormally deviate from 10 DU to 50 DU compared to the  
327 corresponding satellite retrievals and ozonesonde measurements at stations in similar latitudes.

328 In Fig. 6 time dependent errors in differences of TOC between ozonesonde and simulated GEMS  
329 retrievals are evaluated with the corresponding comparison statistics in Table 2. Simulated retrievals  
330 show strong correlation of  $\sim 0.8$  or much larger with ozonesonde measurements at Pohang, Hong Kong,  
331 and three stations from Japan, and with less correlation of  $\sim 0.5$  at other SHADOZ stations in the tropics.

332 However, Indian stations show poor correlation of 0.24. Mean biases and standard deviations are much  
333 smaller at stations where a strong correlation is observed; they are  $\sim 1 \text{ DU} \pm \sim 4 \text{ DU}$  at most ECC  
334 stations, but deviated to  $\sim 4 \text{ DU} \pm \sim 10 \text{ DU}$  at MBM stations. In conclusion, we should exclude  
335 ozonesonde observations measured by MBM to remove irregularities in a reference dataset for  
336 validating both GEMS simulated retrievals in this study and GEMS actual retrievals in future study.  
337 Moreover, time series of ozonesonde and simulated retrievals show a significant transition at three  
338 Japanese stations as of late 2008 and early 2009 when the ozonesonde instruments were switched from  
339 CI to ECC. This transition could be affected by space-borne instrument degradation, but the impact of  
340 balloon-borne instrument change on them is predominant based on a less time-dependent degradation  
341 pattern at neighboring stations during this period. CI ozonesondes noticeably underestimate  
342 atmospheric ozone by 2-3 DU compared to ECC and thereby GEMS TOC biases relative to CI  
343 measurements are estimated as - 2 to - 5 DU, but these biases are reduced to  $< 1.5 \text{ DU}$  when compared  
344 with ECC. Therefore, we decide to exclude these CI ozonesonde observations for evaluating GEMS  
345 simulated retrievals. Compared to other ECC stations, Hanoi Station often changed sensing solution  
346 concentrations and pH buffers (Table 1), which might cause the irregularities due to remaining errors  
347 even though transfer functions were applied to ozonesonde measurements to account for errors due to  
348 the different sensing solution (Witte et al., 2017). This fact might affect the relatively worse performance  
349 compared to a neighboring station, Hong Kong, where the 1.0 % KI buffered sensing solution (SST1.0)  
350 to ECC/SPC sensors have been consistently applied.

351 Fig. 7 compares differences of ozone profiles between ECC ozonesondes and GEMS simulated  
352 retrievals at each station. Among ECC ozonesondes, Singapore's are in the worst agreement with GEMS  
353 simulations in both terms of mean biases and standard deviations, which could be explained by the  
354 discrepancy in collocation time. Sonde observations at Japan, Pohang, Hong Kong, and Hanoi Stations,  
355 where balloons were launched in afternoon ( $\sim 12\text{-}15 \text{ LT}$ ), are collocated within  $\sim 1\text{-}2$  hours of OMI,  
356 whereas the time discrepancy increases to 7 hours at Singapore, where ozonesondes are launched in the  
357 early morning. Photochemical ozone concentrations are typically denser in the afternoon than in the  
358 morning and hence ozonesonde measurements at Singapore are negatively biased relative to afternoon  
359 satellite measurements. For the reason mentioned above, the discrepancy in the observation time could  
360 also affect this comparison at Kuala Lumpur, where sondes were mostly launched in the late morning,  
361 2-3 hours prior to the OMI passing time and thereby ozonesonde measurements tend to be negatively  
362 biased. These indicate that diurnal variations of tropospheric ozone are visible in ozonesonde  
363 measurements, emphasizing the utility of hourly geostationary ozone measurements. The comparison  
364 results could be characterized with latitudes. In the mid-latitudes (Pohang, Tsukuba, and Sapporo),

365 noticeable disagreements are commonly seen in the tropopause region where mean biases/standard  
366 deviations are ~10 %/~15% larger than those in the lower troposphere. In the extra-tropics (Hong Kong,  
367 Naha), consistent differences of a few percent are seen over the entire altitude range with standard  
368 deviations of 15 % or less below the tropopause (~ 15 km). Hanoi and Kuala Lumpur show significantly  
369 larger biases/standard deviations compared to other ECC stations. At Hanoi inconsistencies of solution  
370 concentrations and pH buffers might influence this instability. At Kuala Lumpur the inconsistencies of  
371 observation times might be one of the reasons, considering its standard deviations of ~100 min, but  
372 mostly less than 30 min at other stations. Therefore, we screen out Singapore, Kuala Lumpur, and Hanoi,  
373 together with all MBM measurements at Indian stations and CI measurements at Japanese stations to  
374 improve the validation accuracy of GEMS simulated retrievals in next section. Thus, stations where the  
375 standard procedures for preparing and operating ECC sondes are consistently maintained, are adopted  
376 as an optimal reference for this work.

