Dr. Lars Hoffmann,  
Associate Editor,  
Atmospheric Measurement Techniques

Dear Dr. Hoffmann,

This cover letter is included with the submission of final manuscript for publication (amt-2019-282) entitled

“kCARTA : A fast pseudo line-by-line radiative transfer algorithm with analytic Jacobians, fluxes, Non-Local Thermodynamic Equilibrium and scattering for the infrared”

In writing the manuscript, as before we have adhered as strictly as possible to the AMT manuscript guidelines. This document includes

- Page 1 : this cover letter,
- Pages 2-27 : output from latexdiff between the November 19, 2019 manuscript and today's submission

I am also separately uploading the required files to AMT. Should you need to contact me, my email address is [sergio@umbc.edu](mailto:sergio@umbc.edu).

Sincerely,

A handwritten signature in black ink that reads "S. Souza Machado". The signature is written in a cursive, flowing style.

Sergio De Souza-Machado

# kCARTA : A fast pseudo line-by-line radiative transfer algorithm with analytic ~~Jacobians~~jacobians, fluxes, Non-Local Thermodynamic Equilibrium and scattering for the infrared

## Abstract.

A fast pseudo-monochromatic radiative transfer package using a Singular Value Decomposition (SVD) compressed atmospheric optical depth database has been developed, primarily for simulating radiances from hyperspectral sounding instruments (resolution  $\geq 0.1 \text{ cm}^{-1}$ ). The package has been tested extensively for clear sky radiative transfer cases, using field campaign data and satellite instrument data. The current database uses HITRAN 2016 line parameters and is primed for use in the spectral region spanning  $605 \text{ cm}^{-1}$  to  $2830 \text{ cm}^{-1}$ . Optical depths for other spectral regions ( $15\text{-}605 \text{ cm}^{-1}$  and  $2830\text{-}45000 \text{ cm}^{-1}$ ) can also be generated for use by kCARTA. The clear sky radiative transfer model computes the background thermal radiation quickly and accurately using a layer-varying diffusivity angle at each spectral point; it takes less than 30 seconds (on a 2.8 GHz core using 4 threads) to complete a radiance calculation spanning the infrared. The code can also compute Non Local Thermodynamic Equilibrium effects for the  $4 \mu\text{m}$   $\text{CO}_2$  region, as well as analytic temperature, gas and surface jacobians. The package also includes flux and heating rate calculations, and an interface to ~~a~~an infrared scattering model.

## 1 Introduction

Recent years have seen the launch and routine operation of new generation infrared sounders on board Earth orbiting satellites, for the purposes of providing measurements for data assimilation into Numerical Weather Prediction (NWP) centers and for monitoring atmospheric composition. These hyperspectral instruments have low noise channels with high resolution ( $\geq 0.5 \text{ cm}^{-1}$ ), and provide gigabytes of data daily, from about  $620 - 2800 \text{ cm}^{-1}$ . Examples include the Atmospheric InfraRed Sounder (AIRS)(Aumann et al., 2003) on board NASA's Aqua satellite, the Infrared Atmospheric Sounding Interferometer (IASI) on board the Metop satellites (Clerbaux et al., 2009) and the Cross Track Infrared Sounder (CrIS) on board the Suomi and JPSS-1 satellites (Han et al., 2013).

The radiances measured by these instruments are obtained under all-sky conditions (*i.e.* clear or cloudy). Publicly available thermodynamic profiles retrieved from this voluminous data are presently performed *after* cloud-clearing the radiances (Susskind et al., 1998). Monochromatic line-by-line (MNLBL) codes are too slow for use in the operational retrievals from

the cloud-cleared radiances. Instead, optical depths (or transmittances) produced by these MNLBL codes are parametrized for use in fast Radiative Transfer Algorithms (RTAs), at the instrument resolution. The accuracy of the retrieved products depends on the accuracy of the fast models, which underlines the importance of the accuracy of line parameters and lineshapes used in MNLBL codes, particularly the far-wing effects.

To satisfy the accuracy requirements of convolved optical depths and radiances used in developing and testing these fast models, the high altitude (doppler broadened) lines need to have monochromatic spectral resolutions of  $0.0025 \text{ cm}^{-1}$  or better over the almost  $2500 \text{ cm}^{-1}$  span of a typical infrared sounder. Using true MNLBL codes to produce optical depths for training the fast models is computationally intensive, as accurate lineshapes needed to be computed for millions of spectral points, each at about 100 layers spanning a 0-80 km atmosphere, for about 40-50 gases; this has to be done for 50 or more profiles. The acceleration of this part of the process, needed to develop a fast RTA for the AIRS sounder, was the motivating factor behind the development of the work presented here. For this we also developed a line-by-line code (referred to as UMBC-LBL) to produce an accurate pre-computed database of monochromatic atmospheric optical depths. Singular Value Decomposition (SVD) was then used to produce a highly compressed database (referred to as the kCompressed database (Strow et al., 1998)) that is highly accurate, relatively small, and easy to use. When coupled to an accurate radiative transfer code, this pseudo line-by-line package can be used as a starting point for developing tools for atmospheric retrievals (Rodgers, 2000). The key point to note is that though some optical depth information may be lost due to the compression and/or resolution of the database, *the convolved radiances* are very accurate.

To compute optical depths and radiances at any level for an arbitrary Earth atmospheric thermodynamic + gas profile, we paired together an uncompression algorithm for the kCompressed database with a one dimensional clear sky radiative transfer algorithm (RTA). The RTA works for both a downlooking and an uplooking instrument, with geometric ray tracing accounting for the spherical atmospheric layers. The generation of monochromatic transmittances from the compressed database is at least an order of magnitude faster than using a MNLBL code; for the long paths in the atmosphere the computed transmittances are smooth and well behaved, and can be used to develop fast forward models. Radiances computed using the compressed database are as accurate as those computed with a MNLBL code as our compression procedure introduces errors well below spectroscopy errors (Strow et al., 1998).

The entire package is called kCARTA, which stands for “kCompressed Atmospheric Radiative Transfer Algorithm”. Although kCARTA is much slower than fast forward models which use effective convolved transmittances, it is much more accurate, and can be used to generate optical depths and transmittances for developing the faster models. An example is the Stand Alone Radiative Transfer Algorithm (SARTA) (Strow et al., 2003) for which kCARTA is the Reference Forward Model; SARTA is used to retrieve Level 2 geophysical products from the AIRS (Strow et al., 2003) and CriS (Gambacorta, 2013) instruments. Other fast forward models for the infrared which parametrize the transmittances of the finite width instrument channels include a Principal Component based Radiative Transfer Model (PCRTM; (Liu et al., 2006)), Radiative Transfer for TIROS Operational Vertical Sounder (RTTOV; (Saunders et al., 1999)) and the Jülich Rapid Spectral Simulation Code (JURASSIC; (Hoffmann and Alexander, 2009)).

kCARTA also includes algorithms to rapidly compute analytic jacobians, and is available in a Fortran 90 (f90) package. This package (v1.21, April 2019) uses some of the newer Fortran features such as implicit loops, function overloading and modules, and includes code for computing fluxes, heating rates, and the effects of cloud and aerosol scattering using the Parametrization of Clouds for Longwave Scattering in Atmospheric Models (PCLSAM) (Chou et al., 1999) algorithm. While kCARTA was developed for use in the infrared region ( $605\text{-}2830\text{ cm}^{-1}$ ), it is trivial to extend the database out in either direction, to span the Far InfraRed to the Ultra-Violet. A clear-sky only radiance+jacobian Matlab version is also available.

The speed and accuracy, plus available run-time options of the code make it a very attractive alternative to other existing line by line codes. The literature is replete with papers and books describing spectroscopic calculations, monochromatic radiative transfer and flux calculations (see for example (Goody and Yung, 1989; Edwards, 1992; Clough et al., 1992; Clough and Iacono, 1995; Tjemkes et al., 2002; Buehler et al., 2011; Schreier et al., 2014; Dudhia, 2017; Vincent and Dudhia, 2017)) so here we chose to emphasize the features (and limitations) of kCARTA that would interest researchers working in these and related fields, and apply kCARTA to quantify how different spectroscopic databases impact simulated clear-sky Top of Atmosphere (TOA) brightness temperatures. Focusing on the infrared ( $605 - 2830\text{ cm}^{-1}$ ) region, this paper begins with a description of the line-by-line code and the kCompressed database, followed by a description of the clear sky radiative transfer algorithm, together with jacobians. The paper then discusses in detail some of the internal machinery of kCARTA, such as a background thermal computation developed for kCARTA, flux computations and scattering packages.

