Response to Interactive Comment from Referee #2

General Comment

This paper presents vertical profiles of aerosols, NO₂, and SO₂ retrieved from MAXDOAS measurements at the Fort McKay South field site (Alberta, Canada). This site is located close to two mining plants which are major sources of industrial pollution in this region. The MAXDOAS retrieval results are compared to co-located ancillary observations from lidar, AERONET, active DOAS, Pandora, and airborne in-situ analysers instruments. These comparisons based on data sets from various techniques provide a unique opportunity to investigate the performance of MAX-DOAS retrievals under varying atmospheric conditions in an industrial area.

The manuscript is well written and clearly structured, and presents very interesting results which fit well with the scope of ACP. I recommend the final publication of the manuscript after addressing the following specific comments and technical corrections:

Response: The authors thank referee #2 for reading and commenting on the discussion paper. We are pleased that it meets with your approval, pending the specific comments and technical corrections below.

Specific Comments

1. Page 6, lines 1-12: It is not clear in which direction the active-DOAS measurements are performed. Is it the same direction as the MAX-DOAS instrument ? Maybe this information could be added in Figure 1.

Response: Direction of active-DOAS light path added to Page 6 lines 2-3.

2. End of page 7-beginning of page 8: You should add Wagner et al., Atmos. Meas. Tech. (2019) in the list of references on the O₄ scaling factor. No O₄ scaling is used in the present study. Did you perform sensitivity tests on your aerosol retrievals and you came to the conclusion that a scaling factor was not needed ? Or you simply decided not to use any scaling factor ? I think this should be further discussed in the paper and sensitivity test results could be also added to make the study more robust (e.g. what is the impact of a scaling factor on the agreement with AERONET data ?).

Response: The Wagner et al. 2019 reference was added on page 8 line 5. A statement that the scaling factor was not used because of a lack of conclusive need based on the literature and the

good agreement between the lidar and MAX-DOAS AODs when the modelled S-ratios were applied on Aug 23 was added on page 8 lines 7-9.

Note that while the lidar and MAX-DOAS AODs are expected to be equal within error because the 0-4 km lidar profiles of aerosol extinction were smoothed with the MAX-DOAS retrieval information, the AERONET AODs are expected to be greater than both because the sun photometer observed the entire atmospheric column. Since the MAX-DOAS AODs retrievals used an exponentially decreasing a-priori that reduced to near-zero (<0.005) extinction above 2 km (chosen for reasons discussed in Supplemental Section 8.2.2), the smoothed lidar and MAX-DOAS AODs are expected to capture the extinction between 0-2 km. The AERONET AODs would only be expected to be the same as the MAX-DOAS AODs if either a) there was no aerosol extinction above the boundary layer or b) the AERONET AODs were converted to a 0-4 km profile that was smoothed using the MAX-DOAS retrieval information. There was evidence of non-trivial aerosol extinction above 2 km and even sometimes above 4 km in the lidar measurements. An example of the variation in aerosol extinction at altitudes above 2km observed by the lidar was added to the supplemental (Fig. S9). An expanded discussion of how contributions of aerosol extinction above the boundary layer to the total AOD can be non-trivial was added on page 14 starting on line 5. This includes a reference to measurements of monthly average contribution of free tropospheric AOD to total AOD from satellite observations (Bourgeois et al., 2018, Atmos. Chem. Phys. DOI: <https://www.atmos-chem-phys.net/18/7709/2018/>).

3. Page 9, line 3: According to Rodgers (2000), weighting function K should be equal to $\delta y/\delta x$ and not $\delta F/\delta x$.

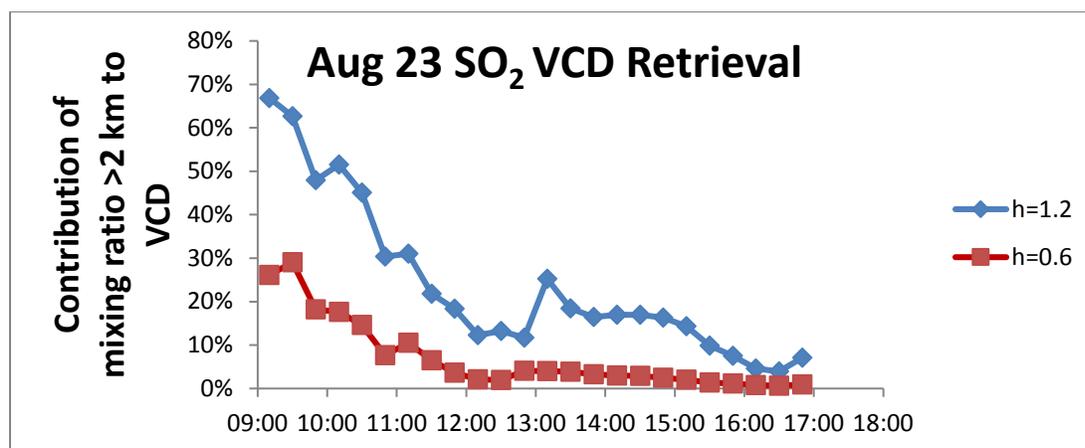

Response: corrected on Page 9 line 8.

4. Page 9: I think you should justify your choice of aerosol extinction and trace gas concentration a priori profiles. Did you perform sensitivity tests for the selection of these a priori profiles, especially in terms of scaling height ?

Response: Results and discussion of sensitivity analysis performed on the a-priori profiles was added to the Supplemental as Section 8.2. Sensitivity studies are shown for two case study days, Aug 23 and Sep 04, including results of a-priori scaling height of 0.3, 0.6 and 1.2 km. The new section is now referred to in the main manuscript on pages 9 line 22 and 10 line 2.