377

### 378 **3.2 Evaluation of GEMS simulated ozone profile retrievals**

379

380 The GEMS simulated retrievals are assessed against ECC ozonesonde soundings at five stations  
381 (Hong Kong, Pohang, Tsukuba, Sapporo, and Naha) identified as a good reference in the previous  
382 section. The comparison statistics include mean bias and standard deviation in the absolute/relative  
383 differences, correlation coefficients, linear regression results (slope (a), intercept (b), error); the error  
384 of the linear regression is defined as  $\frac{1}{n} \sqrt{\sum_i^n (y_{GEMS} - y_{fit})^2}$ ,  $y_{fit} = a \cdot y_{sonde} + b$ . In Fig. 8, GEMS  
385 simulated retrievals are plotted as functions of ozonesondes with and without the vertical resolution  
386 smoothing, respectively, for the stratospheric and tropospheric columns. GEMS simulations  
387 underestimate the tropospheric ozone by  $\sim 2.27 \pm 5.94$  DU and overestimate the stratospheric ozone  
388 by  $\sim 9.35 \pm 8.07$  DU relative to high-resolution ozonesonde observations. This comparison  
389 demonstrates good correlation coefficients of 0.84 and 0.99 for troposphere and stratosphere,  
390 respectively. This agreement is degraded if the rejected ECC sondes (Kuala Lumpur, Hanoi, and  
391 Singapore) are included; for example, the slope decreases from 0.68 to 0.64 while the RMSE increases  
392 6.35 and 6.76 DU for TOC comparison. Smoothing ozonesonde soundings to GEMS vertical resolution  
393 improves the comparison results, especially for the tropospheric ozone columns; standard deviations  
394 are reduced by ~ 5 % with mean biases of less than 1 DU. Similar assessments are performed for OMI  
395 standard ozone profiles based on the KNMI OE algorithm (Kroon et al., 2011) hereafter referred to as  
396 OMO3PR (KNMI) in Fig. 9 and the research product based on the SAO algorithm (Liu et al., 2010)  
397 hereafter referred to as OMPROFOZ (SAO) in Fig. 10, respectively. It implies that GEMS gives good

398 information on Stratospheric Ozone Columns (SOCs) comparable to both the OMI KNMI and SAO  
399 products in spite of insufficient information on Hartley ozone absorption in GEMS. Furthermore, a  
400 better agreement of GEMS TOCs with ozonesonde is found than with the others due to different  
401 implementation details. As mentioned in 2.1., the GEMS algorithm is developed based on the heritages  
402 of the SAO ozone profile algorithm with several modifications. The two main modifications are: (1) a  
403 priori ozone climatology was replaced with a tropopause-based ozone profile climatology to better  
404 represent the ozone variability in the tropopause (2) irradiance spectra used to normalize radiance  
405 spectra and characterize instrument line shapes are prepared by taking 31-day moving average instead  
406 of climatological average to take into account for time-dependent instrument degradation. These  
407 modifications reduce somewhat the spread in deviations of satellite retrievals from sondes, especially  
408 in TOC comparison. KNMI retrievals systematically overestimate the tropospheric ozone by  $\sim 6$  DU  
409 (Fig. 10.c), which corresponds to the positive biases of 2-4 % in the integrated total columns of KNMI  
410 profiles relative to Brewer observations (Bak et al., 2015). As mentioned in Bak et al. (2015), the  
411 systematic biases in ozone retrievals are less visible in SAO-based retrievals (simulated GEMS data,  
412 OMPROFOZ), as systematic components of measured spectra are taken into account for using an  
413 empirical correction called “soft calibration”.

414

#### 415 **4. Summary**

416

417 We simulate GEMS ozone profile retrievals from OMI BUUV radiances in the range 300-330 nm  
418 using the OE-based fitting during the period 2005-2015 to ensure the performance of the algorithm  
419 against coincident ozonesonde observations. There are 10 ozonesonde sites over the GEMS domain  
420 from WOUDC, SHADOZ and KMA archives. This paper gives an overview of these ozonesonde  
421 observation systems to address inhomogeneities in preparation, operation, and correction procedures  
422 which cause discontinuities in individual long-term records or among stations. Comparisons between  
423 simulated GEMS TOCs and ozonesondes illustrate a noticeable dependence on the instrument type.  
424 Indian ozonesonde soundings measured by MBM show severe deviations in seasonal time series of  
425 TOC compared to coherent GEMS simulations and ozonesonde observations measured in similar  
426 latitude regime. At Japanese stations, CI ozonesondes underestimate ECC ozonesondes by 2 DU or  
427 more and a better agreement with GEMS simulations is found when ECC measurements are compared.  
428 Therefore, only ECC ozonesonde measurements are selected as a reference, in order to ensure a  
429 consistent, homogeneous dataset. Furthermore, ECC measurements at Singapore, Kuala Lumpur, and  
430 Hanoi are excluded. At Singapore and Kuala Lumpur, observations were performed in the morning and  
431 thereby are inconsistent with GEMS retrievals simulated at the OMI overpass time in the afternoon. In