## 2 Overview of line-by-line code and kCompressed Database

### 2.1 UMBC-LBL

For an input set of [average temperature, pressure and gas amount (in molecules/cm<sup>2</sup>)] parameters, a custom monochromatic line-by-line code (UMBC-LBL) (De Souza-Machado et al., 2002) has been developed in order to accurately compute optical depths. This code defaults to the Van Vleck and Huber lineshape (Van Vleck and Huber, 1977; Clough et al., 1980) for almost all molecules, using spectroscopic line parameters from the HIGH-resolution TRANsmission (HITRAN) molecular absorption database.

For each spectral region the UMBC-LBL optical depth computations are divided into bins that are typically  $1\text{ cm}^{-1}$  wide in the infrared. The optical depth in each of these bins is accumulated in three stages as shown in Figure 1 : (1) fine mesh stage - absorption due to line centers within  $1\text{ cm}^{-1}$  of the bin edges is included at a very high resolution (typically  $0.0005\text{ cm}^{-1}$ ) and then five point boxcar integrated to the output (typically  $0.0025\text{ cm}^{-1}$ ) grid; in Figure 1 these are the red lines within the bin edges at  $\pm 0.5\text{ cm}^{-1}$  and the blue lines within  $1\text{ cm}^{-1}$  of the same bin edges (2) medium mesh stage - absorption from line centers within  $1\text{-}2\text{ cm}^{-1}$  of the bin edges is included at  $0.1\text{ cm}^{-1}$  resolution, shown in green in the figure and finally (3) coarse mesh stage - absorption from line centers within  $2\text{-}25\text{ cm}^{-1}$  of the bin edges, are included at  $0.5\text{ cm}^{-1}$  resolution (none shown in the figure); for (2) and (3) the results are interpolated to the output grid. The black line is the accumulated optical depth for that bin.

We note three points here. First, the default kCARTA uses  $0.0005 \text{ cm}^{-1}$  resolution between  $605\text{-}880 \text{ cm}^{-1}$  and  $0.0025 \text{ cm}^{-1}$  from  $805\text{-}2830 \text{ cm}^{-1}$  (after the 5 point boxcar). Section 7 demonstrates convolved radiances computed with these resolutions compare very well against other RTAs, especially after convolving with a typical hyperspectral sounder response function. Second, the above line-by-line computations are very similar to those in other models (Edwards, 1992; Dudhia, 2017), but we use the “medium” bins and “coarse” bins for the lines whose centers are within the intervals lying  $\pm [1,2]$  and  $\pm [2,25] \text{ cm}^{-1}$  respectively of the bin edges, instead of using only “coarse” bins. Thirdly we note that for most Earth atmosphere molecules, the line strength  $\times$  gas amount combination means the optical depth contribution due to line centers further than  $25 \text{ cm}^{-1}$  away from the bin is negligible and can be ignored (Dudhia, 2017); the exception for the Earth atmosphere are  $\text{H}_2\text{O}$  and  $\text{CO}_2$  which have countless strong lines further than  $25 \text{ cm}^{-1}$  away from bin edges. To speed up the optical depth calculations, the weak but non-negligible contribution from these “far lines” is added in using a continuum optical depth contribution which depends on temperature and gas absorber amount.

**Figure 1.** Line-by-line calculations from UMBC-LBL. The bin of interest is at  $(-0.5,+0.5) \text{ cm}^{-1}$ . Lineshapes whose line centers are within this bin (red) and within  $\pm 1 \text{ cm}^{-1}$  of the bin edge (blue) are computed using high spectral resolution; line centers that are further out (green) have the lineshapes computed at medium resolution and then interpolated to a higher resolution; line centers even further away (not shown) are computed at coarse resolution. The black curve is the sum over all the line contributions within that bin.

The above steps are followed for almost all molecules. Modifications to the above steps are needed for water vapor (which is separated into the traditional "basement" plus "continuum" contributions (Clough et al., 1980, 1989)) and  $\text{CO}_2$  in the  $4$  and  $15 \mu\text{m}$  region which needs line-mixing lineshapes (Strow and Pine, 1988; Tobin et al., 1996; Niro et al., 2005; Lamouroux et al., 2015). Other molecules have optical depths that are more easily modeled with the Van Huber lineshape, though recently the infrared absorption due to  $\text{CH}_4$  has been modeled using line mixing (Tran et al., 2006). The UMBC-LBL optical depth computation for water vapor should be robust at all frequencies, and allows the addition of water continuum models such as the recent MT-CKD 3.2 coefficients (Mlawer et al., 2012). Spectra from UMBC-LBL have been extensively compared against

optical depths computed by models such as Line-by-line Radiative Transfer Model (LBLRTM) (Clough et al., 1992, 2005) and the General line-by-line Atmospheric Transmittance and Radiance model (GENLN2) (Edwards, 1992).

## 2.2 kCompressed database

110 When applied toward any realistic Earth atmosphere simulation for an observing instrument, the UMBC-LBL calculations described above become impractically slow as they need to be performed for multiple gases in the atmosphere, over  $\sim 100$  atmospheric layers and encompassing a wide spectral range.

UMBC-LBL is therefore primarily used to generate an uncompressed database of look-up tables as described below. For each gas other than water vapor, the spectra are computed using the US Standard Atmosphere temperature profile, as well as five  
115 temperature offsets (in steps of 10K) on either side of the temperature profile, for a total of 11 temperatures. Tests using NWP profiles show this is usually sufficient everywhere except for a handful over the winter Antarctica, which could fall slightly outside the coldest offset (on average by about 3 K) between 600-1000 mb; kCARTA handles these extreme cold cases by extrapolating what has been compressed and zero checking the optical depths.

The default infrared database spans  $605\text{-}880\text{ cm}^{-1}$  and  $805\text{-}2830\text{ cm}^{-1}$ , broken up into 10000 point intervals that are 5  
120  $\text{cm}^{-1}$  and  $25\text{ cm}^{-1}$  wide respectively. Each file contains matrices to compute optical depths for these 10000 points at the set resolution. The one hundred average pressure layers used in making the database are from the AIRS Fast Forward Model. The layers span 1100 mb to 0.005 mb (about ground level to 85 km), and were chosen such that there is less than 0.1 K Brightness Temperature (BT) errors in the simulated AIRS radiances. The layers are about 200 m thick at the bottom of the atmosphere, gradually getting thicker with height (about 0.65 km at 10 km and 6 km at an altitude of 80 km).

125 These  $10000 \times 100 \times 11$  optical depths intervals are then compressed using Singular Value Decomposition (SVD) to produce the kCompressed Database. Each compressed file will have a matrix of basis vectors  $B$  (size  $10000 \times N$ ), and compressed optical depths  $D'$  (size  $N \times 100 \times 11$ ), where  $N$  is the number of significant singular vectors found. The prime denotes the compression worked more efficiently when the optical depths were scaled to the  $(1/4)$  power (Strow et al., 1998; Rodgers, 2000).

130 The self broadening of water is accounted for by generating monochromatic lookup tables for the reference water amount, multiplied by 0.1, 1.0, 3.3, 6.7 and 10.0 at the eleven temperature profiles specified above, meaning  $D'$  for water will have an extra dimension of length 5. Note that for the infrared we treat the HDO isotope (HITRAN isotope 4) as a separate gas from the rest of the water vapor isotopes.

The compressed optical depths  $D'$  vary smoothly in pressure, meaning the user is not limited to only using the 100 AIRS lay-  
135 ers. For an arbitrary pressure layering, the look-up tables are uncompressed using spline or linear interpolation in temperature and pressure, and scaled in gas absorber amount. Temperature interpolation of matrix  $D'$  for an AIRS 100 layer atmosphere therefore results in a matrix  $D''$  of size  $N \times 100$ , and the final optical depths (of size  $10000 \times 100$ ) are computed using  $(BD'')^4$ . Both the spline and linear interpolations allow easy computation of the analytic temperature derivatives, from which kCARTA can rapidly compute analytic jacobians (see Section 5). The cumulative optical depth for each layer in the atmosphere is ob-  
140 tained by a weighted sum of the individual gas optical depths, with accuracy limited by that of the compressed database (Strow

et al., 1998). The interested reader is referred to (Vincent and Dudhia, 2017) for a further discussion of other RTAs that use compressed databases.

The most recent kCompressed database uses line parameters from the HITRAN 2016 database (Rothman et al., 2013; Gordon et al., 2017), which together with the UMBC-LBL lineshape models, determine the accuracy of the spectral optical depths in this database. UMBC-LBL CO<sub>2</sub> line-mixing calculations use parameters that were derived a few years ago. Newer line-mixing models exist and we now use optical depths computed using LBLRTM v12.8 together with the line parameter database file based on HITRAN 2012 (aer\_v\_3.6), and (a) CO<sub>2</sub> line mixing by (Lamouroux et al., 2010, 2015)) and (b) CH<sub>4</sub> line mixing by (Tran et al., 2006).

