Abstract.

The Atmospheric Sounding Infrared Interferometer (IASI) is an essential instrument for Numerical Weather Prediction (NWP). It measures radiances at the top of the atmosphere using 8461 channels. The huge amount of observations provided by IASI has led the community to develop techniques to reduce observations while conserving as much information as possible. Thus, a selection of the 300 most informative channels was made for NWP based on the concept of information theory. One of the main limitations of this method was to neglect the covariances between the observation-errors of the different channels. However, many centres have shown a significant benefit for weather forecasting to use them. Currently, only the observation-error covariances on the current IASI channel selection are estimated, but no studies have yet been carried out a new selection of IASI channels taking into account the observation-error covariances.

The objective of this paper was therefore to perform a new selection of IASI channels by taking into account the observation-error covariances. The results show that with an equivalent number of channels, accounting for the observation-error covariances, a new selection of IASI channels can reduce the analysis-error on average in temperature by 3 %, humidity by 1.8 % and ozone by 0.9 % compared to the current selection. Finally, we go one step further by proposing a robust new selection of 400 IASI channels to further reduce the analysis-error for NWP.

1 Introduction

The use of satellite observations in data assimilation systems has greatly advanced Numerical Weather Prediction (NWP) models. In particular, observations from infrared sounders have significantly improved the quality of weather forecasts (e.g. Hilton et al. 2012; Guidard et al. 2011; Collard and McNally 2009). The Infrared Atmospheric Sounding Interferometer (IASI) is one of the most important satellite instruments supporting NWP centres. This sounder was jointly developed by the Centre National d'Études Spatiales (CNES) and the European Organisation for the Exploitation of Meteorological Satellites (EUMETSAT). IASI spectrum ranges from 645 to 2760 cm^{-1} with a spectral sampling of 0.25 cm^{-1} leading to a set of 8461 radiance measurements with a spectral resolution of 0.5 cm^{-1} after Gaussian apodization.

The high volume of data resulting from hyperspectral infrared sounders such as IASI presents many challenges, particularly in the areas of data storage, computational cost, information redundancy and information content for example. The methods for reducing the data volume are channel selection, spatial sampling or principle components analysis. Channel selection is an effective approach to reduce the amount of observations to be assimilated. One of the most widely used methods is derived from theory by (Rodgers 1996, 2000), which describes an iterative method to determine an optimal set of channels based on their information content. A study by (Rabier et al., 2002) has highlighted an iterative method that sequentially selects the channels with the highest information content. This method was then used to select the most informative channels of infrared sounders such as: the Atmospheric Infrared Sounder (AIRS) (Fourrié and Thépaut, 2003) and IASI (Collard, 2007).

A selection of 300 IASI channels was performed by Collard (2007) for NWP purposes. Channels were mainly selected in the CO₂ long wave (LW) band (for temperature-sounding), in the atmospheric window regions (for surface properties and clouds), in the water vapour (H₂O) band (for humidity-sounding) and in O₃ long wave band (for ozone). CNES added 14 other channels for climate monitoring purposes. Currently at Météo-France, the three IASI sounders on board the Metop-A, B and C polar satellites are used in the Four Dimensional Variational (4D-Var) data assimilation system (Rabier et al., 2000) for the Action de Recherche Petite Échelle Grande Échelle (ARPEGE) global model (Courtier et al., 1991). The 4D-Var method consists in correcting a background from a short-term forecast (Lorenz 1986; Courtier et al. 1994) by observations along an assimilation window allowing to estimate the atmospheric state. This state named analysis is thus used as initial condition in the NWP models. Assimilated radiances from IASI (a subset of 124 channels from Collard's selection) represent more than 60 % of all assimilated observations (conventional and satellite) in 4D-Var data assimilation process.

The contribution of an observation to the variational data assimilation system is strongly influenced by the observation error. So far, observation errors have usually been assumed to be uncorrelated horizontally (thinning) and vertically. Observation errors occur mainly as a consequence of errors in measurement, representativity, spectroscopy and radiative transfer modelling. These errors for infrared sounders are likely to be correlated between channels. Thus, the work of e.g. Stewart et al. (2008); Collard (2004); Liu and Rabier (2003) for the use of hyperspectral sounders has shown that considering the observation-errors as uncorrelated is damaging to the accuracy of the analysis. Fortunately, the growing computational capacity now allows weather centres to use the observation-error covariances. Many studies have shown the benefit of taking into account inter-channel correlations with significant improvements in the use of IASI data and short- and medium-range forecasts in some cases (e.g. Bormann et al. 2016; Migliorini 2015; Stewart et al. 2014; Ventress and Dudhia 2014).

IASI observation-error covariance estimates are performed on subsets of channels from Collard's selection. However, the different channel selections for the infrared sounders AIRS and IASI were made on the assumption that the errors between channels are not correlated with each other and thus taking into account only the observation-error variances. In addition, in order to reduce the impact of spectrally correlated errors, the selection was made by excluding adjacent channels, which removes more than half of all IASI channels.

The objective of this paper is to perform a new selection of IASI channels by taking into account the observation-error covariances in order to extract a maximum of information in a limited number of channels. In order to ensure a robust selection for NWP, specific attention has been paid to the es-

timization of the observation and background error covariance matrices and to the consideration of various atmospheric scenarios. These selections were evaluated in one-dimensional variational (1D-Var) data assimilation experiments.

Section 1 describes the methodology set up for this study, including information on the data, the models used and some theoretical reminders, Section 2 presents the preliminary and main results for the selection of channels (observation, background error covariance and jacobian matrices), then Section 3 proposes a new selection of IASI channels, finally conclusions and perspectives are provided in Section 4.

2 Methodology

In this paper, the notation for data assimilation and information content theory will be expressed as in Ide et al. (1997).

2.1 Description of the experimental setup

In order to achieve optimal channel selection, we used an experimental configuration of the ARPEGE NWP system. This experiment provides access, in addition to other meteorological fields, to variable ozone fields at the horizontal and vertical resolution of the global ARPEGE model. Ozone is not yet a prognostic variable of the model, so the ozone background come from the Chemistry Transport Model (CTM) MOdèle de Chimie Atmosphérique à Grande Échelle (MOCAGE). The MOCAGE ozone background fields are provided at the beginning of each 6 h assimilation window unlike the other meteorological variables for which the backgrounds are provided by ARPEGE 3 h forecast run. The fields from MOCAGE were interpolated on to the geometry of the ARPEGE model both horizontally on a varying mesh (from about 7.5 km over France to 36 km at the antipodes) and vertically on 105 hybrid vertical levels from the surface (10 m) to 0.1 hPa.

Then, from this setup, we selected 6123 IASI pixels at nadir, in clear sky conditions, day time and night time, on land, sea and sea ice, over the entire globe on 14 and 15, August and November 2016. The IASI instrument also includes an Integrated Imaging Subsystem (IIS) that allows to coregister interferometric measurements with high resolution imager AVHRR (Advanced Very High Resolution Radiometer) (Saunders and Kriebel, 1988). AVHRR provides cloud and heterogeneity information in each IASI pixel. Therefore, to ensure that our pixels are clear, we have eliminated all pixels with an AVHRR cloud cover value greater than 0 %.

Atmospheric background profiles (temperature, humidity and ozone) and surface parameters were extracted at the same coordinates and times as the IASI pixels, also 6123 atmospheric profiles. Noteworthy in this study, a realistic temperature for all surfaces considered was used. Thus, the skin temperature was retrieved for each atmospheric profile (and pixels) from the inversion of the radiative transfer

equation (Vincensini, 2013) using the IASI window channel 1194 (943.25 cm^{-1}) (Boukachaba, 2017) from the Radiative Transfer Model (RTM) RTTOV version 12 (Saunders et al., 2018). This retrieval relies on the specification of emissivity values over land from The Combined ASTER MODIS Emissivity over Land (CAMEL) (Borbás et al., 2018) and from a surface emissivity model (IREMIS) (Saunders et al., 2017) over the open sea and sea ice. The IASI 1194 channel will therefore be fixed in the remainder of the study and will not be used for channel selection or assimilated in the evaluation.

In summary, the 6123 profiles are used in the following study for the estimation of the observation-error covariance matrix and at the end to evaluate the channel selections in the 1D-Var data assimilation system. Channel selection was performed from a subset of 60 profiles (and pixels) empirically selected from the 6123 profiles. These 60 profiles were chosen to have a variability close to the set of 6123 profiles. The location of these profiles is shown in Figure 1.

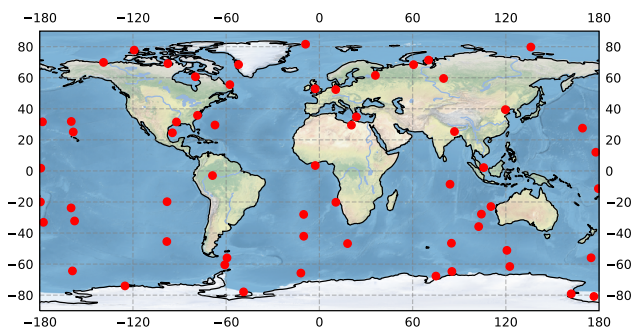

Figure 1. Locations of 60 atmospheric profiles with different scenarios.