432 addition, the observation time for Kuala Lumpur is inconsistent itself compared to other stations; its  
433 standard deviation is  $\sim 100$  min, but for other ECC stations it is less than 30 min. At Hanoi the  
434 combinations of sensing solution concentrations and pH buffers changed 4 times during the period of  
435 2005 through 2015. Therefore, GEMS and ozonesonde comparisons show larger biases/standard  
436 deviations at these stations. Pohang station is unique in South Korea where ECC ozonesondes have  
437 been regularly and consistently launched without a gap since 1995; the standard 1% KI full buffered  
438 sensing solution has been consistently applied to ozone sensors manufactured by SPC (6A model).  
439 Evaluation of Pohang ozonesondes against GEMS simulations demonstrates its high level reliability,  
440 which is comparable to neighboring Japanese ECC measurements at Tsukuba and Sapporo. Reasonable  
441 agreement with GEMS simulated retrievals is similarly shown at adjacent Naha and Hong Kong stations.  
442 Finally, we establish that the comparison statistics of GEMS simulated retrievals and optimal reference  
443 dataset is  $-2.27 (4.92) \pm 5.94 (14.86)$  DU (%) with  $R = 0.84$  for the tropospheric columns and  $9.35$   
444  $(5.09) \pm 8.07 (4.60)$  DU (%) with  $R=0.99$  for the stratospheric columns. This estimated accuracy and  
445 precision is comparable to OMI products for the stratospheric ozone column and even better for the  
446 tropospheric ozone column due to improved algorithm implementation. Our future study aims to  
447 achieve this quality level from actual GEMS ozone profile product.