In addition complete kCompressed databases for the IR using optical depths only from HITRAN 2012, LBLRTM v12.4 code and from GEISA 2015 (Husson et al., 2015) have been generated for comparison purposes. At compile time we usually point kCARTA to the HITRAN 2016 kCompressed database made by UMBC-LBL, but at run time we have switches that easily allow us to swap in for example the CO<sub>2</sub> and CH<sub>4</sub> tables generated from LBLRTM.

The original lookup tables for the thermal infrared occupy hundreds of gigabytes, while the compressed monochromatic absorption coefficients are a much more manageable 824 megabytes (218 megabytes (water+HDO) + 76 megabytes (CO<sub>2</sub>) + 530 megabytes (about 40 other molecular and 30 cross section gases)). A general overview of some of the factors involved in compressing look-up tables for use in speeding up line-by-line codes is found in (Vincent and Dudhia, 2017), while more details about the detailed testing and generation of the kCARTA SVD compressed database are found in (Strow et al., 1998). Appendix B discusses the extension of the database to span 15 cm<sup>-1</sup> to 44000 cm<sup>-1</sup>, though we note that kCARTA lacks built-in accurate scattering calculations in the shorter wavelengths. In order to resolve the narrow doppler lines at the top-of-atmosphere, the resolution  $\delta\nu$  of the spectral bands in Appendix B is adjusted according to  $\delta\nu \sim \nu_0 \sqrt{(k_b T/m)/c}$ , where  $\nu_0$  is the band center, and  $T, m$  are the temperature and mass of the molecule respectively, while  $k_b$  and  $c$  are Boltzmann's constant and speed of light.

The default kCARTA mode is to use the first 42 molecular gases in the HITRAN database, together with about 30 cross-section gases, for which we have reference profiles. If the user does not provide the profiles for any of these gases, kCARTA uses the US Standard profile for that gas. The user can also choose to only use a selected number of specified gases. While running kCARTA, the user can then define different sets of mixed paths, where some of the gases are either turned off or the entire profile is multiplied by a constant number, which is very useful when for example we want to include only certain gases when we parametrize optical depths for SARTA.

### 3 kCARTA Clear sky radiative transfer algorithm

As a stream of radiation propagates through a layer, the change in diffuse beam intensity  $R(\nu)$  in a plane parallel medium is given by the standard ~~Schwarschild~~-Schwartzschild equation (Liou, 1980; Goody and Yung, 1989; Edwards, 1992)

$$\mu \frac{dR(\nu)}{dk_e} = -R(\nu) + J(\nu) \quad (1)$$

where  $\mu$  is the cosine of the viewing angle,  $k_e$  is the extinction optical depth,  $\nu$  is the wavenumber and  $J(\nu)$  is the source function. For a non-scattering “clear sky”, the source function is usually the Planck emission  $B(\nu, T)$  at the layer temperature  $T$ , leading to an equation that can easily be solved for an individual layer. The general solution for a downlooking instrument measuring radiation propagating up through a clear-sky atmosphere can be written in terms of four components :

$$R(\nu) = R_s(\nu) + R_{\text{lay}}(\nu) + R_{\text{th}}(\nu) + R_{\text{solar}}(\nu) \quad (2)$$

which are the surface, layer emissions, downward thermal and solar terms respectively. In terms of integrals the expressions can be written as (see e.g. (Liou, 1980; Dudhia, 2017))

$$\begin{aligned}
 180 \quad R(\nu, \theta) = & \epsilon_s(\nu)B(\nu, T_s)\tau_{atm}(\nu, \theta) + \int_{\text{surface}}^{TOA} B(\nu, T(z)) \frac{\partial \tau(\nu, \theta)}{\partial s} ds + \\
 & \frac{1 - \epsilon_s(\nu)}{\pi} \tau_{atm}(\nu) \int d\Omega^+ \int_{TOA}^{\text{surface}} B(\nu, T(s)) \frac{\partial \tau(\Omega)}{\partial s} \cos(\theta) ds + \\
 & \rho_s(\nu)B_{\odot}(\nu)\cos(\theta_{\odot})\tau_{atm}(\nu, \theta_{\odot})\tau_{atm}(\nu, \theta) \quad (3)
 \end{aligned}$$

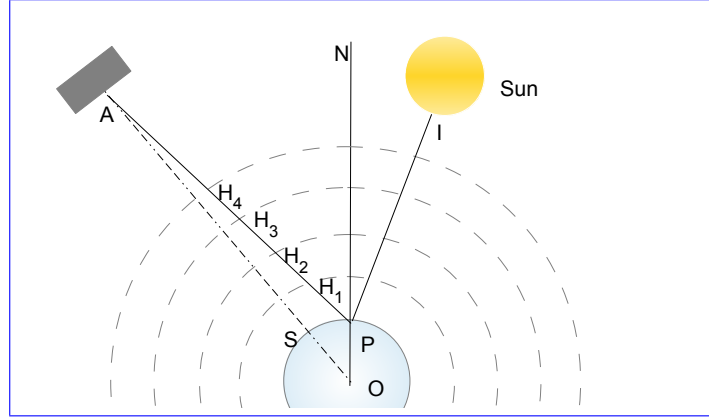

where  $B(\nu, T)$  is the Planck radiance at temperature  $T$ ,  $T_s$  is the skin surface temperature,  $\epsilon_s, \rho_s$  are the surface emissivity and reflectivity;  $B_{\odot}(\nu)$  is the solar radiance at TOA,  $\theta_{\odot}$  is the solar zenith angle;  $\theta$  is the satellite viewing angle,  $\tau(\nu, \theta)$  is the transmission at angle  $\theta$  while  $\tau_{atm}$  is the total atmospheric transmission. The  $d\Omega^+$  in the middle term indicates integration over the upper hemisphere.

In what follows we discretize Eqn. 2 so that layer  $i = 1$  is the bottom and  $i = N$  ( $=100$ ) the uppermost, schematically shown in Figure 2 for a clear sky four layer atmosphere, with  $O$  being the center of the Earth.  $A$  is the satellite while  $S$  is the satellite sub-point directly below it. Point  $P$  is the ground scene being observed by the satellite (slightly away from nadir), and  $N$  is the local normal at  $P$ .  $\angle SAP$  is the satellite scan angle while  $\angle APN$  is the satellite zenith angle  $\theta$ ;  $\angle NPI$  is the solar zenith angle  $\theta_{\odot}$ . Note that as the radiation propagates through the pressure layers from  $P$  to  $H_1$  to  $H_2$  to  $H_3$  to  $H_4$  to  $A$ , the local angle (between the radiation ray and the local normal at any of the concentric circles) keeps changing due to the spherical geometry of the layers (refraction effects can also be included).

The default mode of kCARTA (f90 [version](#)) assumes linear variation of layer temperature with optical depth, uses a background thermal diffusive angle that varies with the layer-to-ground optical depth (instead of a constant value typically assumed to be  $\cos^{-1}(3/5)$ ) and does ray-tracing to account for the spherical atmospheric layers (but with no density effects). The f90 version of kCARTA also allows the user to choose constant layer temperature, and to choose alternate ways of computing the background term, which will be discussed in Section 6.

Here we describe radiative transfer for the constant layer temperature case; see Section 6.2 for a short discussion when using the linear-in-tau option. For an arbitrary layer  $i$  with (nadir) optical depth  $k_i(\nu)$ , the transmittance of a beam passing from the

**Figure 2.** Viewing geometry for the sounders modeled by kCARTA.  $A$  is the satellite and point  $P$  is being observed by the satellite, while  $I$  is the sun

bottom to the top of the layer at angle  $\theta$  is given by  $\tau_i(\nu, \theta) = e^{-k_i(\nu)/\cos(\theta)}$ . The transmittance from the top of layer  $i$  to space is then the product of the individual transmittances of the layers above  $i$

$$\tau_{i+1 \rightarrow TOA}(\nu, \theta) = \prod_{j=i+1}^N \tau_j(\nu, \theta) \quad (4)$$

with the special case of transmission from ground to space ( $i = 0$ ) involving all  $N$  layers.

205 The individual contributions to the upwelling radiance are then computed as follows.

### 3.1 Surface emission

The kCARTA surface emission is given by

$$R_s(\nu) = \epsilon_s(\nu) B(\nu, T_s) \tau_{GND \rightarrow TOA}(\nu, \theta) \quad (5)$$

where  $\epsilon_s(\nu)$  is the user supplied emissivity.