To ensure sufficient variability in our set of 60 profiles, we have calculated and illustrated in Figure 2, the mean (black solid line) \pm standard deviation (shaded area) and the minimum and maximum values (black dashed line) of the temperature (a), humidity (b) and ozone (c) profiles. There is significant variability that is similar to that obtained with the profiles in the database available in the RTTOV RTM (Chevallier et al., 2006).

2.2 Channel selection method

The selection of IASI channels made in this study is intended to benefit NWP. Thus, we aim to extract from this selection a maximum of information in temperature, humidity, ozone and surface temperature. In order to evaluate the ability of the IASI channels to provide information on these parameters, we have chosen the selection method from the the Degree of Freedom for Signal (DFS) which is used to select a set of optimal channels having the largest information content for each atmospheric profile as described by (Rodgers 1996, 2000). The DFS is based on information theory and provides a measure of the gain in information gathered by

the observations according to the formula:

$$\text{DFS} = \text{Tr}(\mathbf{I} - \mathbf{A}\mathbf{B}^{-1}) \quad (1)$$

where Tr denotes the trace, \mathbf{I} the identity matrix, $\mathbf{B} \in \mathbb{R}^{n \times n}$ (n parameters to be retrieved) is the background-error covariance matrix and $\mathbf{A} \in \mathbb{R}^{n \times n}$ is the analysis-error covariance matrix which is calculated as follow:

$$\mathbf{A} = (\mathbf{B}^{-1} + \mathbf{H}^T \mathbf{R}^{-1} \mathbf{H})^{-1} = (\mathbf{I} - \mathbf{B}\mathbf{H}^T \mathbf{R}^{-1} \mathbf{H})^{-1} \mathbf{B} \quad (2)$$

where $\mathbf{R} \in \mathbb{R}^{m \times m}$ (m channels considered) is the observation-error covariance matrix and $\mathbf{H} \in \mathbb{R}^{m \times n}$ (the derivatives of each channel with respect to each parameter) represent Jacobians matrix for all IASI channels.

In contrast to the channel selection made by Collard (2007), we have chosen not to separate the selection by variables. Thus, in this study, all the channels considered have the ability to provide information on temperature, humidity, ozone and surface temperature at each step of the selection process. The total DFS taking into account all the information content for these parameters is used as a figure of merit such as:

$$\text{DFS}_{\text{TOT}} = \text{DFS}_T + \text{DFS}_q + \text{DFS}_{\text{O}_3} + \text{DFS}_{T_{\text{skin}}} \quad (3)$$

Then, only the first 5499 IASI channels (whose specifications are listed in Table 1) included in band 1 (645 to 1210 cm^{-1}) and 2 (1210 to 2000 cm^{-1}) were retained for selection (5500 minus channel 1194 used to retrieve skin temperature). Thus, the channels in band 3 (2000 to 2760 cm^{-1}), influenced by the non-LTE (Local Thermodynamic Equilibrium) effects and the solar irradiance, were not considered. Inter-channel error correlations are considered in this study using a diagnosed observation-error covariance matrix from the 5499 channels of IASI. Finally, in order to ensure the robustness of the channel selection, a cross-validation is carried out on the sample of 60 atmospheric profiles chosen previously.

Spectral regions [cm^{-1}]	Absorption band	Main application
650 to 770	CO_2	Temperature-sounding
770 to 1000	Atmospheric window	Surface & Cloud properties
1000 to 1070	O_3	Ozone
1070 to 1210	Atmospheric window	Surface & Cloud properties
1210 to 2000	H_2O	Humidity-sounding

Table 1. Table of IASI spectrum specifications for bands 1 and 2 between 645 and 2000 cm^{-1} .

For each atmospheric profile, the selection begins by selecting the most informative of the 5499 channels using the total DFS with a matrix \mathbf{R} of dimension (1×1) . Then the first selected channel is fixed and the combination of the two most

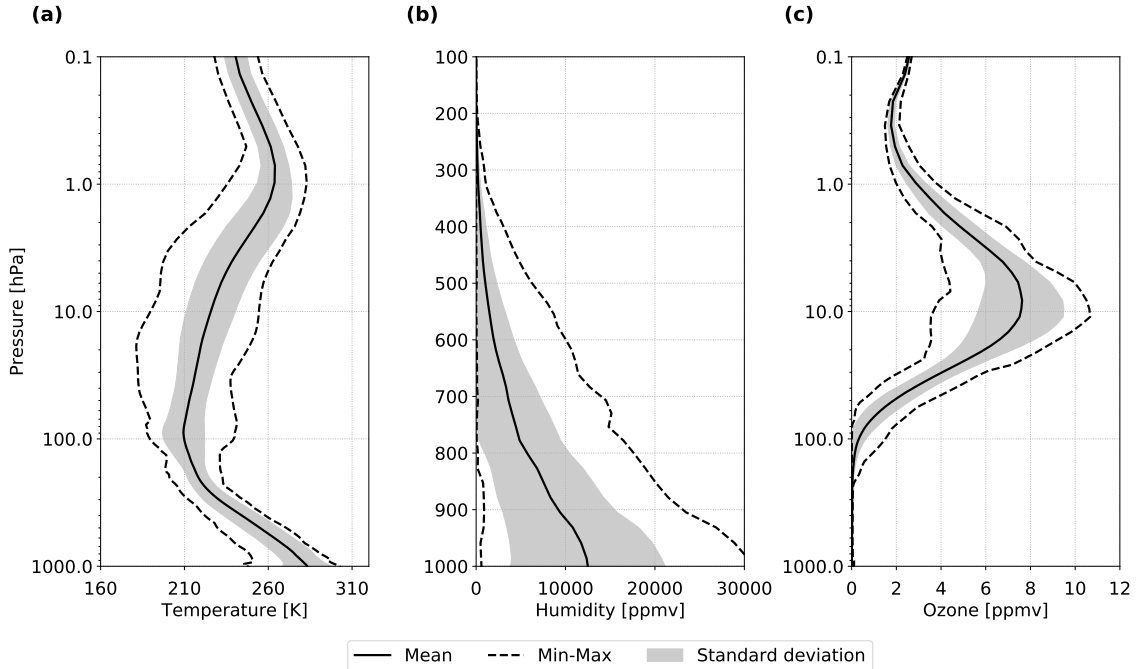

Figure 2. Mean \pm standard deviation and min-max values of temperature (a), humidity (b) and ozone (c) profile with respect to pressure over the subset of 60 atmospheric database. Note that humidity statistics are shown between 1000 and 100 hPa

informative channels is searched for among the (5499 -1) channels with a matrix \mathbf{R} of dimension (2x2). This operation is repeated iteratively until the required number of channels, or the target value of the total DFS, is reached. Here, the channel selection process is stopped when the improvement resulting from the addition of new channels is relatively small. This choice is subjective.

3 Preliminary work

3.1 Radiative Transfer Model experiments

In order to calculate the Jacobians and to simulate IASI radiances, we used the RTM RTTOV version 12. RTTOV is developed and maintained by the Satellite Application Facility (SAF) of EUMETSAT for NWP. In the RTTOV algorithm, the input atmospheric profiles (temperature, humidity and ozone) are variable and provided by the users, the other constituents such as CO_2 , CH_4 , CO , N_2O , etc. can also be provided or assumed to be constant profiles in time and space (depending on the version of the coefficients).

3.1.1 Jacobians calculation

The Jacobian is used to evaluate the sensitivity of a radiance to a physico-chemical parameter. For a specified wavenumber (ν), it represents the sensitivity of the brightness temperature (BT) with respect to a physical parameter (X) such as temperature, humidity or ozone in our case. It is expressed

by the relation:

$$J_\nu(X) = \frac{\partial BT(\nu)}{\partial X} \quad (4)$$

The Jacobian shows to which levels in the atmosphere the BT at given wavenumber is sensitive, with respect to temperature, humidity or concentrations of the different gases present in our case. To take into account the variability that the sensitivity of the IASI channels can have depending on the atmospheric state, the Jacobians of the 5499 channels were calculated on the 60 atmospheric profiles.