**Figure 1.** Flow chart of the GEMS ozone profile retrieval algorithm.

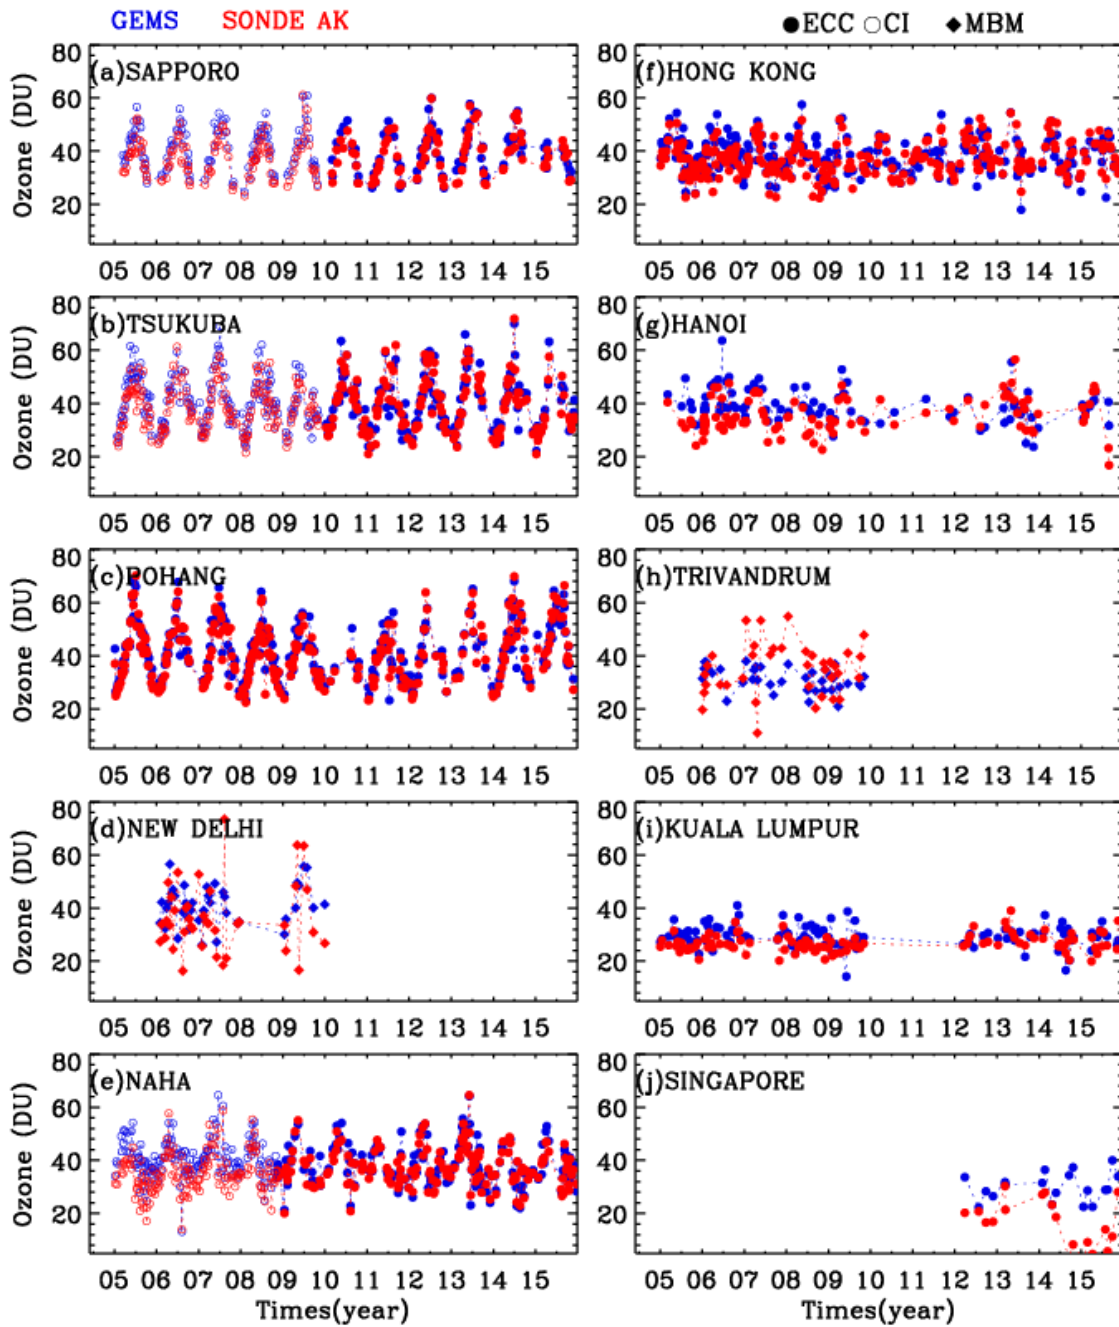

**Figure 2.** Geographic locations of the ozonesonde stations available since 2005 over the GEMS observation domain. Each symbol represents a different type sensor; the modified Brewer-Mast (MBM), the carbon iodine cell (CI), and the electrochemical concentration cell (ECC). The background map illustrates the OMI NO<sub>2</sub> monthly mean in June 2015.

**Figure 3.** Seasonal mean (solid) and standard deviation (dashed) profiles of ozonesonde soundings from 2005 to 2015 at the 10 sites listed in Table 1. 5 mPa is subtracted from standard deviations to fit the x-axis.