Regarding variations in the scale height (except from discussion in supplement 8.2): The a-priori with a scale height of 0.3 km decreased the AODs or VCD retrievals by 0-30% compared to the “base-case”, depending on the day and species (Tables S18-S23). The retrievals using this a-priori resulted in greater chi-squared values for the $h=0.3$ profiles compared to the other profiles for some retrievals after 15:00 (Figs. S14-S16). This smaller a-priori scale height was not used for the retrievals because it was probably too restrictive in terms of the decrease in the a-priori values profile values between ~ 0.5 -1 km under well-mixed, afternoon boundary layer conditions.

The a-priori with a scale height of 1.2 km increased the AOD or VCD retrieved values by ~20% compared to the “base-case”, generally because there was little information content from the MAX-DOAS measurements above ~1.5 km and the retrieval reverted to the non-zero a-priori values (Figs. S21-S25). Consequently, this profile shape increased the proportion of aerosol extinction and trace-gas concentration present at >2 km altitude to the 0-4 km column value (see plot below and Figs. S21-S25). For some of the vertical profiles on both days, the retrieval reduced the aerosol extinction to zero by ~1 km but this a-priori resulted in non-zero values at 2-4 km (Figs. S21-S25). This larger scale height was not used for the retrievals because it resulted in non-zero values at high altitudes where there was little to no information content from the measurements (Figs. S7, S21-S25). Since the values at these higher altitudes were unknown and likely varied temporally, a scale height that allowed the values to be retrieved at zero was chosen (i.e., $h = 0.6$ km). An a-priori scale height that resulted in underestimated rather than overestimated retrievals of the pollution loading where there was a lack of information content was considered preferable.

5. Page 9, lines 30-31: To my knowledge the SCIATRAN RTM is not based on a Monte Carlo approach. This point should be clarified.

Response: The reviewer is correct. “Monte Carlo” was removed on page 10 line 8.

6. Page 10, line 10: The relative error of the a priori was set to 100% for the construction of the Sa matrix. Did you set the extra-diagonal terms to zero and, again did you perform sensitivity tests for the selection of this relative error value. Also related: nothing is said in the paper about the quality control of your MAX-DOAS retrievals. For instance, what are the typical degrees of freedom for signal (DOFS) values of your aerosol and trace gas MAX-DOAS retrievals and what is the level of agreement between measured DSCDs and those modelled using the retrieved profiles as input ?

Response: Extra-diagonal terms of S_a matrix were set to zero and this information was added on page 10 line 19. Sensitivity tests for this relative error value were not performed. Typical degrees of freedom of signal were 1.6-2.1 and 2.3-3.0 for the aerosol and trace-gas retrievals, respectively. This information was added to Supplemental Section 8. Statistical results of the linear correlations between the measured and modelled dSCDs of O_4 , SO_2 , and NO_2 that includes a brief discussion of results were added to the supplemental (section 8.1 Tables S10 and S11). The presence of a “quality of retrieval” section the supplemental was added on page 8 lines 29-30 of the manuscript.

7. Comparisons between MAX-DOAS and AERONET AODs (Figs 4a-9a): MAX-DOAS significantly underestimates (by sometimes more than a factor of 2) AERONET AODs. What happens if you used a different a priori profile with a scaling height larger 0.6 km (e.g. 1.2 km) ? Does it improve the agreement with AERONET without degrading the quality of your retrieval (see point 6) ? Also, is the application of a O_4 scaling factor can improve the agreement with AERONET ?

Response: See response to reviewer comment #2 for discussion of why MAX-DOAS AODs are expected to be significantly less than the AERONET AODs during certain periods such as on Sep 04. As now shown in Supplemental section 8.2, increasing the scaling height of the MAX-DOAS AOD retrieval to 1.2 km from 0.6 km for Sep 04 increased the diurnal AOD by 14% (+/- 13%) (Table S21). The AODs produced by the two scale heights were effectively equal within error for this day (Fig. S17). This result was expected since there appeared to be a significant contribution of aerosol extinction above the boundary layer height on this day that probably occurred on other days as well (see response to comment #2). The Aug 23 MAX-DOAS AODs using a scale height of 1.2 km were significantly greater than the $h=0.6$ km AODs between 15:30 and 16:45 but were significantly smaller after 17:00 with reduced degrees of freedom of signal (Fig. S14). The $h=1.2$ km AOD retrieval also produced a temporal trend less consistent with the lidar temporal trends in AOD compared to the $h=0.6$ km AODs (Fig. S14). Therefore, using an a-priori with $h=1.2$ km for the AOD retrieval appeared to produce a lower quality retrieval for Aug 23. See response to reviewer comment #2 for why an O_4 scaling factor was not applied.

8. Page 22, lines 1-3: You said that a major advantage of the MAX-DOAS technique is the simultaneous retrievals of total columns and vertical profiles of trace gases and aerosol extinctions without requiring a priori information. I am a bit puzzled by this sentence since a priori information is needed in the Optimal Estimation retrieval approach you used. A clarification is needed here.

Response: Agreed, this sentence was unclear. Sentence was modified Page 23 lines 1-3 to make it clear that the a priori information referred in this case to the aerosol characteristics that can be needed to retrieve accurate AODs from lidar compared to MAX-DOAS.

Technical corrections: ‘->’ denotes ‘should be replaced by’

1/'Honninger et al.' -> 'Hönninger et al.'

Response: Corrected throughout.

2/'Clemer et al.' -> 'Clémer et al.'

Response: Corrected throughout.

3/The first sentences of both Sections 2.1 and 2.2 are a bit redundant. I would start Section 2.1 by 'The MAX-DOAS instrument was operated at an elevation of ~10 m. . . .' and Section 2.2 by 'The MAX-DOAS instrument is a mini-DOAS spectrometer from Hoffmann Messtechnik GmbH measuring scattered sunlight. . . .' or something similar.

Response: Updated based on reviewer comments on page 5 on lines 3 and 18.

4/Page 5, line 25: 5°C (C not in superscript)

Response: Corrected on page 5 line 26.

5/Page 22, line 1: 'total column' -> 'total columns'

Response: Corrected on page 23 line 6.

6/List of References: 'Atmospheric Meas. Tech.' -> 'Atmos. Meas. Tech.'; Same 'Atmospheric Chem. Phys.'