Figure 3 shows the averages of temperature (a), water vapour (b), ozone (c) and skin temperature (d) sensitive Jacobians of the 5499 IASI channels with respect to atmospheric pressure. We notice that between 645 and 720 cm^{-1} , IASI channels are mainly sensitive to the temperature from the top of the atmosphere to the lower troposphere. Hence their usefulness is in atmospheric temperature-sounding. There is a slight sensitivity of these channels to ozone in the stratosphere. From 720 to 770 cm^{-1} , the channels are not only sensitive to temperature but also to water vapour in the troposphere. The channels in the atmospheric window between 770 and 1000 cm^{-1} are, as expected, very sensitive to skin temperature and also sensitive for some of them to temperature and water vapour in the lower troposphere. Then the channels in the ozone absorption band between 1000 and 1070 cm^{-1} have ozone sensitivities over a large part of the atmosphere with maximum sensitivity in the stratosphere between 100 and 10 hPa . There is a slight sensitivity of these

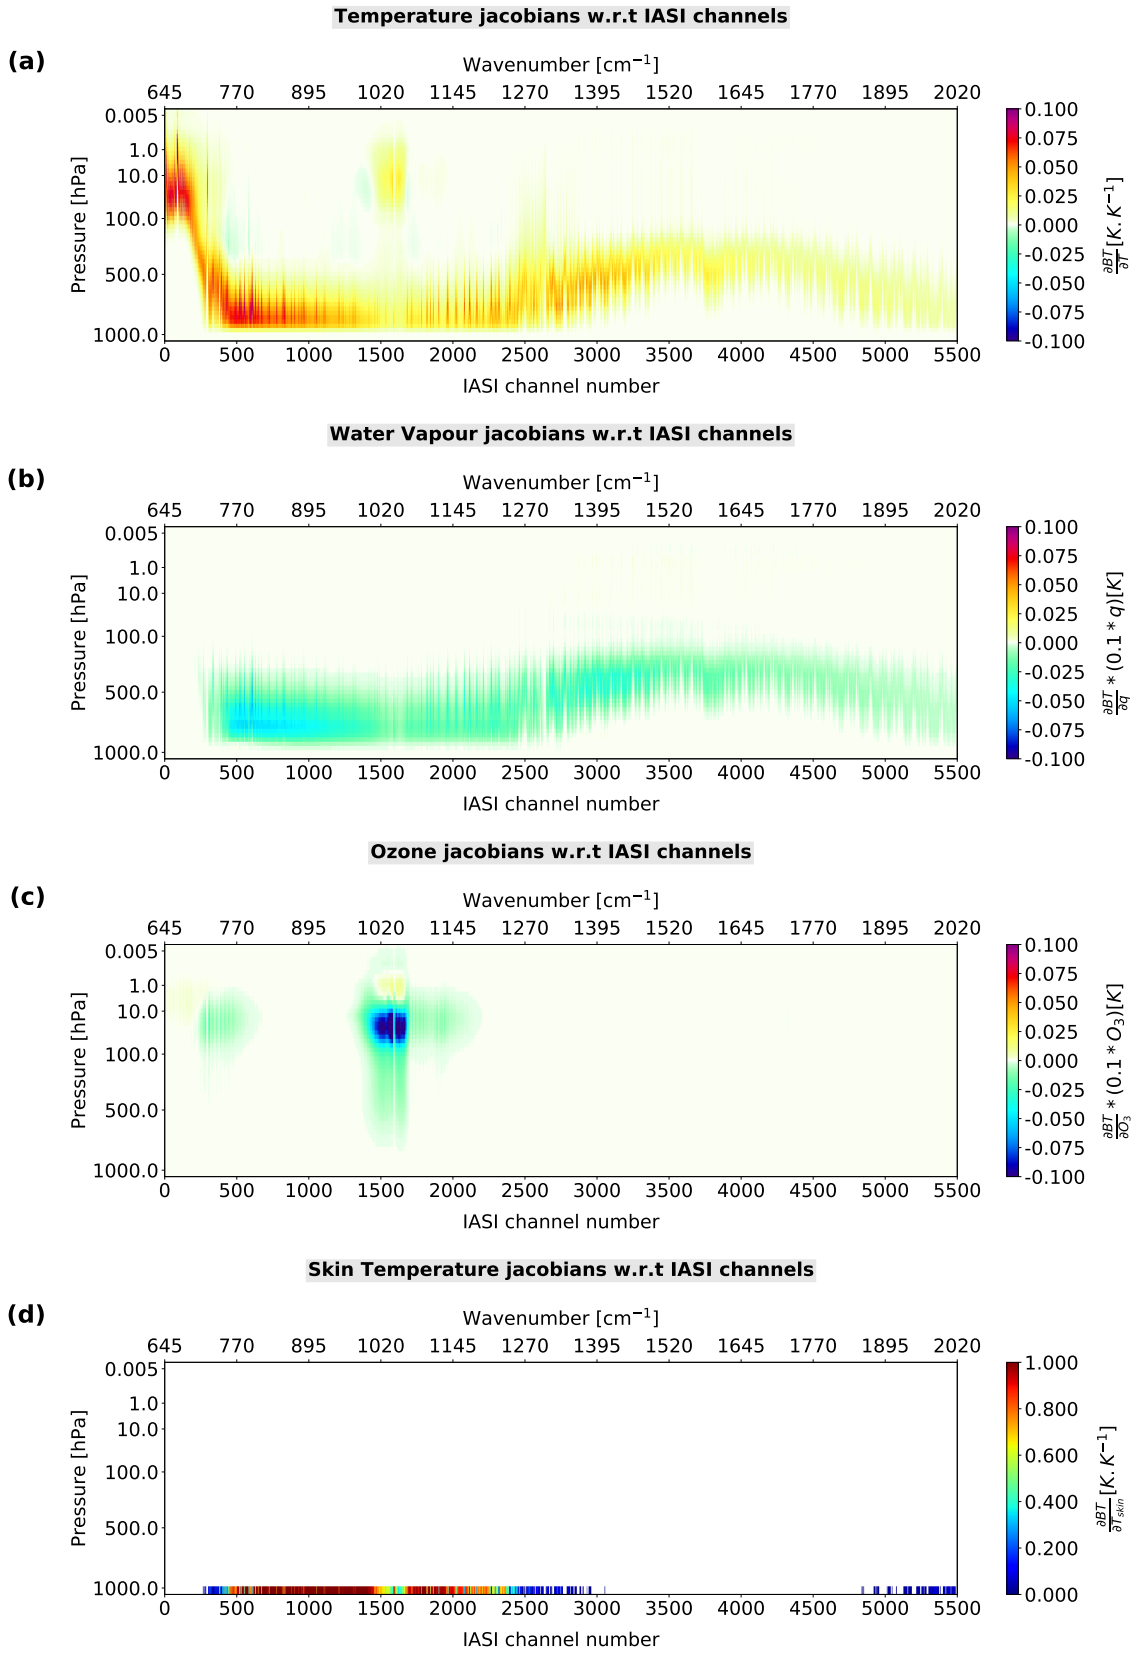

Figure 3. Mean of temperature (a), water vapour (b), ozone (c) and skin temperature jacobians of the first 5499 IASI channels (band 1 and 2) with respect to pressure over the subset of 60 atmospheric profile database (calculated with RTTOV RTM).

channels to temperature in the stratosphere and lower troposphere, to water vapour in the lower troposphere and to skin temperature for some of them. Then the channels located between 1070 and 1210 cm^{-1} are mainly sensitive to skin temperature with slight sensitivities to temperature and water vapour in the lower troposphere. Finally, the channels in the absorption band of H_2O are mainly sensitive to water vapour and temperature over a large part of the troposphere.

We observe that many channels contain information on several variables. This is particularly true for channels located in the two atmospheric windows, some of which have significant temperature and water vapour sensitivities. The selection of these poly-sensitive channels could be beneficial to NWP by allowing information on temperature, humidity and surface temperature to be extracted within the same channel. However, this assumes that the correlations of inter-channel observation-error are correctly taken into account.

3.1.2 Simulated IASI radiances

The first step in calculating the observation error covariance matrix is the estimation of the standard deviations of observation-error. These can be deduced from the calculation of First-Guess (FG) departure standard deviations, i.e. statistics of the differences between the IASI observations measured and simulated using the RTTOV RTM such as:

$$\mathbf{d}_b^o = \mathbf{y} - \mathcal{H}(\mathbf{x}^b) \quad (5)$$

where \mathbf{y} is the observation, \mathbf{x}^b is the background and \mathcal{H} is the observation operator. In order to have a robust statistical representation and to take into account the natural variability, we have simulated for each of the 6123 profiles the 5499 channels of IASI.

Figure 4. Mean \pm standard deviation of FG departures with respect to 5499 IASI channel number and wavenumber [cm^{-1}] (bands 1 & 2 without channel 1194) over the set of 6123 atmospheric profiles.

Figure 4 shows the mean (black line) \pm standard deviation (shaded) of the innovations with respect to the 5499 IASI channels calculated from the 6123 atmospheric profiles. Note that channel biases between 645 and 770 cm^{-1} are less

than 0.5 K with standard deviations between 0.3 and 0.6 K. The channels of the atmospheric window between 770 and 1000 cm^{-1} have approximately the same bias values, with biases less than 0.5 K and standard deviations between 0.2 and 0.7 K. The largest values are obtained with the channels in the ozone absorption band between 1000 and 1070 cm^{-1} with biases between 1.0 and 6.0 K and standard deviations between 0.5 and 2.0 K. These high values are mainly due to the ozone biases found in the MOCAGE CTM. It is able to model the ozone variability correctly but tends to overestimate the ozone concentration (up to 0.75 ppmv) between 300 and 40 hPa and underestimate it (up to 2.5 ppmv) between 30 and 0.1 hPa (Coopmann et al., 2018). These errors in ozone concentrations therefore have a direct impact on the modelling of radiative transfer and on the simulation of IASI channels sensitive to this species. Data assimilation would allow to correct these biases in ozone, this is currently investigated for the ARPEGE and MOCAGE models. Then, the channels present in the second atmospheric window between 1070 and 1210 cm^{-1} have biases lower than 0.9 K with standard deviations between 0.5 and 0.8 K. Finally, the channels in the water vapour absorption band have biases of less than 2.0 K and standard deviations between 0.3 and 1.5 K. The higher values of these channels are also due to errors in humidity modelling in the global ARPEGE model. In addition, these abrupt changes from slight to large values are the result of differences in the level of atmospheric sensitivity that may exist between two channels, even if they are spectrally close to each other.