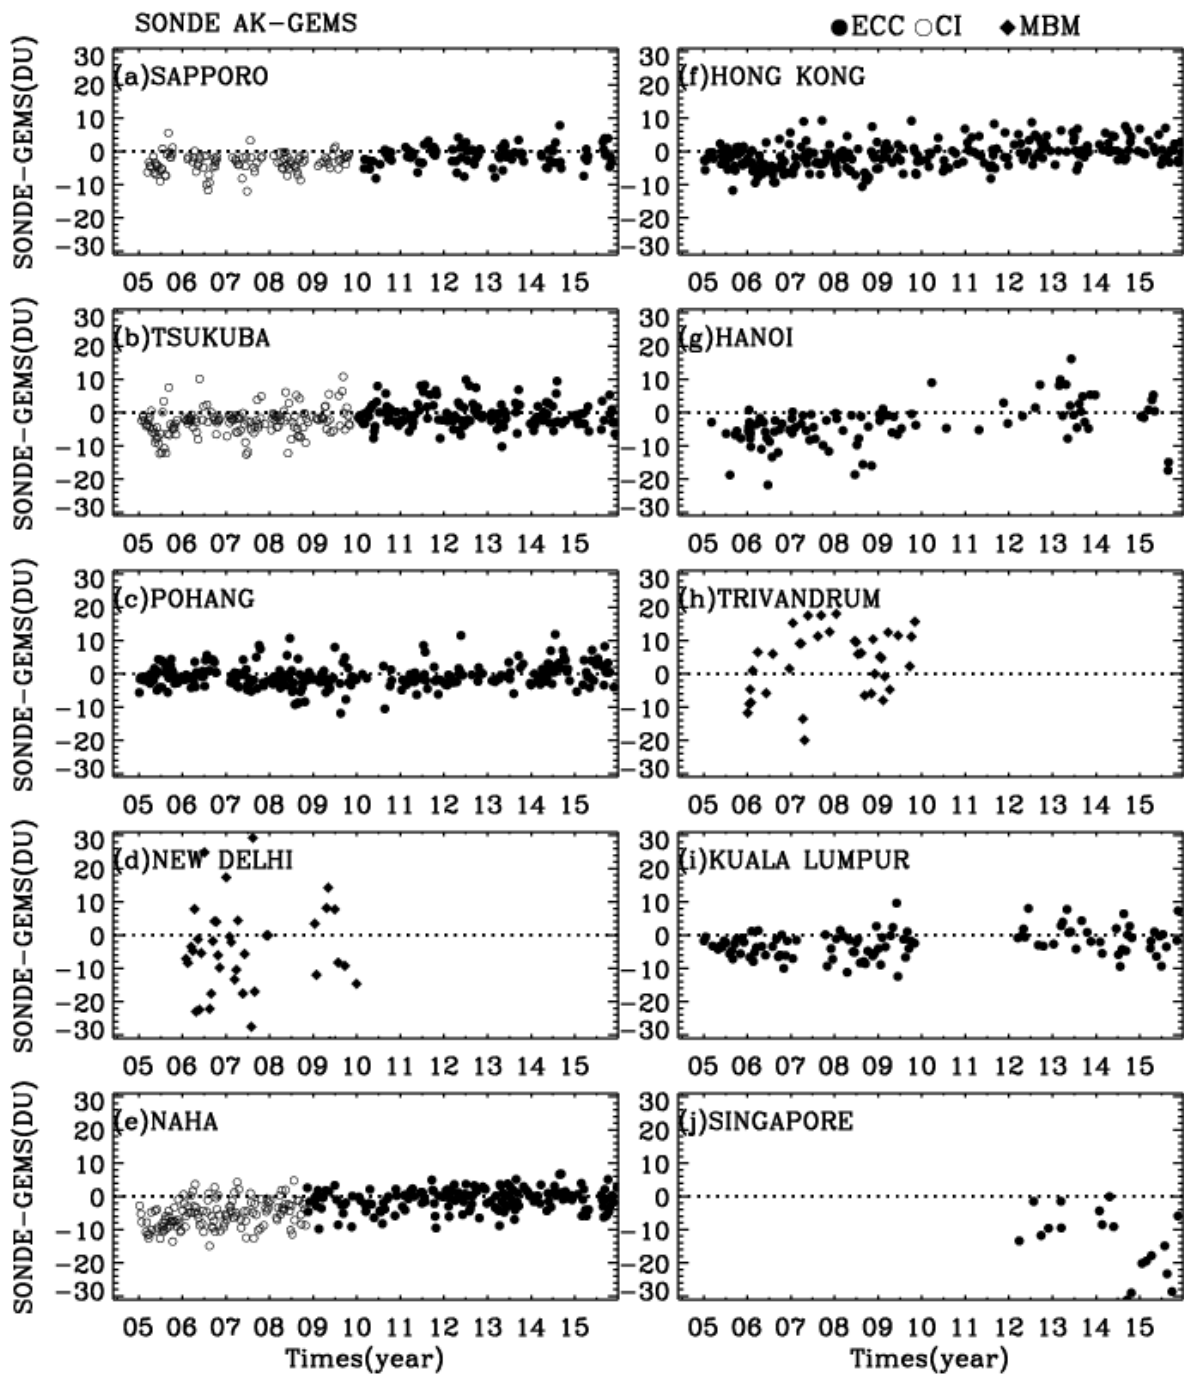

**Figure 4.** Effects of applying a correction factor (CF) to (a) ECC and (b) CI ozonesonde measurements, respectively, on comparisons with simulated GEMS ozone profile retrievals. Solid and dashed lines represent the comparisons with and without applying a CF, respectively, at each Japanese station. The number of data point is included in the legends.

**Figure 5.** Time series of tropospheric ozone columns (DU) of GEMS simulated ozone profile retrievals (blue) and ozonesonde measurements convolved with GEMS averaging kernels (red) from 2005 to 2015 at 10 stations listed in Table 1.