Response: This has been corrected throughout the list of references on pages 49 to 55.

7/Legends of Figures 4-9: You should add a short description of the error bars presented in the plots.

Response: A short description of the error bars was added to the last sentence in the captions of Figures 4-9.

Validation of MAX-DOAS retrievals of aerosol extinction, SO₂ and NO₂ through comparison with lidar, sun photometer, Active-DOAS and aircraft measurements in the Athabasca Oil Sands Region.

Abstract. Vertical profiles of aerosols, NO₂, and SO₂ were retrieved from Multi-Axis Differential Optical Absorption Spectroscopy (MAX-DOAS) measurements at a field site in northern Alberta, Canada, during August and September 2013. The site is approximately 16 km north of two mining operations that are major sources of industrial pollution in the Athabasca Oil Sands Region. Pollution conditions during the study ranged from atmospheric background conditions to heavily polluted with elevated plumes, according to the meteorology. This study aimed to evaluate the performance of the aerosol and trace gas retrievals through comparison with data from a suite of other instruments. Comparisons of AODs from MAX-DOAS aerosol retrievals, lidar vertical profiles of aerosol extinction, and AERONET sun photometer indicate good performance by the MAX-DOAS retrievals. These comparisons and modelling of the lidar S-ratio highlight the need for accurate knowledge of the temporal variation in the S-ratio when comparing MAX-DOAS and lidar data. Comparisons of MAX-DOAS NO₂ and SO₂ retrievals to Pandora spectral sun photometer VCDs and Active-DOAS mixing ratios indicate good performance of the retrievals except when vertical profiles of pollutants within the boundary layer varied rapidly, temporally and spatially. Near-surface retrievals tended to overestimate Active-DOAS mixing ratios. The MAX-DOAS observed elevated pollution plumes not observed by the Active-DOAS, highlighting one of the instrument's main advantages. Aircraft measurements of SO₂ were used to validate retrieved vertical profiles of SO₂. Advantages of the MAX-DOAS instrument include increasing sensitivity towards the surface and the ability to simultaneously retrieve vertical

25

35

profiles of aerosols and trace gases without requiring additional parameters such as the S-ratio. This complex dataset provided a rare opportunity to evaluate the performance of the MAX-DOAS retrievals under varying atmospheric conditions.

1 Introduction

The Athabasca Oil sands operations in Alberta contain significant sources of industrial atmospheric pollutants such as sulphur dioxide (SO₂) and nitrogen dioxide (NO₂) (ECCC, 2018b, 2018c). Oil extraction and upgrading activities such as surface mining, acid gas flaring, and transporting materials in heavy hauler trucks emit aerosols and trace gas pollutants (Liggio et al., 2016). Pollutant emissions from the industrial smokestacks result in uplifted profiles with the potential to be transported farther downwind compared to emission released at the surface, particularly for stacks with high volume flow rates and temperatures that can rise high in the atmosphere (Zhang et al., 2018). While the Athabasca Oil Sands Region (AOSR) experiences moderate annual average concentrations of SO₂ relative to all Canadian in-situ stations, the short-term concentrations can be significantly higher than in most Canadian cities (Government of Canada, 2018). The AOSR contains some of the few monitoring sites in Canada that experience peak 1-hour average concentrations of SO₂ of greater than 70 ppb (Government of Canada, 2018), which is the new 2020 Canadian Ambient Air Quality Standard for SO₂ (Canadian Council of Ministers of the Environment, 2014). SO₂ concentrations of up to 131 ppb were also observed by aircraft measurements downwind of an AOSR industrial facility in 2013, approximately midway between Syncrude Mildred Lake Plant and Fort McKay (Baray et al., 2018). High concentrations of SO₂ over short durations are a health concern because negative pulmonary and respiratory effects of inhalation can occur after exposure periods as small as 10 minutes (Health Canada, 2016; WHO, 2006). Exposure to NO₂ at high concentrations over short-term is also associated with significant health impacts (WHO, 2006) and NO_x (NO + NO₂) is a precursor to tropospheric ozone (O₃), acid rain and fine particulate matter (Seinfeld and Pandis, 2006).

Emissions of NO_x and SO₂ lead to the formation of nitrate and sulphate aerosols, which constitute a significant fraction of the PM_{2.5} air mass in urban and industrially-impacted regions (Pui et al., 2014). The highest peak and annual average PM_{2.5} concentrations in Canada in 2016 were observed at two monitoring stations within Fort McMurray with annual averages of over 18 µg m⁻³ compared to 8 µg m⁻³ in an industrial area of Toronto, Ontario (Government of Canada, 2018). Exposure to PM_{2.5} leads to adverse effects on respiratory and cardiovascular systems (WHO, 2006).

In the troposphere, nearly all SO₂ is oxidized to H₂SO₄ aerosol through reactions in the gas and aqueous phases. The hydroxyl (OH) radical initiates the oxidation route of SO₂ in the gas phase, forming HOSO₂ (Holloway and Wayne, 2010). Sulfuric acid (H₂SO₄) is formed through further oxidation of HOSO₂ and condenses onto already present aerosols or can nucleate with water vapour (H₂O) and gaseous ammonia (NH₃), forming sulphate aerosol (Kulmala et al., 2004). Aqueous phase reactions form sulphate aerosol efficiently with H₂O₂ and O₃ acting as oxidants (Seinfeld and Pandis, 2006). Wet deposition dominates the removal of sulphate aerosol. Therefore, elevated levels of SO₂ and NO₂ observed over the AOSR region are an environmental concern since atmospheric depositions of sulphur oxides (SO_x) and nitrogen oxides (NO_x) can