3.2 Assimilation system

The NWP SAF One Dimensional Variational (1D-Var) data assimilation algorithm (Pavel et al., 2008) is based on the Optimal Estimation Method (OEM) (Rodgers, 2009). The unidimensionality makes this algorithm fast, flexible and suitable for research purposes close to NWP operational frameworks. Similar to other variational data assimilation algorithms (e.g. 3D/4D-Var), the objective of the 1D-Var is to minimize both the observational and background deviation by minimizing a cost function \mathcal{J} . Assuming that the background error is not correlated to the observation error and the errors have a Gaussian distribution, we retrieve state \mathbf{x} by minimizing the cost function such as:

$$\begin{aligned} \mathcal{J}(\mathbf{x}) = & \frac{1}{2} (\mathbf{x} - \mathbf{x}^b)^T \mathbf{B}^{-1} (\mathbf{x} - \mathbf{x}^b) \\ & + \frac{1}{2} (\mathbf{y} - \mathcal{H}(\mathbf{x}))^T \mathbf{R}^{-1} (\mathbf{y} - \mathcal{H}(\mathbf{x})) \end{aligned} \quad (6)$$

where \mathbf{x}^b is the background profiles, \mathbf{y} is the IASI observations, $\mathcal{H}(\mathbf{x})$ represents the BTs which are simulated by RTTOV, \mathbf{B} and \mathbf{R} is the background and observation-error covariance matrix respectively. The retrieved state is called analysis and noted \mathbf{x}^a .

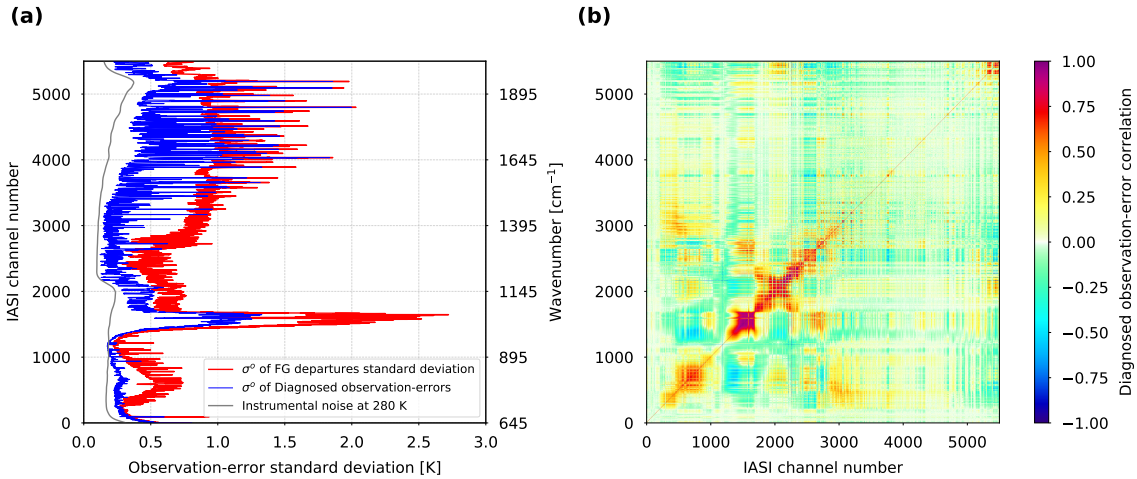

Figure 5. Observation-error standard deviation from FG departures standard deviation in red line, diagnosed observation-errors from Desroziers method using 1D-Var data assimilation system in blue line and instrumental noise at 280 K in grey with respect to 5499 IASI channel number and wavenumber [cm^{-1}] (bands 1 & 2 without channel 1194) over the set of 6123 atmospheric profiles (a). Diagnostic IASI observation-error correlation with respect to the same channels as before (b).

In this paper, the 1D-Var algorithm was also used to compute the observation error covariance matrix from the Desroziers et al. 2005 diagnostic and to evaluate the different channel selections. We modified the code to jointly retrieve temperature, humidity, ozone and surface parameters. The profiles are available on 54 pressure levels from 1050 to 0.005 hPa.

3.3 IASI Observation-errors

A correct estimation of observation-errors is essential in the data assimilation process. Until a few years ago, only the variances of these errors were taken into account (diagonal \mathbf{R} matrix). Then innovative techniques to determine these errors and their correlations more accurately by deriving estimates of the real observation-error from the departure statistics from assimilation systems emerged (e.g. Hollingsworth and Lönnberg 1986; Desroziers et al. 2005). Several research works have successfully applied these methods to infrared hyperspectral instruments in order to estimate their total observation-errors (instrumental noise, spatial representativeness error, error in the calculation of radiative transfer, etc.). For IASI, many NWP centres have explored the use of observation-errors with inter-channel correlations with significant benefits in terms of forecast impact. This is the case at the MetOffice (Stewart et al. 2014; Weston et al. 2014), the Environment and Climate Change Canada (Heilliette and Garand, 2015), Météo-France (Guidard, *pers. comm.*) and the European Centre for Medium-Range Weather Forecasts (ECMWF) (Bormann et al., 2016).

However, these observation errors have been estimated for already selected IASI channels. Considering the significance that inter-channel error correlations can have in the

data assimilation process, they should also have a particular influence on the selection of the most informative channels. Some works have consequently carried out new selections of IASI channels using \mathbf{R} matrices that take into account inter-channel observation-error correlations (e.g. Migliorini 2015; Ventress and Dudhia 2014). They constructed their total \mathbf{R} matrix using a "bottom-up" approach (Walker et al., 2011) by estimating separate sources of forward model uncertainty, as opposed to the "top-down" approach we have chosen to use in this study.

To determine the total \mathbf{R} matrix of the 5499 IASI channels for channel selection, we used the following method:

- First, we constructed a diagonal \mathbf{R} matrix with observation-error variances $(\sigma^o)^2$ derived from the standard deviations of the innovations previously computed from the simulated observations in RTTOV.
- Second, we diagnosed the \mathbf{R} matrix using the Desroziers et al. (2005) method showing that it is possible to estimate in observation space, the matrices of background and observation-error covariances with the deviations of the observations from the background and analysis as:

$$\mathbf{R} = \mathbf{E}[\mathbf{d}_a^o (\mathbf{d}_b^o)^T] \quad (7)$$

where $\mathbf{d}_a^o = \mathbf{y} - \mathcal{H}(\mathbf{x}^a)$ is the Analysis departure and $\mathbf{d}_b^o = \mathbf{y} - \mathcal{H}(\mathbf{x}^b)$ is the First-Guess departure. The diagnostic of the \mathbf{R} matrix is statistically computed by performing 1D-Var data assimilations on the 6123 profiles.

- Finally, diagnose high dimensional error covariance matrices can lead to estimates that are often degenerate or ill-conditioned, making it impossible to invert the matrix. This is precisely the case in this study where the

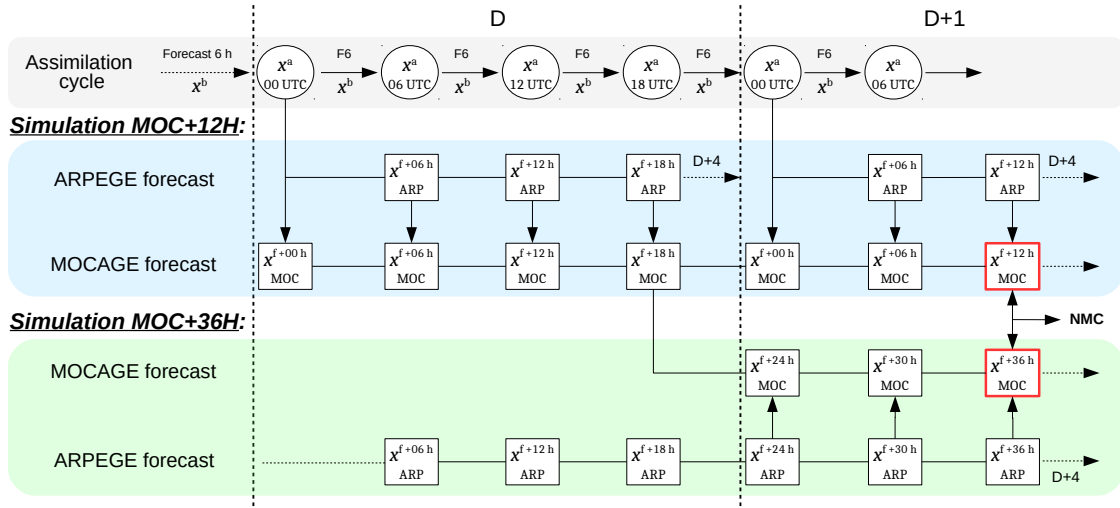

Figure 6. Schematic illustration of the NMC method using MOCAGE CTM, where x_{MOC}^{f+12h} is the forecast from simulation MOC+12H that is valid at time D ; Similarly, x_{MOC}^{f+36h} is the forecast from simulation MOC+36H that is valid at time D+1.

matrix \mathbf{R} is diagnosed on 5499 channels and will have to be inverted for channel selection as shown in Eq.(2). Here we have chosen to apply the minimum eigenvalue method to recondition the \mathbf{R} matrix. This method has shown its robustness in work by Weston et al. (2014), and Tabcart et al. (2020) concluded that it leads to small overall changes in the correlation matrix, but that it can increase off-diagonal correlations. The consideration of over 6000 profiles for the diagnostic of the \mathbf{R} matrix allowed us to recondition the matrix only slightly with very minor changes in the variances and correlations.