### 210 3.2 Layer emission

The atmospheric absorption and re-emission is modeled as :

$$R_{lay} = \sum_{i=1}^{i=N} B(\nu, T_i) (1.0 - \tau_i(\nu)) \tau_{i+1 \rightarrow TOA}(\nu, \theta) \quad (6)$$

Layers with negligible absorption ( $\tau_i \rightarrow 1$ ) contribute negligibly to the overall radiance, while those with large optical depths ( $\tau_i \rightarrow 0$ ) “black” out radiation from below.  $(1.0 - \tau_i(\nu))$  is the emissivity of the layer while  $(1.0 - \tau_i(\nu)) \tau_{i+1 \rightarrow TOA}(\nu, \theta)$  is the weighting function  $W_i$  of the layer.

215

### 3.3 Background thermal radiation

The atmosphere also emits radiation downward, *at all angles*, in a manner analogous to the upward layer emission just discussed. The total background thermal radiance at the surface is an integral over all (zenith and azimuth) radiance streams propagating from the top-of-atmosphere (set to 2.7 K) to surface. This is time consuming to compute using quadrature, and  
 220 one approximation is to use a single effective (or diffusivity) angle of  $\theta_{diff} = \cos^{-1}(3/5)$  at all layers and wavenumbers :

$$R_{th}^{surface}(\nu) = \pi\rho_s \sum_{i=N}^{i=1} B(T_i) [\tau_{i-1 \rightarrow ground}(\nu, \theta_{diff}) - \tau_{i \rightarrow ground}(\nu, \theta_{diff})] \quad (7)$$

The summation is from top-of-atmosphere to ground, and  $\rho_s$  is the surface reflectivity discussed above. Current sounders have channel radiance accuracy better than 0.2K, so while the above term is much smaller than the surface or upwelling atmospheric emission contributions, it has to be computed accurately. Section 6 includes a detailed discussion of how kCARTA  
 225 improves the accuracy of this background term by using a look-up table to rapidly compute a spectrally and layer varying diffusive angle.

### 3.4 Solar radiation

Letting the surface reflectivity be denoted by  $\rho_s(\nu, \theta, \phi)$ , then the solar contribution to the TOA radiance is given by

$$R_{\odot}(\nu) = \rho_s(\nu, \theta, \phi) B_{\odot}(\nu) \cos(\theta_{\odot}) \times \tau_{N \rightarrow ground}(\nu, \theta_{\odot}) \tau_{ground \rightarrow TOA}(\nu, \theta) \Omega_{\odot} \quad (8)$$

230 where  $B_{\odot}(\nu)$  is the solar radiation at the top of atmosphere and accounts for the solar disk. Over ocean, if the wind speed and solar and satellite azimuth angles are known, the reflectivity can be pre-computed using the Bi-directional Reflectance Distribution Function (BRDF) and input to kCARTA; see for example Appendix C in (Nalli et al., 2016). It is not easy to compute the BRDF over land, and the reflectivity could be simply modeled as  $\rho_s(\nu) = \frac{1-\epsilon_s(\nu)}{\pi}$ .

235  $\Omega_{\odot} = \pi(r_s/d_{se})^2$  is the solid angle subtended at the earth by the sun, where  $r_s$  is the radius of the sun and  $d_{se}$  is the earth-sun distance. The solar radiation incident at the TOA  $B_{\odot}(\nu)$  comes from data files related to the ATMOS mission (Farmer et al., 1987; Farmer and Norton, 1989), and is modulated by the angle the sun makes with the vertical,  $\cos(\theta_{\odot})$  (day-of-year effects are not included in the earth-sun distance).

## 4 Non Local Thermodynamic Equilibrium computations

During the daytime, incident solar radiation is preferentially absorbed by some CO<sub>2</sub> and O<sub>3</sub> infrared bands, whose kinetic  
 240 temperature then differs from the rest of the bands or molecules. This leads to enhanced emission by the lines in these bands.

Limb sounders detect NLTE effects in the 15  $\mu m$  CO<sub>2</sub> bands (and in other molecular bands for example O<sub>3</sub>) due to the extremely long paths involved, but these are not modeled in the package as kCARTA is designed for nadir sounders.

For a nadir sounder, the most important effects are seen in the CO<sub>2</sub> 4 μm (ν<sub>3</sub>) band. kCARTA includes a computationally intensive line-by-line Non Local Thermodynamic Equilibrium (NLTE) model to calculate the effects for this CO<sub>2</sub> band. The model requires the kinetic temperature profile and NLTE vibrational temperatures of the strong bands in this region, to compute the optical depths and Planck modifiers for the strong NLTE bands and the weaker LTE bands (Edwards et al., 1993, 1998; Lopez-Puertas and Taylor, 2001; Zorn et al., 2002), which are then used to compute a monochromatic top-of-atmosphere nadir radiance.

AIRS provided the first high resolution nadir data of NLTE in the 4 micron CO<sub>2</sub> band. Using the kCARTA NLTE line-by-line model, a Fast NLTE Model (De Souza-Machado et al., 2007) for sounders has already been developed, which is used in the NASA AIRS L2 operational product.

## 5 Clear Sky **Jacobian** algorithm

Retrievals of atmospheric profiles (temperature, humidity and trace gases) minimize the differences between observations and calculations, by adjusting the profiles using the linear derivatives (or jacobians) of the radiance with respect to the atmospheric parameters. This section describes the computation of analytic jacobians by kCARTA. Note that kCARTA currently computes jacobians and weighting functions using a constant layer temperature assumption. For a downward looking instrument, for simplicity consider only the upwelling terms in the radiance equation (atmospheric layer emission and the surface terms). Assuming a nadir satellite viewing angle, the solution to Equation 1 is :

$$R(\nu) = \epsilon_s B(T_s, \nu) \tau_{1 \rightarrow TOA}(\nu) + \sum_{i=1}^{i=N} B(T_i, \nu) (1.0 - \tau_i(\nu)) \tau_{i+1 \rightarrow TOA}(\nu) \quad (9)$$

Differentiation with respect to the  $m$ -layer variable  $s_m$ , (gas amount or layer temperature  $s_m = q_{m(g)}, T_m$ ) yields

$$\frac{\partial R(\nu)}{\partial s_m} = \epsilon_s B(T_s) \frac{\partial \tau_{1 \rightarrow TOA}(\nu)}{\partial s_m} + \sum_{i=1}^N B(T_i, \nu) (1.0 - \tau_i(\nu)) \frac{\partial \tau_{i+1}(\nu)}{\partial s_m} + \sum_{i=1}^N \tau_{i+1 \rightarrow TOA}(\nu) \frac{\partial}{\partial s_m} [B(T_i, \nu) (1.0 - \tau_i(\nu))] \quad (10)$$

where as usual,  $\tau_m(\nu) = e^{-k_m(\nu)}$ ,  $\tau_{m \rightarrow TOA}(\nu) = \prod_{j=m}^N e^{-k_j(\nu)}$ . The differentiation yields

$$\begin{aligned} \frac{\partial R(\nu)}{\partial s_m} &= [\epsilon_s B(T_s) \tau_{1 \rightarrow TOA}] (-1) \frac{\partial k_m(\nu)}{\partial s_m} + \\ &\quad \left[ \sum_{i=1}^{m-1} (1.0 - \tau_i(\nu)) B_i(\nu) \tau(\nu)_{i+1 \rightarrow TOA} \right] (-1) \frac{\partial k_m(\nu)}{\partial s_m} + \\ &\quad \left[ (1.0 - \tau_m(\nu)) \frac{\partial B_m(\nu)}{\partial s_m} - B(T_m, \nu) \frac{\partial \tau_m(\nu)}{\partial s_m} \right] \tau_{m+1 \rightarrow TOA}(\nu) \end{aligned} \quad (11)$$

The individual jacobian terms  $\frac{\partial k_m}{\partial s_{m(g)}}$  are rapidly computed by kCARTA, as follows. The gas amount derivative is simply  $\frac{\partial k_m}{\partial q_{m(g)}} = \frac{k_m}{q_{m(g)}}$  (with added complexity for water, to account for self broadening), and the temperature derivative  $\frac{\partial k_m}{\partial T}$  is cumulatively obtained while kCARTA is performing the temperature interpolations during the individual gas database uncompression.

270 The solar and background thermal contributions are also included in the jacobian calculations. The thermal background jacobians are computed at  $\cos^{-1}(3/5)$  at *all* levels, for speed. This would lead to slight differences when comparing the jacobians computed as above to those obtained using finite differences. kCARTA also computes the weighting functions, and jacobians with respect to the surface temperature and surface emissivity.