Field Code Changed

lead to freshwater and soil acidification (Psenner, 1994; Zhao et al., 2009). Deposition of nitrogen compound can harm sensitive ecosystems through eutrophication (excessive nutrient richness) of water bodies (Fenn et al., 2015). High concentrations of SO₂ and other pollutants over the AOSR have prompted measurements using aircraft studies (Baray et al., 2018; Gordon et al., 2015; Liggio et al., 2016, 2019; Simpson et al., 2010), in-situ measurements (Amiri et al., 2018; Hsu, 2013; Tokarek et al., 2018), sun photometer (Fioletov et al., 2016), and satellite (McLinden et al., 2012, 2014, 2016). Long-term monitoring through satellite measurements is an attractive choice due to the large scale of the operations. However, surface concentrations are difficult to determine accurately from satellite measurements (Fioletov et al., 2016), and data acquisition is limited to the satellite overpass times. Satellite retrievals in the AOSR region are also complicated by multiple factors: landscapes are complex, emissions can change relatively rapidly, and the winds within the higher boundary layer can quickly disperse pollution emissions. Rapid industrial expansion can also require updating retrieval algorithms (McLinden et al., 2014). Apparent peak concentrations are reduced, and small-scale variability cannot be resolved, due to spatial averaging within the footprint of a pixel that can be large relative to the scale of point-source plumes. SO₂, NO₂ and aerosol levels in the total column and near-surface can be simultaneously monitored using the Multi-Axis Differential Optical Absorption Spectroscopy (MAX-DOAS) technique (Hönninger et al., 2004). The elevated levels of SO₂ observed in the AOSR increase the ease of MAX-DOAS measurements compared to within most Canadian cities, where SO₂ levels are significantly lower. Differential Optical Absorption Spectroscopy (DOAS) is a remote sensing technique that quantifies tropospheric trace gases using light spectra and the unique spectral absorption cross sections of trace gases. Since its introduction by Platt et al. (1979) DOAS has been used to quantify trace gases in the troposphere, including NO₂, SO₂, OH, BrO, NO₃, NH₃, ClO and others. The technique has the advantage of allowing the simultaneous quantification of multiple trace gases (Platt et al., 2008). The MAX-DOAS method measures scattered sunlight spectra at multiple viewing directions and/or elevation angles to allow sensitive quantification of tropospheric pollutants. Spectra measured at elevation angles close to horizon-pointing have a higher sensitivity to ground-level pollutants since the light paths are longer near the surface (Hönninger et al., 2004). Ground-based MAX-DOAS measurements determine tropospheric vertical column densities (VCDs) of trace gases, quantifying total boundary layer pollution loading. VCDs have the advantage of being independent of boundary layer height and are spatially averaged (horizontally) on the order of a few kilometres along the light path. Ground-based MAX-DOAS data combined with radiative transfer modelling allows retrieval of vertical profiles of aerosol extinction and trace gases (Frieß et al., 2006; Hönninger et al., 2004; Hönninger and Platt, 2002; Irie et al., 2008; Wagner et al., 2004). The MAX-DOAS technique has been used to retrieve vertical profiles of aerosol extinction (Clémer et al., 2010; Frieß et al., 2011; Irie et al., 2008, 2015; Li et al., 2010; Zieger et al., 2011), BrO (Frieß et al., 2011; Hönninger and Platt, 2002), HCHO (Heckel et al., 2005; Wagner et al., 2011), SO₂ (Tan et al., 2018) and NO₂ (Tan et al., 2018; Wagner et al., 2011). There are few comparisons of vertical profiles of aerosol extinction from MAX-DOAS to vertical profiles from other instruments in the literature. MAX-DOAS aerosol extinction profiles have been compared to smoothed extinction profiles

Field Code Changed

from a sun photometer (Frieß et al., 2011) and aircraft aerosol profiles (Wagner et al., 2011). Near-surface MAX-DOAS retrievals of aerosol extinction have been compared with in-situ measurements of aerosols (Zieger et al., 2011). There are also relatively few published comparisons of MAX-DOAS AODs with lidar AODs (Irie et al., 2008, 2015). Relatively few studies have focused on MAX-DOAS measurements of anthropogenic SO₂ (Irie et al., 2011; Jin et al., 2016; Wang et al., 2014, 2017; Wu et al., 2018, 2013). Most studies that present MAX-DOAS vertical profile retrievals compare them to trace gas VCDs or near-surface measurements from in-situ or LP-DOAS instruments. Tan et al. (2018) and Wang et al. (2017) compared MAX-DOAS SO₂ VCDs to satellite VCDs of trace gases. Tan et al. (2018) and Wagner et al. (2011) compared MAX-DOAS retrievals of vertical profiles of NO₂ to satellite VCDs and near-surface NO₂ mixing ratios from LP-DOAS, respectively.

10 In this study, a MAX-DOAS instrument was deployed during a comprehensive air quality campaign conducted during August and September 2013. Pollution conditions ranged from background to heavily polluted with a well-mixed boundary layer to distinctly elevated pollution plumes. Vertical profiles of aerosols, NO₂, and SO₂ in the troposphere were retrieved using optimal estimation inverse modelling from the MAX-DOAS measurements. These retrievals allowed characterization of the vertical structure of the boundary layer. The retrieval used a two-step approach: 1) aerosol extinction profiles are retrieved from measured MAX-DOAS O₄ Differential Slant Column Densities (dSCDs), and 2) the aerosol extinction profiles are used as forward model parameters for retrieval of trace gas profiles from measured trace gas dSCDs.

15 Our study adds to the current literature by comparing MAX-DOAS aerosol and trace gas retrievals with data from numerous other instruments deployed during the campaign. The aerosol retrievals were compared to aerosol extinction data from a co-located lidar instrument and a nearby sun photometer. Validation of the aerosol retrievals is essential because these profiles are used as model parameters for the trace gas retrievals. MAX-DOAS NO₂ and SO₂ retrievals were compared to mixing ratios from a co-located active-DOAS instrument and tropospheric VCDs of trace gas from a Pandora sun photometer. In-situ measurements of SO₂ from an aircraft allowed comparison of MAX-DOAS vertical profiles of SO₂. Evaluation of the retrievals was aided by co-located, near-surface measurements of particle size distribution and composition, and nearby, high-resolution measurements of vertical profiles of wind speed and -direction.