Figure 5 shows the observation error standard deviation from FG departures standard deviation in red line, diagnosed observation-errors in blue line and instrumental noise of IASI at 280 K in grey with respect to 5499 IASI channel number (a) and the diagnostic IASI observation error correlation for the same channels (b). The diagnosed observation error standard deviations are above instrumental noise but below the standard deviations of FG departure. Furthermore, our diagnosed standard deviations of observational error are consistent with those obtained by Bormann et al. (2016) for a subset of channels except for the ozone-sensitive channels which the ozone background differed from ours. The values of the observation-error correlations are also consistent with values obtained in other similar studies.

3.4 T, q, O₃ Background-errors

In the same way as the observation-error covariance matrix, it is necessary to estimate accurately the background-error covariance matrix \mathbf{B} . Since the ozone background-errors are not yet available in the ARPEGE NWP model and the temperature and humidity fields forcing the MOCAGE CTM come

from ARPEGE, we have chosen to estimate the background-errors of temperature, humidity and ozone together using a statistical method with the MOCAGE model.

The National Meteorological Center (NMC) method by (Parrish and Derber, 1992) is a technique that defines background errors from the difference between NWP forecasts of various range valid at the same time. This method is here applied to ozone forecasts. We consider differences from between 36 h and 12 h forecast ranges. The background error covariance matrix \mathbf{B} is then constructed using long-term modelling results. Two twin simulations were performed. For each one, the configuration uses 60 hybrid levels, from the ground up to 0.1 hPa, and a global domain with a 1 ° horizontal resolution and the ARPEGE meteorological fields are provided to MOCAGE every 3 h. The model was run from September 2016 to April 2018, the first 6 months being considered as spin-up. The various forecasts used in our application of the NMC method are illustrated in Figure 6:

- The first simulation uses the operational setup (named here MOC+12H), i.e. every day an ozone forecast up to 24 h is produced by MOCAGE. The initial ozone state of this forecast is the 24 h forecast of the previous day. The meteorological fields used for the forcing of this ozone forecast come from ARPEGE forecast beginning at the same moment (ARPEGE analysis for 00 UTC, then ARPEGE forecasts every 3 h). 1.5 yr simulation has been produced with this cycling mode;
- In the second simulation (named here MOC+36H), an ozone forecast up to 36 h range is produced. Each day, the ozone forecast is initialized from the MOC+12H ozone initial field valid at the same date. Meteorological

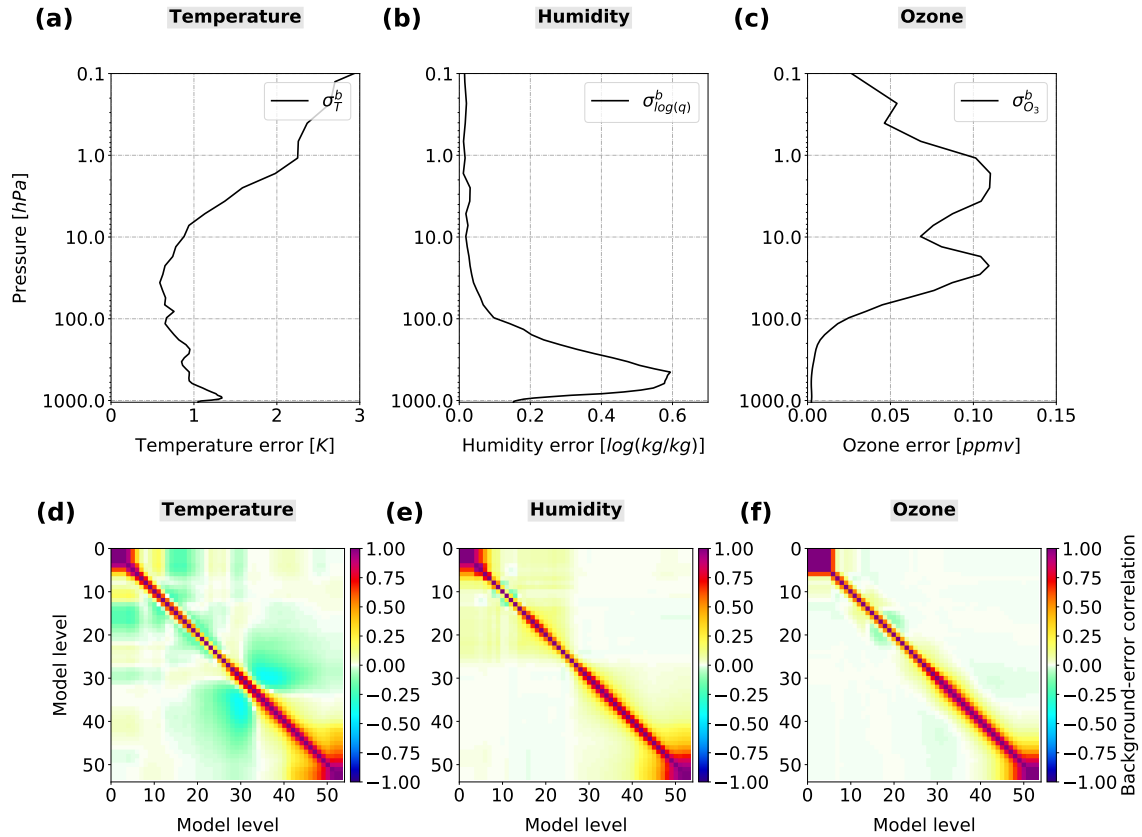

Figure 7. Background-error standard deviation of temperature [K] (a), humidity [log(kg/kg)] (b) and ozone [ppmv] (c) with respect to pressure. Background-error vertical correlation of temperature (d), humidity (e) and ozone (f) with respect model levels. Note that level 0 is the top model level at 0.005 hPa and level 54 is lowest model level at 1050 hPa.

forcing are ARPEGE forecasts starting the same day at 00 UTC and ranging from 0 to 36 h.

Finally, **B** matrix with temperature, humidity and ozone background-errors is computed statistically from MOC+12H/MOC+36H forecast differences, valid at the same time, over a one year period (March 2017 to March 2018). It should be noted that the ozone background-errors estimated here are the result of differences in meteorological forcing from ARPEGE and not chemical differences. Nevertheless, this is a reasonable approximation since the photochemical lifetime of ozone in the Upper Troposphere Lower Stratosphere (UTLS) region is relatively long (Semane et al., 2009). In order to be used in the 1D-Var algorithm, the MOCAGE fields were interpolated on 56 levels from 1050 to 0.005 hPa before calculating the **B** matrix. As the MOCAGE fields are provided up to 0.1 hPa, the interpolated fields have 4 levels above 0.1 hPa with similar values. Thus, we have chosen not to use the levels above 0.1 hPa for temperature and ozone background-errors. In the same manner, the interpolated fields go up to 1050 hPa, which is in fact rarely reached. We have therefore chosen not to use the first 2 levels. Finally, as for the **B** matrix provided by the

1D-Var, we have chosen not to use the levels located in the stratosphere for the humidity background-errors.

In conclusion, the 1D-Var experiments and the channel selections will use the temperature [K] and ozone [ppmv] background-errors in over 48 levels from 1013 to 0.1 hPa and the humidity background-errors [log(kg.kg⁻¹)] from 1013 to 100 hPa. The **B** matrix was calculated in a multivariate approach but here we chose to use a univariate **B** matrix, which means that cross-correlation between temperature, humidity and ozone variables are not taken into account. This assumption prevents feedback effects of ozone on temperature and humidity (Dethof and Holm, 2004).