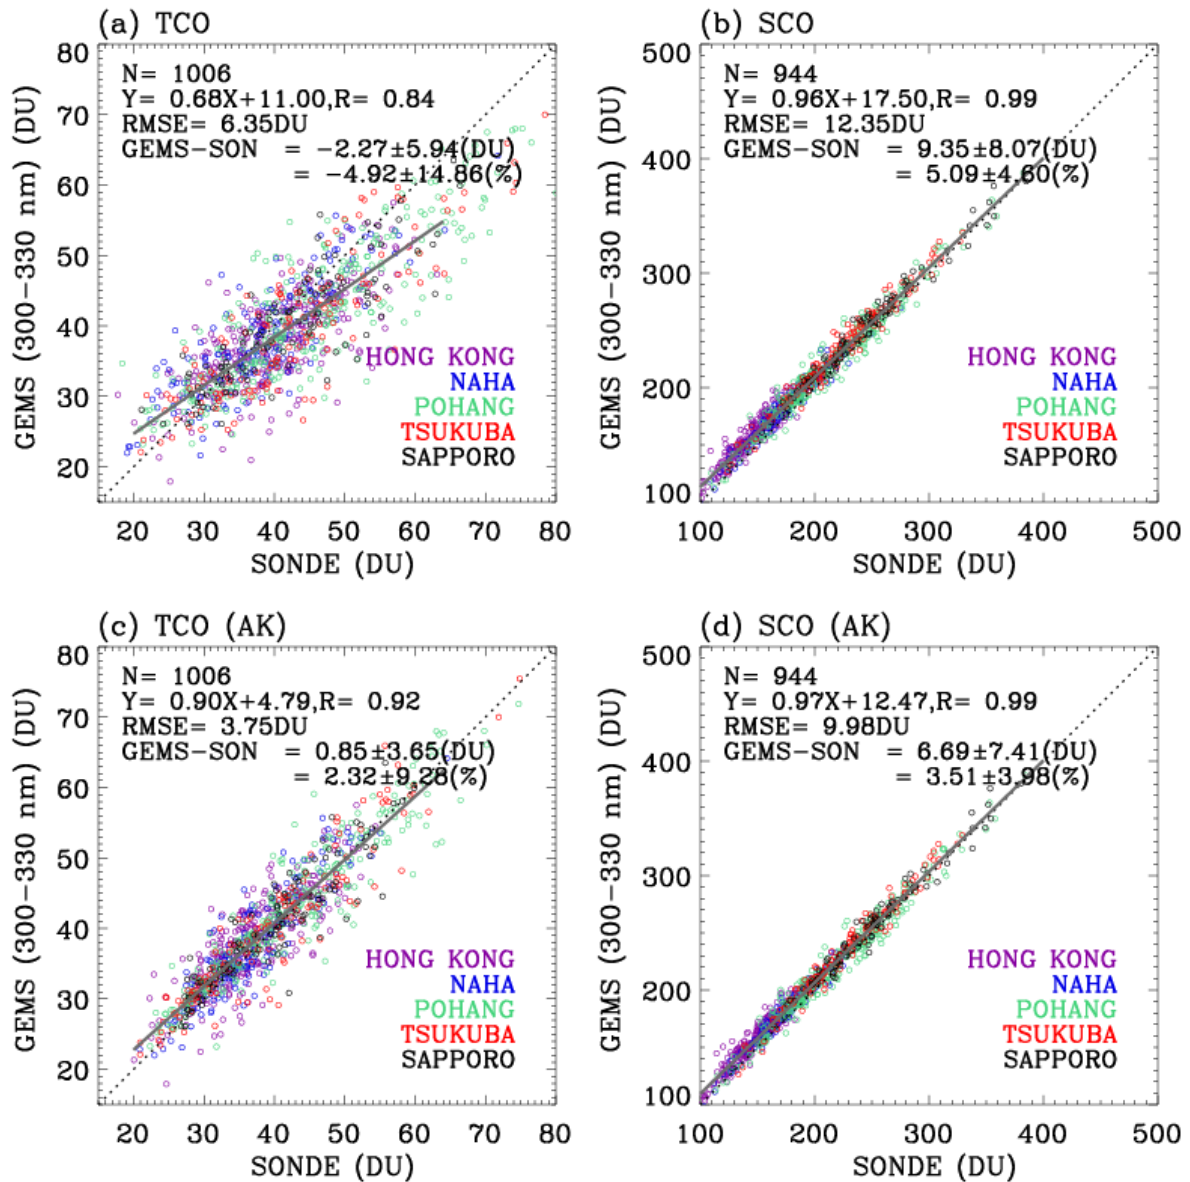

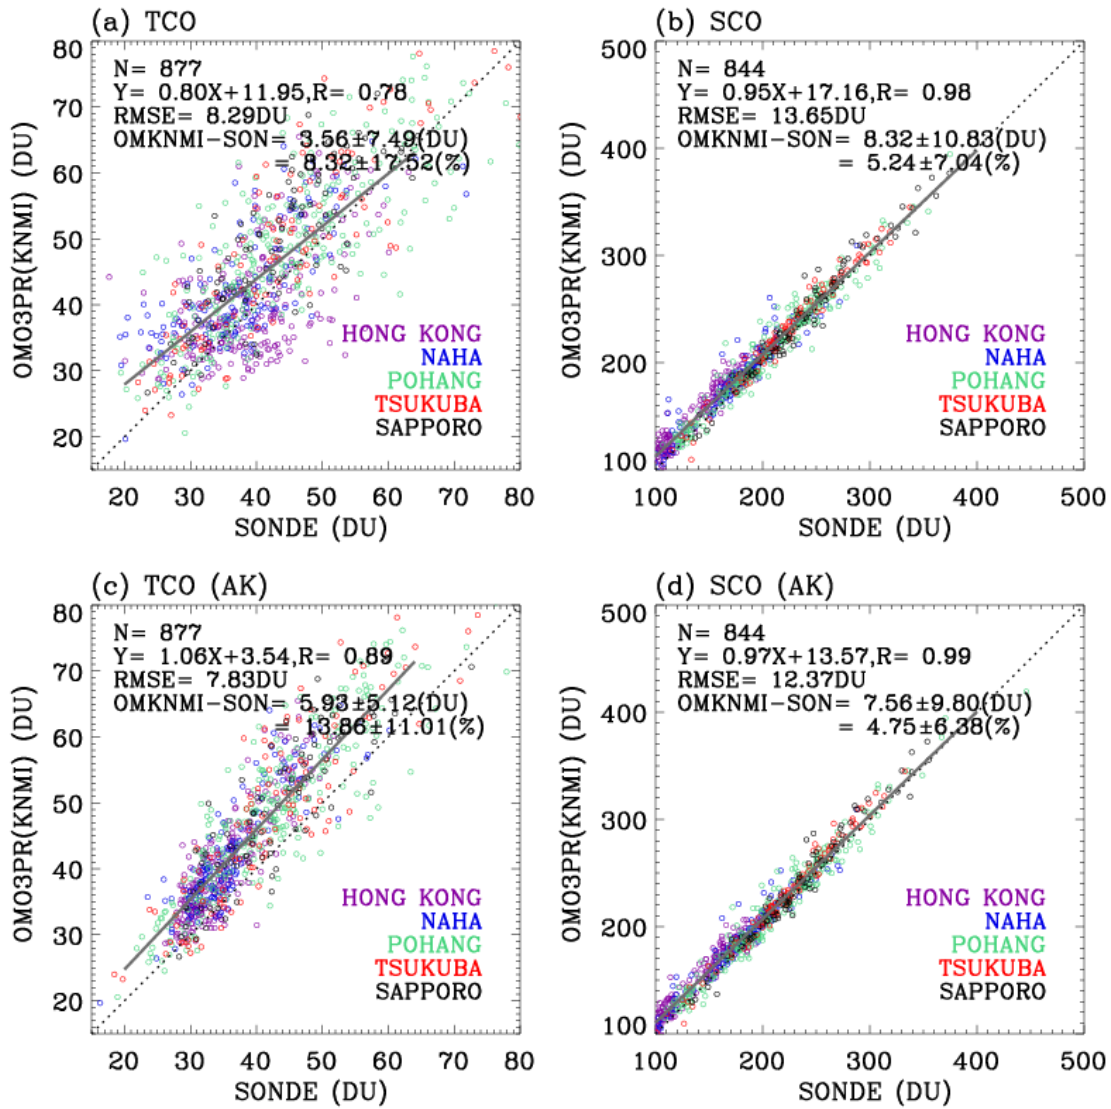

**Figure 6.** Same as Figure 5, but for absolute differences of tropospheric ozone columns (DU) between ozonesonde measurements and GEMS simulated retrievals.

**Figure 7.** Mean biases and  $1\sigma$  standard deviations of the differences between ozonesonde convolved with GEMS averaging kernels and GEMS simulated ozone retrievals as a function of GEMS layers, at individual ECC ozonesonde stations. The relative difference is defined as  $(\text{SONDE AK} - \text{GEMS}) \times 100\% / (\text{a priori})$ .

**Figure 8.** Upper: Scatter plots of GEMS vs. ozonesonde for tropospheric and stratospheric ozone columns, respectively. The lower panels are the same as the upper ones, except that ozonesonde measurements are convolved with GEMS averaging kernels. A linear fit between them is shown in red, with the 1:1 lines (dotted lines). The legends show the number of data points (N), the slope and intercept of a linear regression, and correlation coefficient (r), with mean biases and  $1\sigma$  standard deviations for absolute (DU) and relative differences (%), respectively. Note that we use 5 stations identified as a good reference among 10 stations listed in Table 1 in this comparison.