20 The objectives of our study were to 1) determine the factors required to validate MAX-DOAS aerosol retrievals through comparison with lidar and sun photometer data, 2) evaluate the performance of the aerosol and trace gas retrievals through comparison to other datasets, 3) identify conditions that limit the use of the MAX-DOAS technique, and 4) identify conditions under which the MAX-DOAS method was advantageous over other instruments.

25 This complex dataset from comprehensive measurements in the vicinity of oil sand operations provided a unique opportunity to test the performance of the MAX-DOAS aerosol and trace gas retrievals.

Field Code Changed

2 Experimental

2.1 Field Sites

The MAX-DOAS instrument was operated at an elevation of ~10 m above the surface from Aug. 14 – Sept. 9, 2013 at the Fort McKay South field site (57.149N, 111.642W) north of Fort McMurray, Alberta concurrent with an Environment and Climate Change Canada (ECCC) intensive measurement campaign (Figs. 1 & S1). The MAX-DOAS instrument (Hoffmann Messtechnik GmbH) measured scattered sunlight at an elevation of ~10 m above the surface from Aug. 14 – Sept. 9, 2013 at the Fort McKay South field site (57.149N, 111.642W) north of Fort McMurray, Alberta concurrent with an Environment and Climate Change Canada (ECCC) intensive measurement campaign (Figs. 1 & S1). A second site was located 4 km north of Fort McKay South (Oski-Ôtin; 57.184N, 111.640W) in the Fort MacKay community. Two major sources of aerosols, NO₂, SO₂ and other pollutants are located south of Fort McKay South: the Syncrude Mildred Lake Plant and the Suncor Millennium Plant, 12 km South and 20 km South-South-East, respectively (Fig. 1). The 2013 NPRI reported emissions of SO₂ and NO_x from these facilities were 63 and 14 kilotonnes (kt) and 14 and 8 kt, respectively (ECCC, 2018a)(ECCC, 2018). Relatively smaller sources of pollutants are located north of Fort McKay South: Shell Jackpine and Muskeg River Mines, CNRL Horizon, and Imperial Oil Kearl Mine (Fig. 1). Tables S1 and S2 show the 2013 NPRI emissions of SO₂ and NO_x from these five facilities. A recent study suggests that total industrial emissions of NO_x were underestimated in the NPRI report, particularly for ground sources (Zhang et al., 2018). Since there are NO_x sources that are not included in the NPRI emissions data, also included in Tables S1 and S2 are the 2010 vehicular emissions associated with each facility and 2012-2013 annual stack and area source emissions from Zhang et al. (2018).

2.2 Instrumentation

The mini-MAX-DOAS instrument from Hoffmann Messtechnik GmbH measured scattered sunlight with a viewing azimuth angle of 155° South-South-East (SSE) at sequential viewing elevation angles 2o, 4o, 8o, 15o, 30o and 90o (zenith) above the horizon. A mini-MAX-DOAS instrument measured scattered sunlight with a viewing azimuth angle of 155° South-South-East (SSE) at sequential viewing elevation angles 2°, 4°, 8°, 15°, 30° and 90° (zenith) above the horizon. The instrument consisted of a sealed metal box containing entrance optics, UV fibre-coupled spectrograph and all electronics. The instrument field of view was approximately 0.6°. Incident light was focused on a cylindrical quartz lens (focal length = 40 mm) into a quartz fibre that transmitted the light into the OceanOptics USB2000 spectrograph. The spectrograph detector was a Sony ILX511 linear silicon Charge-Coupled Device (CCD) array (2048 pixels, pixel size 14x200 microns, signal-to-noise ratio at full signal 250:1). The spectrograph had a spectral range of 290-433 nm, a 50 µm wide entrance slit and a spectral resolution of ~0.6 nm FWHM. The spectrograph was cooled by a Peltier stage to maintain the selected temperature (5°C). Spectrometer data was transferred to a laptop computer via USB cable. The instrument was controlled using the software package DOASIS, which allowed automated measurements by JavaScript programs. The instrument was mounted on

Formatted: Superscript

Formatted: Not Superscript/ Subscript

an elevated scaffold approximately 10 m above ground level (a.g.l.), approximately at the height of the surrounding forest canopy. Each recorded measurement spectrum was an average of 2000 measured spectra with an exposure time that varied between 50 and 200 milliseconds, depending on the ambient light levels.

MAX-DOAS aerosol and trace gas retrieved data were inter-compared with data from various other instruments deployed during the campaign. Table 1 provides information on these instruments and papers that describe their operation.

An Active-DOAS instrument located at the same site was used to retrieve mixing ratios of NO₂ and SO₂ at 3.5 m a.g.l. [The Active-DOAS light path was pointed in a South-South-East direction, approximately parallel to the MAX-DOAS viewing azimuth angle \(Fig. 1\).](#) Measurements of trace gases with the active-DOAS system have been described previously

(McLaren et al., 2010, 2012; Wojtal et al., 2011) although details changed in the current study. DOAS measurements were made using a modified DOAS 2000 Instrument (TEI Inc.) utilizing a 150W high-pressure Xe-arc lamp and a coaxial Cassegrain telescope. The outgoing beam traversed the atmosphere for 1.15 km (pathlength =2.3 km) at an average height of 3.5 m a.g.l. where it impacted a retroreflector array composed of 30x2" hollow corner cubes mounted on a raiseable tower. The beam traversed through an exploration line cut (5-10 m wide x 2 km) in a mature coniferous forest. Return light was collected with a 2 m x 600 μm UV transparent fibre optic cable and spectrometer (Ocean Optics USB2000, Grating #10, λ=288-492 nm, 1800 lines mm⁻¹, 2048 element CCD, 25 μm slit, UV2 upgrade, L2 lens). Integration times of 30-40 ms and 4000 averages gave ≈ 2 min resolution with detection limits (3σ) of 120 ppt and 170 ppt for NO₂ and SO₂, respectively. Xenon lamp, Hg calibration, offset and dark noise spectra were collected for spectral fitting with DOASIS software. A small diffuser was installed in the entrance of the fibre to lower atmospheric turbulence noise (Stutz and Platt, 1993) in addition to using an optical fibre bending mode mixer.