We have shown in Figure 7, the temperature (a), humidity (b) and ozone (c) background error standard deviation with respect to pressure and the temperature (d), humidity (e) and ozone (f) background-error vertical correlations with respect model levels. We notice that the correlations for the three variables have higher values in the troposphere between 1013 and 100 hPa (model levels 54 and 25 respectively). These results for temperature and humidity are consistent with the study carried out by Berre (2000) and Hólm and Kral (2012). Finally, ozone background-errors have values up to 0.11 ppmv. This maximum is consistent with values obtained

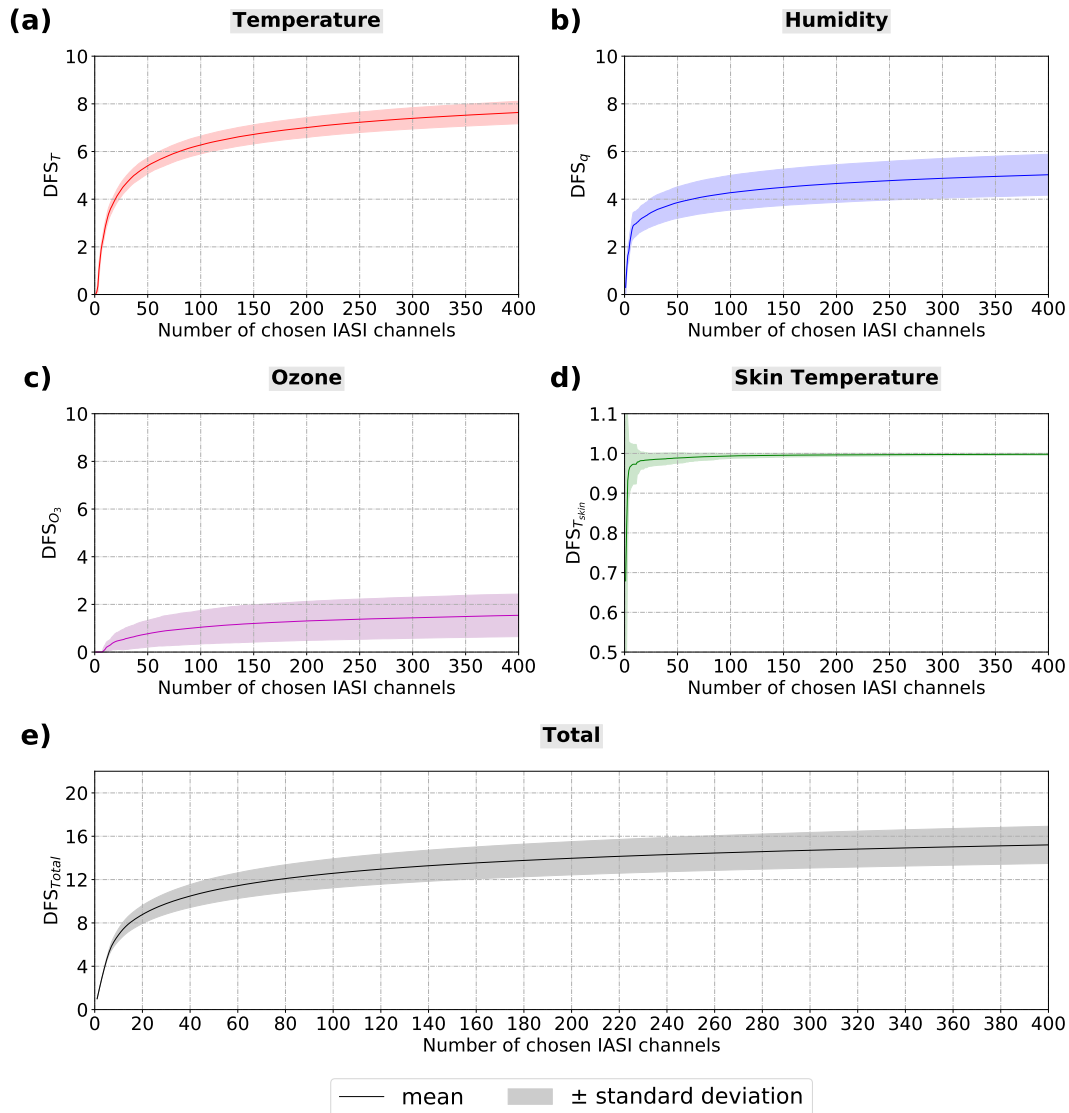

Figure 8. Evolution of the mean DFS \pm standard deviation for temperature (a), humidity (b), ozone (c), skin temperature (d) and total (e) during the channel selection over the subset of 60 atmospheric profile database.

in other studies, e.g. the work by Dragani (2016) and Dragani and McNally (2013) which were carried out using ozone background error standard deviations with maximum values up to 0.10 ppmv. In addition, the Inness et al. (2015) study for the assimilation of ozone satellite data product (Level 2) into the Composition Integrated Forecasting System (CIFS) model as part of the Copernicus Atmospheric Monitoring Service (CAMS) program, used ozone background-error standard deviations with maximum values between 1.4 and 1.6 kg.kg⁻¹, or about 0.08 and 0.10 ppmv, respectively.

4 Results

4.1 Channel selection

Once the matrices **R**, **B** and **H** were determined, we carried out the selection of the most informative channels by solving Eq.(1) with Eq.(3) as the figure of merit. The selection threshold is achieved when the difference in total DFS between the last selected channel and the previous one is less than 0.005, which corresponds to the 397th selected channel in average over the 60 profiles. We decided to stop our selection at 400 channels. In Figure 8, we plotted the evolution of the DFS mean \pm standard deviations in temperature (a), humidity (b), ozone (c), skin temperature (d) and total (e) during the IASI channel selection on the subset of

Figure 9. Percentage of the number of channels selected (up to 400 channels) on the subset of 60 atmospheric profile database divided by spectral group to temperature-sounding (in red), window (in green), ozone (in purple), humidity-sounding (in blue) and total (in black).

60 atmospheric profiles. A large part of the possible maximum total DFS is reached quickly since 90 % of the maximum total DFS over the 400 channels is achieved with only 172 channels. The maximum skin temperature DFS is obtained very quickly as only 172 channels are sufficient to provide more than 90 % of the maximum skin temperature DFS over the 400 selected channels. The humidity DFS also increases very quickly. Finally the total DFS with 400 selected channels consists of 50.3 % temperature DFS, 33.1 % humidity DFS, 10.1 % ozone DFS and 6.5 % skin temperature DFS.

In order to characterize the channel selection process, a histogram of the percentage of the selected number of channels (up to 400 channels) on the subset of the 60 atmospheric profiles is shown in Figure 9. These percentages are separated by the main spectral bands to temperature-sounding (in red), atmospheric window (in green), ozone (in purple), humidity-sounding (in blue) and total (in black). This means that if a channel is selected for all profiles, it achieves 100 % selection. Conversely, a channel never selected among the 60 profiles reaches 0 % selection. In this selection, out of the 5499 available channels only 44 channels are always selected (41 for the temperature-sounding and 3 for the humidity-sounding) and 3720 channels are never selected, mainly humidity-sounding channels (2417) and channels of the at-

mospheric window (1060). The channels which are selected the more often (> 80 %) mainly are temperature-sounding channels. Then humidity-sounding channels are more diversely selected until the end of the process.

4.2 Comparison

The objective here is to demonstrate that the use of an **R** matrix accounting for the inter-channel observation-errors during the channel selection process allows a more accurate selection of the most informative channels compared to a selection using a diagonal **R** matrix. Therefore, we compared our selection to the channel selection made by Collard (2007) by applying the inter-channel observation errors to it. In this study, we chose not to use the IASI channels in band 3; Collard’s selection counts 24 of them. Channel 1194 is excluded for the selection, as it is used for skin temperature retrieval. Which leaves us with 275 channels from the Collard’s selection, hereafter named CS275. We have taken the first 275 channels in our new selection, hereafter named NS275.

The first difference between the two selections is that there are less than 30 % channels in common. Only 60 channels are common in the temperature-sounding spectral group, one in the atmospheric window, 4 in the ozone band and 13 in the humidity-sounding spectral group. Which represents a total of 28 % of common channels between CS275 and

30

35

Figure 10. Comparison between the 275 channels selected by Collard (a) and the 275 new channels selected (b) on a typical IASI spectrum in brightness temperature on bands 1 & 2. The red, green, purple and blue circles represent the channels of temperature-sounding, window, ozone and humidity-sounding spectral groups, respectively.

NS275. It can also be noticed in Table 2 that our selection has more channels in the temperature-sounding and ozone spectral groups and less in the atmospheric window and humidity sounding spectral group.

Spectral group	Number of channels	
	CS275	NS275
Temperature-sounding	122	141
Atmospheric window	29	17
Ozone	15	31
Humidity-sounding	109	86

Table 2. Spectral band comparison between Collard’s and the new channel selection.

The two selections can also be compared in terms of location on the IASI spectrum. In Figure 10, we have located the selected channels on a typical IASI spectrum in brightness temperature. The red, green, purple and blue circles repre-

sent the channels of the temperature-sounding, atmospheric window, ozone and humidity-sounding spectral groups, respectively. Note that NS275 mainly selects channels at the beginning of the spectral bands. Indeed, the channels selected in the atmospheric window are mainly located at the beginning of the first window band. The same is observed with the channels selected for the humidity sounding. More ozone channels are selected and distributed over the entire ozone-sensitive spectral band.