## 6 Background thermal and temperature variation in a layer

275 In this section we take a closer look at the computation of downwelling background thermal radiation, and layer temperature variation.

### 6.1 Background thermal radiation

The contribution of downwelling background thermal to top-of-atmosphere upwelling radiances is negligible in regions that are blacked out as the instrument cannot see surface leaving emission. Similarly in layers/spectral regions where there is very little  
 280 absorption and re-emission, the contribution is negligible as the effective layer emissivity (denoted by  $\Delta\tau_i(\nu)$  below) goes to zero. The background contribution thus needs to be done most accurately in the window regions (low but finite optical depths); depending on the surface emissivity (and hence reflectivity) in the window regions, in terms of BT this term contributes as much as 4 K of the total radiance when reflected back up to the top of the atmosphere.

The contribution at the surface by a downwelling radiance stream propagating at angle  $(\theta, \phi)$  through layer  $i$  is given by

$$285 \quad \begin{aligned} \Delta R_i(\nu, \theta, \phi) &= B(\nu, T_i)(1.0 - \tau_i(\nu, \theta, \phi))\tau_{i-1 \rightarrow \text{ground}}(\nu, \theta, \phi) \\ &= B(\nu, T_i)(\tau_{i-1 \rightarrow \text{ground}}(\nu, \theta, \phi) - \tau_{i \rightarrow \text{ground}}(\nu, \theta, \phi)) \end{aligned} \quad (12)$$

where  $\theta$  is the zenith and  $\phi$  is the azimuth angle, and  $\tau_{i \rightarrow \text{ground}}$  are the layer-to-ground transmittances, derived from layer-to-ground optical depths  $x$ . This equation can be rewritten as

$$\Delta R_i(\nu, \theta, \phi) = B(\nu, T_i) \times \Delta\tau_i(\nu, \theta, \phi) \quad (13)$$

290 An integral over  $(\theta, \phi)$  would give the contribution from the layer. The total downwelling spectral radiance at the surface would be a sum over all  $i$  layers (and the downwelling flux at the surface would be the integral over all wavenumbers).

The integral over the azimuth is straightforward (assuming isotropic radiation), but the integral over the zenith is more complex. Since the reflected background term is much smaller than the surface or atmospheric terms, a single stream at the effective angle  $\theta_{diff} = \cos^{-1}(3/5)$  (Liou, 1980) is often used as an approximation, at all layers and wavenumbers.

295 We have refined the computation as follows. Recall that  $\Delta R(\nu)$  in Equation 13 depends on the layer-to-ground optical depth  $x$ . Letting  $\mu = \cos\theta$  the integral over the zenith ( $\int_0^1 e^{-x/\mu} \mu d\mu = E_3(x)$ ), more commonly known as the exponential Integral of

the third kind). The area under the  $E_3(x)$  curve would be the total flux coming from all optical depths ( $0 \leq x \leq \infty$ ); over 77% of this area comes from the range  $0 \leq x \leq 1$ .

Applying the Mean Value Theorem for Integrals (MVTI) to  $E_3(x)$ , we can write Eq. 13 in terms of two effective diffusive angles  $\theta_d^i, \theta_d^{i-1}$  at each layer  $i$  :

$$\Delta\tau(i, i-1) = \tau(i-1 \rightarrow \text{ground}, \theta_d^{i-1}, \nu) - \tau(i \rightarrow \text{ground}, \theta_d^i, \nu)$$

$$R_{th}^{surface}(\nu) = 2\pi\rho_s \sum_{i=N}^{i=1} B(\nu, T_i) \Delta\tau(i, i-1) \quad (14)$$

with the effective angles varying as a function of the layer to ground space optical depth of that layer, and the layer immediately below it. Numerical solutions to the MVTI show that when  $x \rightarrow 0$  then  $\mu_d \rightarrow 0.5$  (or  $\theta_d \rightarrow 60^\circ$ ). Similarly as  $x \rightarrow \infty$  then  $\theta_d \rightarrow 0^\circ$ , but this optically thick atmosphere means an instrument observing from the TOA cannot see the surface, so we use a lower limit (of  $30^\circ$ ) for the diffusive angle. Finally when  $x = 1.00$  we find the special case  $\mu_d = 0.59274 \simeq (3/5)$ . For “optically thin” regions, the layers closest to the ground contribute most to  $R_{th}(\nu)$ .

With today’s high speed computers, kCARTA uses an effective diffusive angle  $\theta_d$  tabulated as a function of layer to ground optical depth  $x$ , as follows. For each  $25 \text{ cm}^{-1}$  interval spanning the infrared the layer  $L$  above which  $\cos^{-1}(3/5)$  can be safely used was determined; below this layer, the lookup table is used. The table has higher resolution for  $x \leq 0.1$  and becomes more coarse as  $x$  increases, with the effective diffusive angle cutoff at  $30^\circ$  when the optical depths are larger than about 15.

We have tested this method of computing the background thermal against both 20 point Gauss-Legendre quadrature and the 3 point exponential Gauss-quadrature (used by LBLRTM flux computations), and found the method to very accurate and fast, both in terms of the downwelling flux at the surface, and also the final TOA computed radiance, even when the emissivity is as low as 0.8 (which means a significant contribution from the reflected thermal). At this low emissivity value, the constant  $\cos^{-1}(3/5)$  diffusivity angle model produces final TOA BT which differ from the Gauss-Legendre model by as much as 1.3 K (for the tropical profile) at for example  $900 \text{ cm}^{-1}$ , while the exponential quadrature and our model have errors smaller than 0.005 K.

## 6.2 Variation of layer temperature with optical depth

LBLRTM (Clough et al., 1992, 2005) has been extensively tested and shown to be very accurate, in its computation of optical depths, radiances and fluxes. In the computation of radiances, both kCARTA and LBLRTM codes use a “linear in  $\tau$ ” layer temperature variation; the former uses a higher order expansion (accurate to  $O(\tau^5)$  for small  $\tau$ ), and also has an option to use “constant” layer temperature. Here we summarize the relevant equations. For an individual layer, with lower and upper boundary temperatures  $T_L, T_U$ , the “linear in  $\tau$ ” approximation leads to the following expression for the radiance at the top of the layer (re-written from Equation 13 in (Clough et al., 1992))

$$I(\nu) = I_0(\nu)T + (1-T) \left\{ B_{av}(\nu) + (B_u(\nu) - B_{av}(\nu)) \left( 1 - 2 \left( \frac{1}{\tau} - \frac{T}{1-T} \right) \right) \right\} \quad (15)$$

where the optical depth  $\tau$  includes the view angle  $\tau = \tau_{layer}/\cos(\theta)$  and transmission  $T = \exp(-\tau)$ .  $I_0(\nu)$  is the radiation incident at the bottom of the layer,  $B_{av}(\nu)$  is the Planck radiance corresponding to the average layer temperature, while  $B_u(\nu)$  is the Planck radiance corresponding to the upper boundary. For large  $\tau$ ,  $T \rightarrow 0$  and  $I(\nu) \rightarrow B_u(\nu)$ . For small  $\tau \rightarrow 0$  the expression can be further expanded as follows

$$I(\nu) = I_0(\nu)T + (1 - T) \left\{ B_{av}(\nu) + (B_u(\nu) - B_{av}(\nu)) \left( \frac{\tau}{6} - \frac{\tau^3}{360} + \frac{\tau^5}{15120} \right) \right\} \quad (16)$$

Comparing to the top of layer radiance in the "constant in  $\tau$ " model,

$$I(\nu) = I_0(\nu)T + (1 - T)B_{av}(\nu) \quad (17)$$

one sees the expressions are identical if there is no temperature variation i.e. ( $B_u(\nu) = B_{av}(\nu)$ ). The default kCARTA model layers are approximately 0.25 km thick (or a temperature spread of about 1.5 K for a 6K/km lapse rate) at the bottom of the atmosphere, and about 2 km thick in the stratosphere (a temperature difference of 10 K). The gaseous absorption in these upper layers is typically negligible, except deep inside the strongly absorbing 15  $\mu m$  and 4  $\mu m$  CO<sub>2</sub> bands, which is where one would expect the largest differences between a linear-in-tau versus a constant-in-tau temperature model.

## 7 RTA inter-comparisons : kCARTA versus LBLRTM

In this section we describe brightness temperature differences ( $\Delta BT$ ) between kCARTA and LBLRTM. As kCARTA is designed to be accurate for typical hyperspectral sounders, we show that after convolution the kCARTA spectral radiances compare very well against similarly convolved LBLRTM radiances; for completeness we also discuss how the monochromatic ( $\Delta BT$ ) change as a function of resolution in the 10-15  $\mu m$  O<sub>3</sub> and temperature sounding regions.