A Pandora spectral sun photometer at Oski-Ôtin measured in direct-sun and zenith-sun viewing modes to retrieve total atmospheric column VCDs of SO₂ and NO₂ with precisions (1σ) of 4.6x10¹⁵ and 0.3 x10¹⁵ molecules cm⁻², respectively (Fioletov et al., 2016). Tropospheric VCDs of NO₂ were determined from the Pandora total column VCDs by subtracting

stratospheric VCDs modelled using the PRATMO stratospheric photochemical box model (McLinden, 2000). PRATMO was used as described in Adams et al. (2016) except monthly-mean OSIRIS ozone profiles (Degenstein et al., 2009) and

MODIS surface reflectivities (McLinden et al., 2014) were employed. The Pandora SO₂ VCDs presented are assumed to be representative of tropospheric SO₂ VCDs since stratospheric SO₂ was assumed to be negligible. Pandora trace gas and MAX-DOAS data were both available for inter-comparison for 4 days during the study. SO₂ and NO₂ mixing ratios were also measured from the air on board a Convair 580 research aircraft (Baray et al., 2018) using Thermo Scientific 43iTLE and 42i-TL analyzers, respectively, between 12 August and 7 September 2013, including a spiral ascent near Fort McKay South (Sep 03).

Aerosol optical depths (AOD) at 380 nm and 340 nm were obtained from Level 2.0 AERONET data, measured by second sun photometer at Oski-Ôtin. Aerosol extinction profiles at 532 nm from 0.1-12 km a.g.l. were retrieved using a ground-based, zenith-pointing lidar operated at Fort McKay South (Strawbridge, 2013). In this study, the lidar profiles from 0.1-4 km were considered in order to match the vertical observation extent of the MAX-DOAS. The lidar has the advantage over

Field Code Changed

sun photometer instruments because it can determine the vertical profile of optical extinction rather than just a column-averaged value but has higher uncertainty when the S-ratio is variable (Strawbridge, 2013). Aerosol extinction profiles are retrieved from the measurements of the laser return signal using a chosen S-ratio value. The S-ratio is the ratio of the volume extinction coefficient to the backscatter coefficient and dictates the signal strength of the received return of the lidar's pulsed laser source (Strawbridge, 2013). Lidar S-ratios are known to be variable but are often estimated given the type of particles expected in an environment (Irie et al., 2015). The S-ratio depends on the shape, size distribution and chemical composition of the aerosol particles, as well as the relative humidity (Weitkamp, 2005). A constant lidar ratio ("S-ratio") of 25 was used for the lidar retrievals unless otherwise specified. S-ratios were modelled using Mie scattering theory and measurements of surface-level particle composition and size distribution at Fort McKay South for various times during Aug 23 to determine temporal variability in the S-ratio. Source code for the Mie scattering calculations can be found in (Aggarwal et al., 2018). Ground-level particle composition was measured using an Aerodyne high resolution soot-particle aerosol mass spectrometer (SP-AMS) (Lee et al., 2019). Particle size distributions were measured using Scanning Mobility Particle Sizer (SMPS) ("dry" line mode) and Aerodynamic Particle Sizer (APS) instruments (see supplementary information in (Tokarek et al., 2018) for more details). Particle diameters measured by the SMPS and by the APS were 0.014-0.74 μm and 0.5-19.81 μm , respectively. Data from these instruments were combined to determine particle size distributions from 0.014 to 19.81 μm , assuming the particles were unit density. Use of "dry" line mode SMPS increased uncertainties in the size distributions because ambient aerosols have more volume than dry aerosols. However, even in the highest relative humidity range, the ambient aerosol had only 30% more volume compared to the dry aerosol which, assuming spherical particles, only results in a maximum increase in particle diameter of 9%. The resulting error is expected to be much smaller than other errors such as converting mobility and aerodynamic diameters to optical diameters.

A radio acoustic meteorological profiler (windRASS, model MFAS, Scintec, Germany) at Oski-Ôtin measured temperature, wind speed and -direction at 10 m intervals from 40 m to up to a maximum altitude of 800 m (Gordon et al., 2017).

Field Code Changed

2.3 MAX-DOAS Data Analysis

2.3.1 MAX-DOAS Fitting

Trace gas Differential Slant Column Densities (dSCDs) were obtained using the DOAS technique (Platt et al., 2008) with DOASIS software (Institute of Environmental Physics, Heidelberg, Germany). All spectra were corrected for dark current and electronic offset and wavelength calibrated using a measurement of a Hg lamp. Table 2 shows the wavelength windows and fit components used to retrieve dSCDs of NO_2 , SO_2 and O_4 . Cross sections were obtained from the MPI-MAINZ UV/VIS Spectral Atlas of Gaseous Molecules of Atmospheric Interest (Keller-Rudek et al., 2013). Examples of spectral retrievals of the gases are shown in Fig. S2. Each non-zenith measured spectrum was fit against the closest zenith spectrum in time, also known as the Fraunhofer Reference Spectrum (FRS). The statistical error of the O_4 dSCDs was $<1.1 \times 10^{42}$

Field Code Changed

Field Code Changed

molecules cm⁻². The O₄ error for off-axis measurements relative to the FRS are <6% for angles below 30° and <10% for the 30° measurements. The statistical fit errors of the SO₂ and NO₂ dSCDs were 0.4-1.2x10¹⁶ and 0.4-1.6x10¹⁵ molecules cm⁻², respectively. Uncertainties in the absorption cross sections result in systematic errors in the retrieved dSCDs. The reported uncertainty in the SO₂ and NO₂ absorption cross sections used is approximately 3% (Bogumil et al., 2003). The absolute value of the O₄ cross section and its dependence on temperature is uncertain. Some studies suggest that the absolute value of the cross section may be overestimated by up to 25%, requiring the use of a scaling factor (Clémer et al., 2010; Wagner et al., 2002, 2009, 2019). However, Frieß et al. (2011) found that the best results for measured O₄ dSCDs and the retrieved vertical profiles of aerosol extinction retrieved from them were achieved without a scaling factor. Irie et al. (2015) found that a scaling factor of 1.25 resulted in an overestimation of near-surface aerosol extinction coefficients (AECs) but also reduced residuals at high viewing elevation angles. Wagner et al. (2019) found that measured and radiative transfer modelled O₄ absorptions showed good agreement on one study day but poor agreement on the second. A scaling factor was not used for the O₄ fitting in this study because of the lack of consensus on the need for a scaling factor within the DOAS community and the good agreement between the MAX-DOAS and smoothed lidar AODs for the Aug 23 data (see section 3.1.2).