Finally, we compared the Jacobians in the channels of the two selections. We have represented on Figure 11, mean jacobians of CS275 for temperature (a), water vapour (b), ozone (c) and mean jacobians of NS275 for temperature (d), water vapour (e), ozone (f). The red, green, purple and blue lines represent the channels to temperature-sounding, window, ozone and humidity-sounding respectively. The visualization of the Jacobians of the newly selected channels confirms this assumption of channel homogeneity. Indeed, we observe that the temperature Jacobians (d) for the temperature-sounding channels (in red) are relatively evenly distributed especially in the stratosphere for the NS275. We

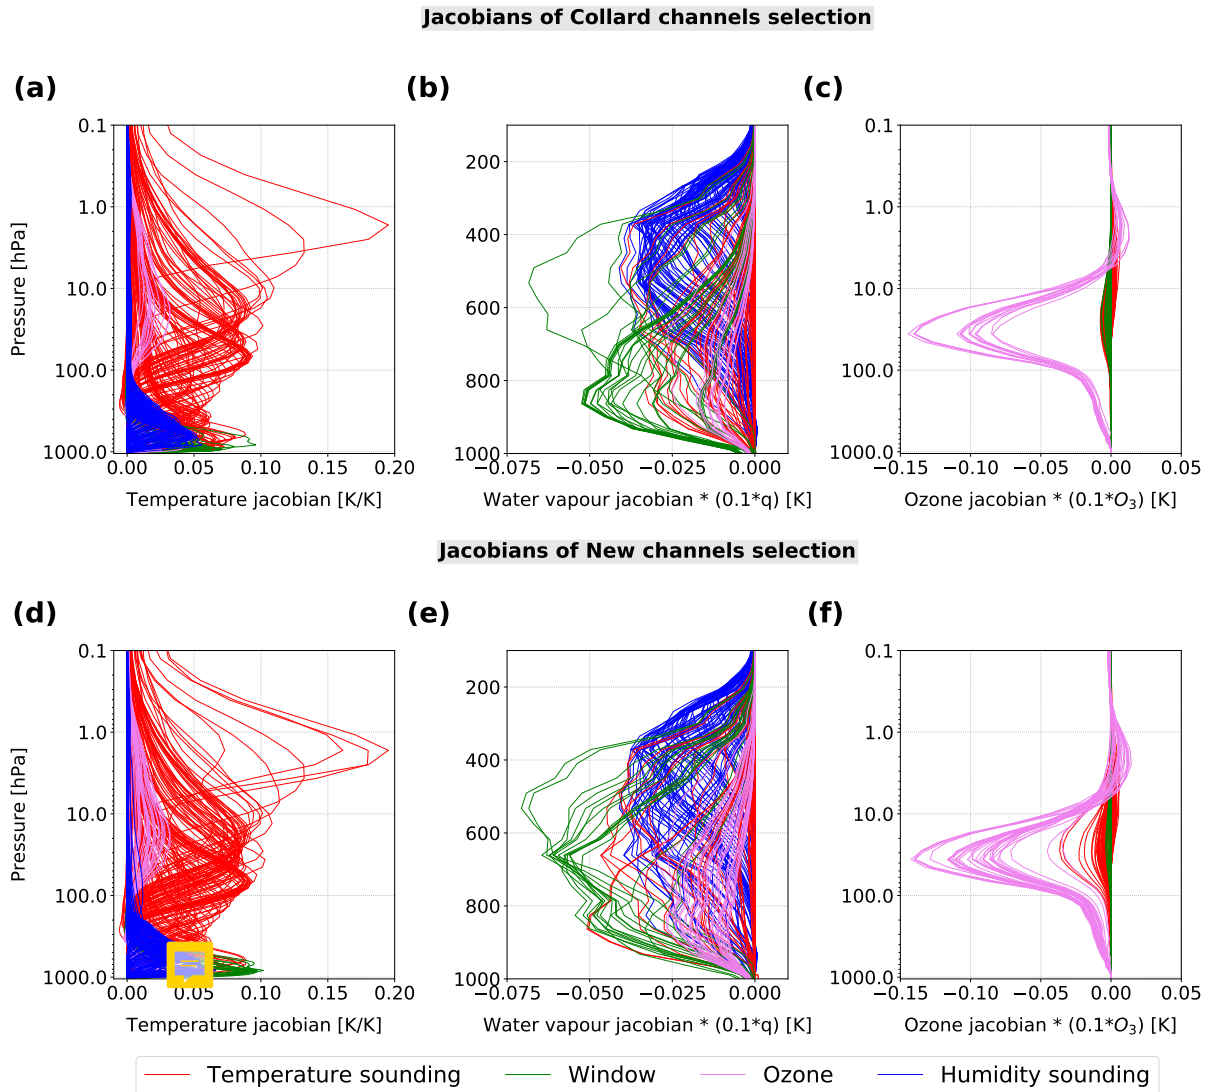

Figure 11. Comparison between mean jacobians of Collard channels selection (275) for temperature (a), water vapour (b), ozone (c) and mean jacobians of new channels selection (275) for temperature (d), water vapour (e), ozone (f). The red, green, purple and blue lines represent the channels sensitive to temperature-sounding, window, ozone and humidity-sounding respectively. Note that the water vapour jacobians (b) and (e) are only shown between 1000 and 100 hPa.

also notice that the temperature Jacobians of the channels selected in the atmospheric window (in green) are higher in the lower troposphere than in the upper troposphere (in red). The water vapour Jacobians (e) also show a more homogeneous distribution with the new channels selected mainly there also for the channels in the atmospheric window (in green). The water vapour Jacobians of the ozone (purple) and temperature-sounding channels (red) are also stronger than those of Collard. Finally, as before, the ozone Jacobians (f) have a more homogeneous distribution with the new selection and smaller Jacobian values carried by the temperature-sounding channels (in red). Globally, it is conceivable that this homogeneous distribution of the Jacobians is due to the precise taking into ac-

count of inter-channel observation-errors during the channel selection process. This allows the selection of the most informative channels to cover the full range of the atmosphere. Furthermore, we have seen earlier that 90 % of the maximum skin temperature DFS is obtained with only 3 channels. In addition, Jacobians of the Figure 3 shows that channels in first atmospheric window are also sensitive to temperature and water vapour in the lower troposphere. Uses these channels could be beneficial to provide additional information for NWP.

15
20

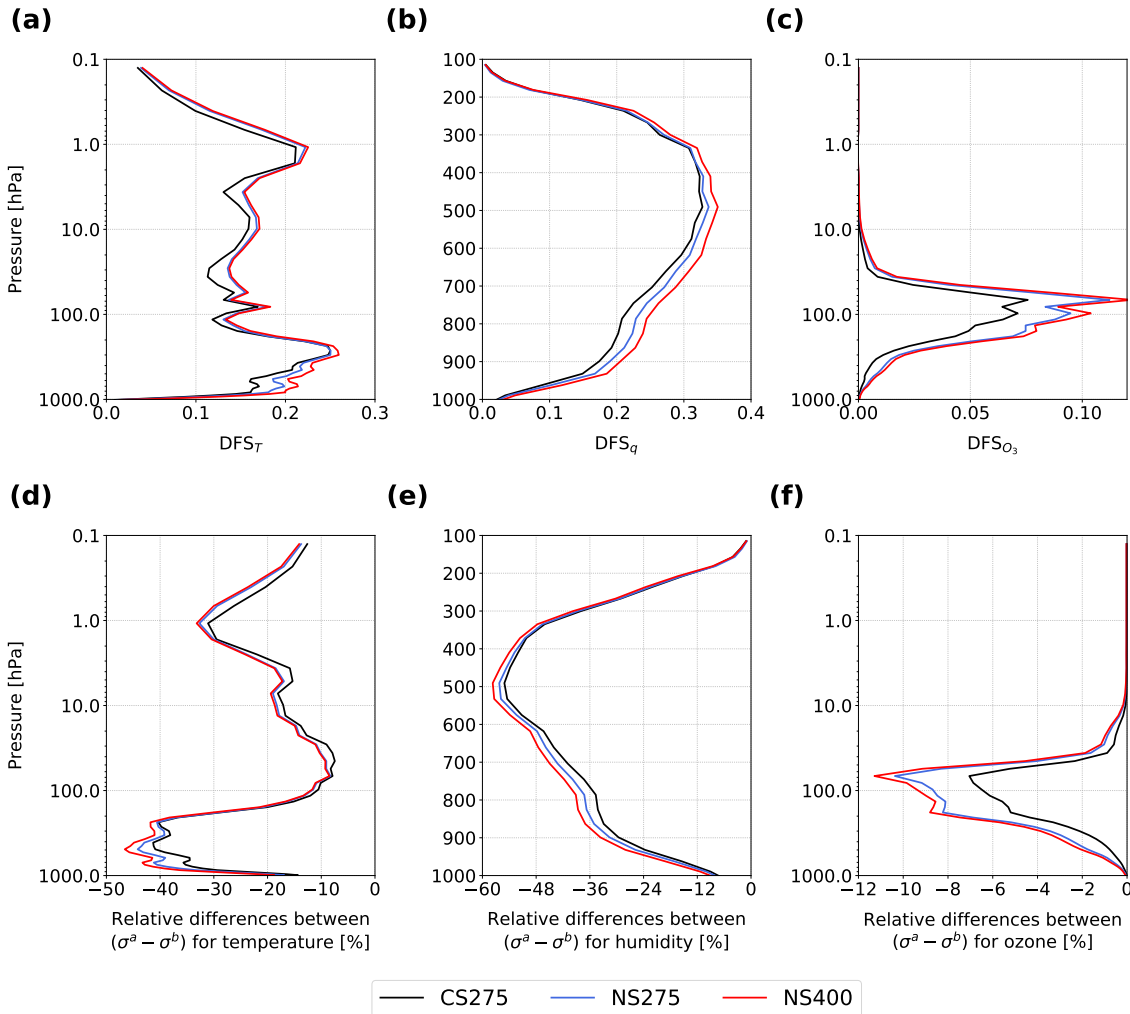

Figure 12. Vertical profiles of mean DFS for temperature (a), humidity (b) and ozone (c) with respect to pressure and vertical profiles of relative difference between analysis-error standard deviation (σ^a) and background-error standard deviation (σ^b) for temperature (d), humidity (e) and ozone (f) with respect to pressure. These results are derived from 1D-Var data assimilation experiments over the set of 6123 atmospheric profiles with Collard channels selection (275) in black line, New channels selection (275) in blue line and New channels selection (400) in red line. Note that the vertical profiles of DFS_q (b) and relative differences for humidity (e) are shown between 1000 and 100 hPa.