For these runs we use our 49 regression profiles, with emissivity = 1 and reflectivity = 0 to exclude differences due to reflected thermal contributions. To exercise the kCARTA ray tracing, we use a ground satellite zenith angle of 24.5° which becomes a TOA satellite scan angle of 22° (typical average sounder scan angle). The tests are run at various kCARTA database resolutions. Note that when results are stated for a particular resolution, this means the kCARTA database (after 5 point boxcar integration) was at this resolution; similarly the internal LBLRTM radiances were output at a resolution such that we can apply the same 5 point boxcar for the radiance comparisons.

The comparisons are divided into two sets. For the first set of comparisons, we use an atmosphere consisting only of H<sub>2</sub>O, CO<sub>2</sub>, O<sub>3</sub>, with the optical depths generated using LBLRTM v12.8. This is done to assess the linear-in-tau radiative transfer while limiting differences due to spectroscopy, especially in the high altitude 15  $\mu m$  CO<sub>2</sub> and 10  $\mu m$  O<sub>3</sub> sounding regions. For these tests, three resolutions spanning 605-1205 cm<sup>-1</sup> were used : 0.0025 cm<sup>-1</sup>, 0.0005 cm<sup>-1</sup> and 0.0002 cm<sup>-1</sup>.

At low resolution (0.0025 cm<sup>-1</sup>), the mean differences right on top of the high altitude temperature sounding lines in the 630-700 cm<sup>-1</sup> region are large ( $\geq 10$  K). However, these differences drop significantly as we increase the resolution, to within

**Figure 3.** The top/bottom panels show the monochromatic BT differences (LBLRTM- kCARTA), with statistics obtained over 49 regression profiles, with the emissivity set to 1.0 and a  $22^\circ$  satellite scan angle. Both sets of panels shows the differences at  $0.0005 \text{ cm}^{-1}$  resolution when only  $\text{H}_2\text{O}$ ,  $\text{CO}_2$  and  $\text{O}_3$  optical depths from LBLRTM v12.8 are used. The largest differences are at the peaks of the high altitude  $15 \mu\text{m}$   $\text{CO}_2$  lines, and decrease as the resolution is increased. The right hand panels are a zoom in of the left hand panels, for a typical  $15 \mu\text{m}$  region.

$4 \text{ K} \pm 1.2 \text{ K}$  at  $0.0005 \text{ cm}^{-1}$  (default kCARTA resolution) and  $1 \text{ K} \pm 0.4 \text{ K}$  at  $0.0002 \text{ cm}^{-1}$ . The default kCARTA  $0.0005 \text{ cm}^{-1}$  resolution results are shown in the left hand panels (a),(b) of Figure 3. The top panel is the mean while the bottom panel is the standard deviation. Note that in the  $10 \mu\text{m}$   $\text{O}_3$  sounding region (where the doppler broadened width of the high altitude lines would be wider than in the  $15 \mu\text{m}$  region), the differences are consistently much smaller :  $-0.3 \pm 0.1 \text{ K}$  at  $0.0005 \text{ cm}^{-1}$  resolution, dropping to  $-0.1 \pm 0.05 \text{ K}$  at  $0.0002 \text{ cm}^{-1}$  resolution.

The right hand (c),(d) panels of Figure 3 are a zoom-in of a typical unit wavenumber interval deep in the  $15 \mu\text{m}$  region, and shows the differences are zeros away from lines and largest around the peaks of the high sounding lines, each encompassing a very narrow spectral range of less than  $\sim 0.005 \text{ cm}^{-1}$ . These would be expected to contribute minimally to the convolutions using typical sounder spectral response functions, as will be shown below.

Taken together these mean that the kCARTA RTA is working as expected : in the very long wavelength  $15 \mu\text{m}$   $\text{CO}_2$  region the differences reduce as we increase the spectral resolution while at  $10 \mu\text{m}$  the differences remain quite small. We conjecture the remaining differences between kCARTA and LBLRTM are due to (a) algorithms : we use Equation 16 to fifth order while LBLRTM may use a Padé approximation and/or Equation 16 to first order; (b) there may be some very slight broadening effects right on top of the high altitude  $\text{CO}_2$  lines that we have not captured when generating the compressed database.

For the second set of monochromatic tests, kCARTA and LBLRTM used 42 molecular gases and 13 cross section gases, using the current kCARTA default resolution of  $0.0005 \text{ cm}^{-1}/0.0025 \text{ cm}^{-1}$  for the spectral ranges  $605\text{-}880 \text{ cm}^{-1}/805\text{-}2830 \text{ cm}^{-1}$ ; the overlap region allows us to convolve the resulting radiances with AIRS Spectral Response Functions (SRFs). Note that we used the default optical depths for kCARTA (currently HITRAN 2016, except for  $\text{CO}_2$  and  $\text{CH}_4$  which come from LBLRTM v12.8),

**Figure 4.** Results for 49 regression profiles, with 42 molecular gases and 13 cross section gases, convolved using AIRS SRFs. The emissivity was set to 1.0 and a  $22^\circ$  satellite scan angle. The left hand panels show the AIRS SRF convolved differences using the monochromatic differences (LBLRTM- kCARTA) seen in Figure 3, with the gray curves being the AIRS NeDT at 250 K, and are due primarily to the different spectroscopy used by the two RTAs (except for the  $\text{CO}_2$  and  $\text{CH}_4$  gases). The right hand panels show the mean calculated brightness temperature (top) and standard deviation (bottom). The variation in the  $800\text{-}1200\text{ cm}^{-1}$  region (and  $2400\text{-}2680\text{ cm}^{-1}$ ) is due to surface temperature differences and column water, while the variation in the other regions such as  $10\ \mu\text{m}$  and  $7.6\ \mu\text{m}$  is due to differing gas profiles of e.g.  $\text{O}_3$  and  $\text{H}_2\text{O}$ ; the variation in the  $4\ \mu\text{m}$  and  $15\ \mu\text{m}$  regions is due to temperature profile differences.

while the LBLRTM v12.8 line-file is based on HITRAN 2012. We only briefly summarize the monochromatic differences :  
 375 deep in the  $15\ \mu\text{m}$  they are the same as the left hand panels of Figure 3, but are noticeably different in other regions because  
 of differences in underlying spectroscopy and (for high altitude lines) possibly also resolution; for example on top of the  $10\ \mu\text{m}$   
 $\text{O}_3$  lines they could be as large as 5 K. Instead we show the differences after convolution with AIRS SRFs. The left hand  
 panels (a),(b) of Figure 4 shows the biases and standard deviations of these differences; as described the noticeable differences  
 at  $10\ \mu\text{m}$  and  $6.7\ \mu\text{m}$  arise primarily because of spectroscopy. For completeness, the right hand panels (c),(d) show the mean  
 380 BT spectra for the 49 regression panels (top panel) and the variation in computed BT (bottom panel) which are due to profile  
 differences (temperature,  $\text{H}_2\text{O}$  and  $\text{O}_3$ ) as well as surface temperatures. Any user interested in reducing the monochromatic  
 differences could easily do so by generating and using higher resolution compressed databases.

## 8 Flux Computations

Longwave fluxes at the top and bottom of the atmosphere, as well as the heating and cooling rates are computed by integrating  
 385 spectral radiances from Equation 2 over all angles, and over the infrared spectral region : kCARTA is limited to the spectral  
 range  $15\text{ - }3000\text{ cm}^{-1}$  spanned by the different bands of kCARTA (see Appendix B). As in Section 7 the limitation of kCARTA

for flux calculations is the spectral (infrared) resolution at every layer, compared to the varying-with-height resolution employed by other models such as LBLRTM. This impacts the high altitude longwave cooling in the 15  $\mu m$  CO<sub>2</sub> band.

390 We use the Rapid Radiative Transfer (Longwave) Model (RRTM-LW) (Mlawer et al., 2012) as our reference model for flux and heating rate comparisons in a clear sky atmosphere. This fast model computes fluxes and heating rates in 16 bands spanning 10 cm<sup>-1</sup> to 3000 cm<sup>-1</sup>, and was developed using LBLRTM; the latter uses a varying spectral resolution at each layer ( $\delta\nu$  equal to 4 points per half-width in each layer) which means the spectra for the upper atmosphere layers have very high resolution. kCARTA uses the same approach as RRTM-LW and LBLRTM to compute fluxes and heating rates : the angular integration uses an exponential Gauss-Legendre with 3 or 4 terms, with a "linear in  $\tau$ " layer temperature variation.