**Figure 9.** Same as Fig. 8, but for validating OMI standard ozone profiles (OMO3PR) produced by the KNMI OE-based algorithm.

**Figure 10.** Same as Fig. 8, but for validating OMI research ozone profiles (OMPROFOZ) produced by the SAO OE-based algorithm.

**Table1.** List of ozonesonde stations.

Station <sup>a</sup>	Lon (°), Lat (°)	Altitude (m)	Observation Time <sup>b</sup>	Instrument Type <sup>c</sup>	ECC-SST <sup>d</sup>	Post Correction	
Singapore	103.9, 1.3	40	07:30-08:00 (9)	Jan 12 - Sep 15	ECC/EN-SCI Z	SST0.5	No correction
				Nov15 - Dec15	ECC/SPC 6A

				Jan 05 - Dec 15	ECC/EN-SCI 1Z	SST0.5	
Hong Kong	114.1, 22.3	70	13:00-14:30 (11)	Jan 05 - Dec 15	ECC/SPC 6A	SST1.0	No correction
Naha	127.7, 26.2	30	14:30-15:00 (06)	Jan 05 - Oct 08	CI/ KC-96		Correction factor
				Nov 09 - Dec 15	ECC/EN-SCI 1Z	SST0.5	
New Delhi	77.1, 28.3	270	11:00-14:30 (69)	Feb 06 - Dec11	MBM		Correction factor
Pohang	129.2, 36.0	40	13:30-15:30 (24)	Jan 05 - Dec 15	ECC/SPC 6A	SST1.0	No correction
Tsukuba	140.1, 36.1	330	14:30-15:00 (08)	Jan 05 - Nov 09	CI/ KC-96		Correction factor
				Dec 09 - Dec 15	ECC/EN-SCI 1Z	SST0.5	
Sapporo	141.3, 43.1	30	14:30-15:00 (06)	Jan 05 - Nov 09	CI/ KC-96		Correction factor
				Dec 09 - Dec 15	ECC/EN-SCI 1Z	SST0.5	

<sup>a</sup> Data are downloaded from the WOUDC (<http://woudc.org>) data archive, except for Kuala Lumpur and Hanoi, which are from the SHADOZ (<https://tropo.gsfc.nasa.gov/shadoz/>) network, and Pohang, which are from the Korea Meteorological Administration (KMA).

<sup>b</sup> The range of the observation time (LT) with 1  $\sigma$  standard deviations of them (min) in parentheses.

<sup>c</sup> Ozonesonde sensor type (ECC: Electrochemical Condensation Cell, CI: Carbon iodine cell Japanese sonde, MBM: Modified Brewer-Mast Indian sonde). ECC sensors manufactured by either ECC sensor manufactures; Science Pump Corporation (Model type: SPC-6A) and Environmental Science cooperation (Model type EN-SCI-Z/1Z/2Z).

<sup>d</sup> Potassium Iodide (KI) cathode sensing solution type (SST) implemented in ECC ozone sensors: SST0.5 (0.5 % KI, half buffer), SST1.0 (1.0 % KI, full buffer), and SST 2.0 (2.0 % KI, no buffer). Singapore station changed it to SST1.0 as of 2018.

**Table 2.** Comparison statistics (mean bias in DU, 1 $\sigma$  standard deviation in DU, and  $R$ , correlation coefficient) between GEMS simulated tropospheric ozone column and ozonesonde measurements convolved with GEMS averaging kernels.

Station	Collocation Time difference	Type	Data Period (Year)	SONDE AK – GEMS		
				#	Mean Bias + 1 $\sigma$	$R$
Singapore	6:44	ECC	12-15	20	-13.67 $\pm$ 9.61	0.17
Kuala Lumpur	2:29	ECC	05-15	106	-2.54 $\pm$ 4.13	0.44
Trivandrum	1:46	MBM	06-11	37	3.55 $\pm$ 9.75	0.24
Hanoi	0:32	ECC	05-15	100	-3.82 $\pm$ 6.03	0.52
Hong Kong	0:27	ECC	05-15	259	-1.19 $\pm$ 3.91	0.82
Naha	0:47	CI	05-08	135	-5.48 $\pm$ 4.07	0.85
		ECC	08-15	166	-0.94 $\pm$ 3.22	0.91
New Delhi	1:46	MBM	06-11	39	-4.57 $\pm$ 13.36	0.24
Pohang	0:54	ECC	05-15	281	-0.75 $\pm$ 3.13	0.95