4.3 Evaluation

We evaluated CS275, NS275 and selection of 400 channels (named NS400) by assimilating them into the 1D-Var. We used the diagnosed observation error covariance matrices with the appropriate number of channels for each selection. Data assimilation experiments were performed on the 6123 profiles in order to closely approximate the variability of the operational NWP models. In a first step, the DFS mean values of the 6123 profiles for the 3 selections were calculated. The mean vertical profiles of the DFS for the 3 selections (Collard in black, the new selection with 275 channels in blue and with 400 channels in red) are shown in Figure 12 for temperature (a), humidity (b) and ozone (c) and

results of DFS values are summarized in Table 3. Compared to CS275 and the equivalent number of channels, the NS275 increases the information content since the DFS for temperature is increased by 0.62, for humidity by 0.23 and for ozone by 0.33. It is observed that for temperature, the new selections increase the information content mainly in the stratosphere between 100 and 1.0 hPa and in the lower troposphere between 1000 and 300 hPa. For humidity, the information content is increased mainly between 950 and 300 hPa, while for ozone the information content is increased especially at UTLS. It can be noted that the assimilation of NS400 allows to increase the information content to a greater extent than CS275 and to a lesser extent than the new selection with 275

channels, especially in the troposphere for temperature and humidity.

Mean DFS	CS275	NS275	NS400
Temperature	7.24	7.86	8.24
Humidity	5.32	5.55	5.86
Ozone	0.64	0.97	1.07
Skin temperature	0.99	0.99	0.99
Total	14.19	15.37	16.16

Table 3. Mean of degrees of freedom over 6123 profiles for temperature, humidity, ozone and skin temperature for the 3 channel selections.

Finally, we evaluated the impact of the different selections by comparing the analysis-error standard deviations (σ^a) to the background-error standard deviations (σ^b). Figure 12 shows the mean vertical profiles of the relative differences between σ^a and σ^b with respect to the pressure for CS275 in black (d), NS275 in blue (e) and NS400 in red (f). Interestingly, the profiles of DFS and the relative differences between σ^a and σ^b are consistent. In addition, NS400 improves everywhere on top of NS275 with additional contribution in the troposphere for temperature and humidity and at the UTLS for ozone.

As expected, the new channel selections further reduce the σ^a compared to the σ^b at the same atmospheric levels as previously identified where the information content has been increased. The mean results are summarized in Table 4. We will describe a more detailed description of the benefit of the new selections compared to the results with CS275:

- Compared to CS275, NS275 allows to reduce on average the temperature analysis-error by 3.0 % (3.9 % in troposphere and 1.8 % in stratosphere) with a maximum reduction up to 8.6 % at 700 hPa. Humidity analysis-error is reduced by an average of 1.8 % with a maximum reduction of 4.1 % at 745 hPa. Finally, the ozone analysis-error is reduced by an average of 0.9 % with a maximum reduction of 3.6 % at 70 hPa.
- Compared to CS275, NS400 allows to reduce the temperature analysis-error by an average of 4.8 % (6.8 % in troposphere and 2.2 % in stratosphere) with a maximum reduction up to 11.8 % at 700 hPa. The humidity analysis-error is reduced by an average of 3.9 % with a maximum reduction of 7.1 % at 750 hPa. Finally, the ozone analysis-error is reduced by an average of 1.2 % with a maximum reduction of 4.6 % at 70 hPa.

Mean of relative difference between σ^a and σ^b [%]	CS275	NS275	NS400
Temperature	- 27.64	- 30.19	- 31.56
Humidity	- 13.69	- 14.24	- 14.82
Ozone	- 0.08	- 0.12	- 0.13

5 Conclusions and perspectives

A new IASI channel selection method was presented in this paper. The objective was to select the most informative channels in the first two spectral bands of IASI between 645 and 2000 cm^{-1} (5499 channels) taking into account the inter-channel observation-errors. Indeed, the evolution of the computing capabilities of the weather centres allows them to begin to take into account these error covariances showing a significant benefit in the use of observations and improvements in weather analysis and forecasts. However, the estimation of these observation-error covariances for IASI is often applied to Collard's channel selection, which was performed using a diagonal \mathbf{R} matrix without the inter-channel correlations. Some recent studies have therefore considered the issue of a possible benefit of selecting again the most informative channels of IASI but this time accounting for these inter-channel error correlations. In these studies, the \mathbf{R} matrix was estimated using a "bottom-up" method which represents the \mathbf{R} matrix as a sum of random and spectrally correlated components.

The Desroziers et al. (2005) diagnostic is an efficient method to estimate the observation error covariances accurately. We used this method as a "top down" method that uses First-Guess and analysis departure statistics to diagnose variances and covariances of observation-error. It is this method we have chosen to use here to diagnose our \mathbf{R} matrix for the 5499 IASI channels considered. We used the 1D-Var data assimilation algorithm to perform assimilation experiments on 6123 atmospheric profiles (and IASI pixels) in order to have a statistically robust sample to diagnose the \mathbf{R} matrix and to approximate the possible variabilities that can be found in an operational setting. The diagnosed \mathbf{R} matrix provides consistent and satisfying results with other studies on the same subject.

Then, in order to take into account the variability the Jacobians in these channels may have according to atmospheric conditions, we calculated the means of the Jacobians in temperature, humidity, ozone and skin temperature subset of 60 profiles selected among the 6123 and representative

of the variability of the variables considered. We also constructed a background-error covariance matrix containing the errors of temperature, humidity, ozone and surface parameters. This matrix was computed using the NMC statistical method over 1 year, over the entire globe using the CTM MOCAGE model. The results are still satisfied with errors similar to those used in the weather centres.

A selection of channels using the maximum total DFS (temperature, humidity, ozone and skin temperature) as a figure of merit was made. We chose to stop the channel selection objectively, when the difference in DFS between the last selected channel and the previous one is less than 0.005. This threshold leads to a selection of up to 400 channels. A comparison with Collard's selection (275 channels in bands 1 and 2) showed that our selection of 275 channels has only 28 % of channels in common and that the newly selected channels are more homogeneously distributed over the IASI spectrum. We also noticed that the new selection uses channels in the atmospheric window that also have sensitivities to temperature and water vapour. The study of the Jacobians of the newly selected channels indeed shows that the channels are better distributed along the atmospheric column and that the channels selected in the atmospheric window have a capacity to provide additional temperature and humidity information. Finally, evaluation of the channel selections using the means of the vertical profiles of the DFS and the means of the vertical profiles of the relative differences between the analysis and background-error standard deviations shows that for an equivalent number of channels, NS275 reduces the analysis error by more than CS275, on average by 3 % in temperature, 1.8 % in humidity and 0.9 % in ozone. Considering the new channel selection, these error reductions can be as high as 4.8 % in temperature, 3.9 % in humidity and 1.2 % in ozone. In this study, we show that NS275 provides additional information on temperature and humidity especially in the troposphere. The use of inter-channel error correlations exploits the multi-informative potential of the available channels in the atmospheric window and ozone channels. Indeed, we have shown in a previous study that the ozone-sensitive IASI channels can also be exploited to provide additional information on temperature and humidity which is beneficial to the analysis during the data assimilation process.

These results can bring significant improvements in the use of IASI observations by data assimilation systems and be useful for weather forecasting. In the near future, CS275 and NS275 will be evaluated in the 4D-Var data assimilation of the ARPEGE NWP global model, and possibly the NS400 selection. The set of 400 selected channels is given in Appendix A.

Appendix A: List of the selection of the 400 new IASI channels

IASI channel No.	Wavenumber [cm ⁻¹]	Channel selection percentage [%]	Main sensitivity

Code availability. Codes of the Radiative Transfer Model RTTOV and the uni-dimensional data assimilation system 1D-Var used in this study are all available on <https://www.nwpsaf.eu/site/software/rttov/download/>.

Data availability. IASI data are available from EUMETSAT or AERIS: <https://www.aeris-data.fr/>. Model data are available upon request.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. This research has been conducted within the framework of O. Coopmann's PhD thesis, which funded by CNES (Centre National d'Études Spatiales) and the Région Occitanie. The authors would like to acknowledge Jean-François MAHFOUF for his help in revising and increasing the quality of the manuscript.