The SO₂ fitting range was determined based on an experiment using an SO₂ calibration cell from Resonance Ltd. with a slant column density (SCD) of 2.2x10¹⁷ (+/- 10%) molecules cm⁻² placed inside the MAX-DOAS telescope. Scattered solar light spectra were recorded around solar noon at multiple viewing elevation angles above the horizon, followed by a 90° measurement without the cell (the FRS). For each of the measured spectra, dSCDs of SO₂ were fit in DOASIS by varying the fitting windows in ~0.3 nm increments with a range of lower and upper limits of 303-318 nm 309-340 nm, respectively. The fit components are the same as in Table 2. See Supplemental Section 2 for details. The NO₂ and O₄ fitting ranges were from McLaren et al. (2010) and Frieß et al. (2011), respectively.

2.3.2 Retrieval of Vertical Profiles from MAX-DOAS dSCDs using Optimal Estimation

Aerosol and trace gas profiles were retrieved using a two-step approach: 1) aerosol extinction profiles were retrieved from measured MAX-DOAS O₄ dSCDs and 2) aerosol extinction profiles were used as forward model parameters for retrieval of NO₂ and SO₂ profiles from dSCDs of NO₂ and SO₂, respectively. Vertical profiles were determined from dSCDs using retrieval algorithms based on the (Rodgers, 2000) optimal estimation technique (Frieß et al., 2011, 2016, 2019). Generally, the desired state of the atmosphere (\mathbf{x}) can be estimated from remote sensing measurements (\mathbf{y}) using a forward model \mathbf{F} .

$$\mathbf{y} = \mathbf{F}(\mathbf{x}, \mathbf{b}) + \boldsymbol{\varepsilon} \quad (1)$$

Where $\boldsymbol{\varepsilon}$ is the measurement error and \mathbf{b} is the vector of model parameters that are assumed to be known and not determined by the modelling, such as aerosol microphysical properties. In this study, the SCIATRAN radiative transfer model was used as the forward model (Roazanov et al., 2005).

The optimal estimation method determined the most probable atmospheric state, $\hat{\mathbf{x}}$, based on a set of measurements, \mathbf{y} , and an a-priori state vector \mathbf{x}_a . The \mathbf{x}_a was the best guess of the vertical profile to be retrieved. The $\hat{\mathbf{x}}$ was the aerosol extinctions or the trace gas mixing ratios at a series of altitude intervals, for the aerosol retrieval and trace gas retrievals, respectively.

Field Code Changed

The \mathbf{y} was the O_4 dSCDs and the trace gas dSCDs measured at different angles, for the aerosol and trace gas retrievals, respectively. [The agreements between measured and modelled dSCDs based on linear regressions for the retrievals are shown in Supplemental 8.1 in Tables S10 and S11 as well as typical degrees of free of signal for the aerosol and trace-gas retrievals.](#) Note that in our retrievals, \mathbf{y} was the dSCDs measured at sequential elevation angles during 20-minute periods

5 before 17:00 local time and during 30-minute periods after 17:00. The wavelengths for the optimal estimation retrievals of O_4 , NO_2 and SO_2 were 360.8, 422.5, and 318.0 nm, respectively.

The optimal estimation solution $\hat{\mathbf{x}}$ is the maximum a posteriori (MAP) solution, which selects the most probable state from the set of possible states described by maximizing the probability of \mathbf{x} occurring given the observations \mathbf{y} (Rodgers, 2000).

The MAP solution is found by minimizing the cost function (χ^2).

$$\chi^2 = (\mathbf{y} - \mathbf{F}(\mathbf{x}, \mathbf{b}))^T \mathbf{S}_E^{-1} (\mathbf{y} - \mathbf{F}(\mathbf{x}, \mathbf{b})) + (\mathbf{x} - \mathbf{x}_a)^T \mathbf{S}_a^{-1} (\mathbf{x} - \mathbf{x}_a) \quad (2)$$

10 where \mathbf{S}_a and \mathbf{S}_E are the error covariance matrices associated with the a-priori and measurement vectors, respectively (Rodgers, 2000). The retrieval yields important quantities that allow the characterization of the retrieval. These include the

weighting function, $\mathbf{K} = \frac{\partial \mathbf{y}}{\partial \mathbf{x}} \mathbf{K} = \frac{\partial \mathbf{F}}{\partial \mathbf{x}}$, which quantifies the sensitivity of the measurement towards the atmospheric state, and the averaging kernel matrix, $\mathbf{A} = \frac{\partial \hat{\mathbf{x}}}{\partial \mathbf{x}}$, which quantifies the vertical resolution of the retrieval. \mathbf{A} describes the sensitivity of the

15 retrieved profile to changes in the true atmospheric profile. Rows of \mathbf{A} are averaging kernels for each altitude interval in the retrieved profile. The full width half maximum (FWHM) of each kernel gives an estimate of the retrieval's vertical resolution at height z . Each averaging kernel ideally peaks at a magnitude of 1.0 at the height of the kernel. However, the peak value of a kernel is generally less than 1.0 due to finite vertical resolution and may peak at a slightly different height, resulting in the smoothing of the true atmospheric profile into the retrieved profile.