395 The accuracy of the flux and heating rate algorithm in kCARTA at the various resolutions was assessed by comparing fluxes and heating rates in the dominant 15  $\mu m$  to 10  $\mu m$  bands (fourth to eighth RRTM-LW bands, spanning 630-1180 cm<sup>-1</sup>) computed using RRTM-LW and kCARTA, using the 49 regression profile set.

At 0.0025 cm<sup>-1</sup> resolution the kCARTA and RRTM-LW heating rates differ by less than 0.2 K/day on average for altitudes below 40 km, but at higher altitudes the differences were much larger, and could be 1.5 K/day. Switching to the 605-1205 cm<sup>-1</sup> 400 H<sub>2</sub>O, CO<sub>2</sub> and O<sub>3</sub> test atmosphere database at 0.0005 cm<sup>-1</sup> significantly improves the results, with heating rate differences dropping to about 0.2 K/day almost everywhere.

Figure 5 shows the heating rate differences between kCARTA and RRTM-LW. The left panel shows differences between kCARTA and RRTM-LW, with the mean and standard deviation being solid and dashed respectively; the right panel shows mean calculations as a function of height. The blue curves were done at 0.0025 cm<sup>-1</sup> resolution while the red curves were 405 done at higher 0.0005 cm<sup>-1</sup> resolution. While the agreement is better than 0.05 K/day in the lowest 30 km, Figure 5 shows the heating rates using the low resolution begin to differ noticeably above 45 km (blue curve); conversely the high resolution heating rates (red curves) are within 0.2 K/day till about 65 km.

## 9 Scattering package included with ~~f90~~ kCARTA [Fortran 90 version](#)

The daily coverage of hyperspectral sounders provides us with information pertaining to the effects of cloud contamination on 410 measured radiances. Ignoring these effects can negatively impact retrievals used for weather forecasting and climate modeling. A scattering package based on the PCLSAM (Parametrization of Cloud Longwave Scattering for use in Atmospheric Models) scheme (Chou et al., 1999) has been interfaced into [the f90 version of kCARTA](#) (see Appendix C). The implementation allows kCARTA to compute radiances very quickly in the presence of scattering media such as clouds or aerosol. For a given scattering species and assumed particle shape and distribution, the extinction coefficients, single scattering albedo and asymmetry 415 parameters needed by the scattering code are stored in tables as a function of wavenumber and effective particle size (for a particle amount of 1 g/m<sup>2</sup>). The PCLSAM package is optimized for use in the thermal infrared, away from regions where solar contributions are important. As kCARTA currently does not handle e.g. Rayleigh scattering, one can easily use kCARTA to output monochromatic optical depths that can be imported into well known scattering packages. More details about PCLSAM and our cloud representation models are found in Appendix C.

**Figure 5.** Heating rates for the  $630\text{-}1180\text{ cm}^{-1}$  region computed using low ( $0.0025\text{ cm}^{-1}$ ; blue curves) and high ( $0.0005\text{ cm}^{-1}$ ; red curves) resolution kCARTA databases for 49 spanning Earth atmosphere profiles, compared to RRTM-LW. (a) The left panel shows differences in the heating rates, while (b) the right panel shows the mean heating rates.

## 420 10 Conclusions

We have described the details of a very fast and accurate pseudo- monochromatic code, optimized for the thermal infrared spectral region used by operational weather sounders for thermodynamic retrievals. It is much faster than line-by-line codes, and the accuracy of its spectroscopic database has been extensively compared against GENLN2 and more recently to LBLRTM. Updating the spectroscopy in a selected wavenumber region for a specified gas is as simple as updating the relevant file(s) in the database : for example, our custom UMBC-LBL enables us to re-build entire databases within weeks of the latest HITRAN release.

The computed clear sky radiances includes a fast, accurate estimate of the background thermal radiation. Analytic temperature and gas amount jacobians can be rapidly computed. Early in the AIRS mission, comparisons of AIRS observations against kCARTA simulations allowed for the quick implementation of modifications to gas optical depths : our modifications to the CKD2.4 and MT-CKD 1.0 continuum versions are very similar to what is now in the MT-CKD2.5 version. We now use the MT-CKD 3.2 continuum, together with the  $\text{N}_2$  and  $\text{O}_2$  continuum contributions bundled with that same version. We use two resolutions in the infrared :  $0.0005\text{ cm}^{-1}$  for the  $605\text{-}880\text{ cm}^{-1}$  region (to accurately resolve the high altitude  $\text{CO}_2$  lines) and  $0.0025\text{ cm}^{-1}$  elsewhere; an user can easily switch to an alternate resolution by generating the appropriate compressed databases for use with kCARTA, though this could be at the expense of speed (at these current resolutions kCARTA takes 30 seconds to compute TOA spectra from  $605\text{-}2830\text{ cm}^{-1}$  while LBLRTM takes over three minutes). Tests show that brightness temperature differences between kCARTA and for example LBLRTM are largest right on top of a small number of high altitude temperature sounding lines in the  $15\text{ }\mu\text{m}$  region (and close to zero elsewhere); these differences reduce as the resolution is

increased. Since the disparity is right at the peaks of the lines, the differences after convolution with a typical sounder SRF such as AIRS are on average much smaller than the NeDT.

440 kCARTA is fast enough to be used in Optimal Estimation retrievals for instruments spanning a reasonably small wavenumber range. The kCARTA database has been extended to include 15-44000  $\text{cm}^{-1}$ , which eventually needs to be updated to HITRAN 2016 (see the Appendix). In the future we plan to augment the optical depth calculations performed by UMBC-LBL by using speed-dependent lineshapes as parameters become available.

## Appendix A: Code availability

445 The UMBC-LBL code has been developed in Matlab, with extensive use of Mex files to speed up loops. The package is available at [https://github.com/sergio66/UMBC\\_LBL](https://github.com/sergio66/UMBC_LBL), and is fully described in (De Souza-Machado et al., 2002). The compression code is available upon request.

The f90 and Matlab versions of kCARTA can be cloned from [https://github.com/sergio66/kcarta\\_gen](https://github.com/sergio66/kcarta_gen) and <https://github.com/strow/kcarta-matlab> respectively.

### 450 A1 UMBC-LBL and kCARTA downloads and auxiliary requirements

The kCompressed Database is supplied in Fortran little-endian binary files that contain the optical depths for a specific gas. Each file contains optical depths at 10000 spectral points  $\times$  average pressures corresponding to the 100 AIRS layers. Links to the (605 - 2830  $\text{cm}^{-1}$ ) compressed database can be found at <http://asl.umbc.edu/pub/packages/kCompressedDatabase.html>

We also supply the US Standard Profile for all gases in the database, and kLAYERS, a program that takes in a point profile  
455 (from sondes and NWP) and outputs an AIRS 100 layer path averaged profile (in molecules/ $\text{cm}^2$ ). kLAYERS needs our supplied HDF file implementation (RTP) source code.

The Matlab version should work with R2012+ while the compiler for the Fortran version must support structures, such as Absoft, ifort and PGF. As the RTP file contains the atmospheric profile and scan geometry, both the Matlab and f90 kCARTA only need a simple additional (namelist) file to drive either code. The f90 version of kCARTA outputs binary files, which  
460 typically have header information such as kCARTA version number, number of layers and gases and parameter setting values, followed by panels, each 10000 points long, containing the optical depths, radiances, jacobians or fluxes computed and output by kCARTA. A number of Matlab based readers can then be used to further process the kCARTA output as needed. More information is found at <http://asl.umbc.edu/pub/packages/kcarta.html>.

A new compressed database (spanning the infrared 500-2830  $\text{cm}^{-1}$  region) is generated for kCARTA every four years,  
465 roughly within a few months of a HITRAN database release. The current f90 version described in this paper is identified on github as SRCv1.21\_f90 and currently uses HITRAN 2016 line parameters for all gases except  $\text{CO}_2$  and  $\text{CH}_4$  where we used LBLRTM v12.8 optical depths, together with MT-CKD3.2 continuum. These were used to generate the most recent SARTA v2.01 fast model coefficients; earlier SARTA versions were developed using kCARTA v1.07 and v1.18 (with HITRAN databases updated as they became available).

Table B1. Spectral bands for kCARTA

Band ( $\text{cm}^{-1}$ )	Point Spacing ( $\text{cm}^{-1}$ )	Band center ( $\mu\text{m}$ )	number of files
15-30	0.00005	444.4	30
30-50	0.00010	250.0	20
50-80	0.00015	153.8	20
80-140	0.00025	90.9	28
140-300	0.00050	45.4	34
300-500	0.00100	25.0	21
500-605	0.00050	18.1	21
605-880*	0.00050	14.18	40
805-2830*	0.00250	5.5	81
2830-3550	0.00250	3.1	30
3550-5550	0.00100	2.2	21
5550-8250	0.01500	1.4	19
8250-12000	0.02500	0.98	16
12000-25000	0.05000	0.54	26
25000-44000	0.10000	0.29	19

The UMBC-LBL line-by-line code has been used to generate optical depths in the spectral regions seen in Table B1. The 605-2830  $\text{cm}^{-1}$  band is marked with an asterisk, since our work focuses on this spectral region. The current database in this spectral region uses lineshape parameters from HITRAN 2016. The Van Vleck and Huber lineshape is used for all HITRAN molecules from ozone onward; water vapor uses the “without basement” plus MT-CKD 3.2, and  $\text{CO}_2, \text{CH}_4$  use line-mixing optical depths generated from LBLRTM v12.8. Note that in the important 4.3  $\mu\text{m}$  temperature sounding region, the f90 version can also include the  $\text{N}_2/\text{H}_2\text{O}$  and  $\text{N}_2/\text{CO}_2$  Collision Induced Absorption (CIA) effects modeled in (Hartmann et al., 2018; Tran et al., 2018), which depend on  $\text{CO}_2, \text{H}_2\text{O}$  and  $\text{N}_2$  absorber amounts.

A clear-sky radiance calculation in the infrared takes about 30 seconds, using a 2.8 GHz 32 core multi-threading Intel machine. The run-time goes to 120 seconds if jacobians are also computed (for 9 gases). A full radiance calculation from 15 to 44000  $\text{cm}^{-1}$  takes less than 5 minutes.

Table B2 lists a number of the features of kCARTA, with the ones marked by a asterisk only available in the f90 version. Note that the tables defaults to describing the spectroscopy for the infrared region.

Table B2: kCARTA features; \* indicates currently only available in the f90 version

Feature	Default	Options
<u>SPECTROSCOPY</u>		
(1) IR Database	HITRAN 2016	HITRAN 2012, GEISA 2015
(2) Resolution	0.0005/0.0025 cm <sup>-1</sup>	can make other resolutions
(3) Molecular gases	HITRAN ID 1-42	choose some
(4) Cross-section gases	HITRAN (CFCs etc)	choose some
(5) Water continuum	MT-CKD 3.2	e.g. MT-CKD 1.0, 2.5
(6) CO <sub>2</sub> line mixing	from LBLRTM v12.8	UMBC-LBL line mixing
(7) CO <sub>2</sub> /H <sub>2</sub> O, CO <sub>2</sub> /N <sub>2</sub> CIA*	off	Hartmann and Tran*
(8) CH <sub>4</sub> line mixing	from LBLRTM v12.8	None (voigt)
(9) O <sub>2</sub> and N <sub>2</sub>	HITRAN 2016 and LBLRTM v1.28 continuum	
(10) NLTE	line by line *	SARTA approximation
(11) Uncompressiom	linear	spline
<u>RADIATIVE TRANSFER</u>		
(1)Temperature variation	Linear in $\tau^*$	Constant
(2) Background thermal	acos(3/5) in upper layers, accurate angle lower layers	acos(3/5) all layers gauss quadrature*
(3) Background thermal	lambertian	
Surface reflection	$(1 - \epsilon_s(\nu))/\pi$	
(4) Solar reflection	user specified	
(5) Ray tracing	Spherical atmosphere, $n=1$	$n$ varies*
(6) Direction	upwelling	downwelling
(7) Solar	from tables	use 5600 K
(8) Jacobians	100 layer $T, WV$ , weighting functions acos(3/5) backgrnd thermal	column jacs
(9) Fluxes*	upwell, downwell	Heating rates
<u>RADIATIVE TRANSFER</u>		
(1) TwoSlab Cloud model*	PCLSAM	fluxes and jacobians
(2) couple to LBLDIS*		

The spline versus linear temperature interpolation differences, as tested on 49 regression profiles, are  $0.0004 \pm 0.0040$  K, with a maximum absolute difference of 0.342 K (in the 15 um region).

## Appendix C: PCLSAM scattering algorithm

The PCLSAM scattering algorithm for longwave radiances has applications ranging from dust retrievals (De Souza-Machado et al., 2010), to modeling the effects of clouds on sounder data (Matricardi, 2005; Vidot et al., 2015). This scattering model changes the extinction optical depth from  $k(\nu)$  to a parametrized number  $k_{eff.extinction}^{scatterer}(\nu)$  (Chou et al., 1999), and is designed  
 490 for cases of the single scattering albedo  $\omega$  being much less than 1, such as in the thermal infrared, where  $\omega$  for cirrus and water droplets and aerosols is typically on the order of 0.5.

Since  $k_{eff.extinction}^{scatterer}(\nu)$  is now effectively the absorption due to the cloud or aerosol, for each layer  $i$  that contains scatterers we replace the gas absorption optical depth with the total absorption optical depth

$$k_{total}(\nu) = k_{atm}^{gases}(\nu) + k_{eff.extinction}^{scatterer}(\nu) \quad (C1)$$

495 where (Chou et al., 1999)  $k_{eff.extinction}^{scatterer}(\nu) = k_{extinction}^{scatterer}(\nu) \times (1 - \omega(\nu))(1 - b(\nu))$  and the backscatter  $b(\nu) = (1 - g(\nu))/2$ , with  $g(\nu)$  being the asymmetry factor. Using this for every layer containing scatterers, the radiative transfer algorithm is now the same as clear sky radiative transfer, with very little speed penalty.

kCARTA is capable of using a TwoSlab (De Souza-Machado et al., 2018) cloud representation scheme for use with PCLSAM. This allows for non unity fractions for up to two clouds, so that radiative transfer then assumes the total radiance is a sum of  
 500 four radiance streams (clear, cloud 1, cloud 2 and the cloud overlap) weighted appropriately :

$$r(\nu) = c_{overlap} r^{(12)}(\nu) + c_1 r^{(1)}(\nu) + c_2 r^{(2)}(\nu) + f_{clr} r^{clr}(\nu) \quad (C2)$$

With this model kCARTA allows the user to specify up to two types of scatterers in the atmosphere (ice/water, ice/dust, water/dust or even ice/ice, water/water, dust/dust); the two scatterers are placed in separate "slabs" which occupy complete AIRS layers and are specified by cloud top/bottom pressure (in millibars), cloud amount (in g/m<sup>2</sup>), cloud effective particle  
 505 diameter (in  $\mu m$ ). After the computations are done, all five radiances are output when two clouds are defined (overlap, two clouds separately, clear, and the weighted sum), and three radiances if only one cloud is defined (one cloud, clear, weighted sum).

Analytic jacobians for temperature, gas amounts, and cloud micro-physical parameters (effective size and loading) can also be computed, as can be fluxes and associated heating rates, though the slab boundaries could introduce spikes in the heating  
 510 rate profiles.

kCARTA does not have built-in multiple scattering capabilities to handle for example Rayleigh scattering in the ultra-violet. To handle this we have written Matlab routines to read in kCARTA optical depths and pipe them into LBLDIS (Turner et al., 2003; Turner, 2005), a code that merges optical depths and scattering using the extensively tested Discrete Ordinates Radiative Transfer (DISORT) (Stamnes et al., 1988) algorithm.

## 515 **Author contribution**

Sergio DeSouza-Machado prepared the manuscript with contributions from all (living) co-authors. The initial compressed database coding and testing was done by L. Strow, H. Motteler and S. Hannon. Following this deS-M wrote the Fortran and Matlab wrapper codes for clear sky radiative transfer and jacobians, which were tested and validated by the other authors. Scattering and flux capabilities were added and tested by deS-M.

## 520 **Competing interests**

The authors declare that they have no conflict of interest.

## **Acknowledgments**

We thank the anonymous reviewers whose comments/suggestions helped improve this manuscript. This work was supported in part by NASA grant number NNG04GG03G-2. Dave Tobin of UW-Madison helped with UMBC-LBL CO<sub>2</sub> line-mixing code and modifying the water continuum coefficients. Dave Edwards of NCAR provided the GENLN2 line-by-line code to compare kCARTA against. Both Dave Edwards and Manuel Lopez-Puertas of the Instituto de Astrofisica de Andalucia (Spain) contributed to the NLTE portions of the code. Optical depth and flux comparisons against LBLRTM were facilitated by Eli Mlawer (Atmospheric and Environmental Research, Lexington MA), while Guido Masiello (University of Basilicata, Italy) helped with the radiance inter-comparisons.