20 Aerosol Extinction Retrievals

Retrieval of aerosol extinction profiles was non-linear since the aerosol extinction affects the radiative transfer in the forward model. The input for the aerosol retrieval was the measurement vector of the O_4 dSCDs at different elevation angles and an a-priori state vector that decreased exponentially with altitude with a scale height of 0.6 km and a surface magnitude of 0.1 km^{-1} . A single a-priori profile choice is preferable for a set of consecutive measurements where information content is

25 potentially limited since the a-priori will always have some impact on the retrieved profile (Rodgers, 2000). Otherwise, diurnal and day-to-day trends in the retrieved profiles due to real atmospheric changes could be indistinguishable from changes due to a variable a-priori profile. [Sensitivity studies of the a-priori choice were conducted by varying one a-priori parameter while keeping the remainder of settings the same: Gaussian shape, Boltzmann shape, scale height of 0.3 km, or scale height of 1.2 km. The results of the sensitivity studies are shown in Supplemental section 8.2.](#)

30 Our aerosol retrieval used an iterative algorithm based on the Levenberg-Marquardt method (Levenberg, 1944; Marquardt, 1963). For aerosol retrievals, the weighting function \mathbf{K} is calculated using the a-priori \mathbf{x}_a and the measurement vector \mathbf{y} . The \mathbf{K} of each retrieval depended on the state vector and changed depending on the determined aerosol extinction profile. The

Field Code Changed

Field Code Changed

height resolution of the aerosol extinction vertical profile grid was 100 m with a maximum height of 4 km. A detailed description of the aerosol retrieval algorithm can be found in (Frieß et al., 2006).

Field Code Changed

Trace gas Retrievals

The retrievals of NO₂ and SO₂ vertical profiles were linear because these weak absorbers do not significantly impact the radiative transfer. The inputs for the NO₂ and SO₂ retrievals were the measurement vectors of the NO₂ and SO₂ dSCDs at different elevation angles, respectively, and an a-priori state vector that decreased exponentially (scale height = 0.6 km and surface magnitude = 30 ppb and 10 ppb for SO₂ and NO₂, respectively). Sensitivity studies of the a-priori choice were conducted by varying one a-priori parameter while keeping the remainder of settings the same: Gaussian shape, Boltzmann shape, scale height of 0.3 km, or scale height of 1.2 km. The results of the sensitivity studies are shown in Supplemental section 8.2.

In this linear case, the forward model is independent of the atmospheric state \mathbf{x} , and the weighting function matrix represents the forward model.

$$\mathbf{y} = \mathbf{F}(\mathbf{x}, \mathbf{b}) + \boldsymbol{\varepsilon} = \mathbf{K}\mathbf{x} + \boldsymbol{\varepsilon} \quad (3)$$

In our retrieval, the box-air mass factors (AMF) that are components of \mathbf{K} were modelled using the ~~Monte Carlo~~ radiative transfer model in SCIATRAN (Deutschmann et al., 2011; Frieß et al., 2010; Rozanov et al., 2005). The aerosol profiles retrieved in step 1 were used to recalculate the Box-AMFs for each trace gas retrieval since the extinction profiles varied. The height resolution of the trace gas vertical profile grid was 100 m with a maximum height of 4 km a.g.l.

Field Code Changed

Determination of Retrieval Errors

The retrieval covariance matrix $\hat{\mathbf{S}}$ quantifies the error of the state vector and is the sum of the independent sources of error: smoothing error \mathbf{S}_s , representing the retrieval's limited vertical resolution, and the retrieval noise \mathbf{S}_M , representing the uncertainty due to errors in the measurement. $\hat{\mathbf{S}} = \mathbf{S}_M + \mathbf{S}_s$. The error covariance matrix produced by the retrieval does not include model parameter errors or forward model errors (Frieß et al., 2006). The error covariance matrix is calculated following Eq. (4):

$$\hat{\mathbf{S}} = (\mathbf{K}^T \mathbf{S}_e^{-1} \mathbf{K} + \mathbf{S}_a^{-1})^{-1} \quad (4)$$

\mathbf{S}_E and \mathbf{S}_a are the measurement and a-priori covariance matrices, respectively. In our retrievals, \mathbf{S}_a was determined by setting the relative error of the a-priori to 100% and the extra-diagonal terms were set to zero. The \mathbf{S}_E was the diagonal matrix of errors of the retrieved dSCDs as determined by the DOASIS retrievals.

Field Code Changed

2.3.3 Conversion of Other Instruments' Data for Comparison to MAX-DOAS Data

Lidar and AERONET extinction data were converted to the MAX-DOAS aerosol retrieval wavelength of 361 nm following Eq. (5):

$$E(361nm) = E(\lambda_1) * \left(\frac{361nm}{\lambda_1}\right)^{-\alpha} \quad (5)$$

Equation (5) accounts for the dependence of aerosol extinction on wavelength based on the Angstrom exponent, α . AERONET 300-500nm and 340-440nm Angstrom exponents were used to convert the 532 nm lidar aerosol extinctions and the 380 nm and 340 nm AERONET AODs, respectively. The two resulting AERONET AODs at 361 nm were then averaged. The Angstrom exponent was assumed to be constant with altitude and representative of both field sites. The similarity in trends in AODs and trace gas VCDs between the two sites can indicate when the Angstrom exponent determined from Oski-Ôtin was valid for both sites.

Due to the limited vertical resolution of the MAX-DOAS measurements, MAX-DOAS vertical profiles of aerosol extinction and AODs can only be directly compared to lidar profiles and AODs after smoothing the 361 nm lidar profiles using the MAX-DOAS averaging kernel matrix, \mathbf{A} (Rodgers and Connor, 2003). The lidar AODs referred to in the paper below and shown in plots are the smoothed AODs determined by vertically integrating the smoothed lidar vertical profiles of extinction at 361 nm unless otherwise stated.

The lidar profiles were averaged into the same altitude and temporal intervals as the MAX-DOAS retrievals and then smoothed using the respective matrix \mathbf{A} following Eq. (6):

$$\mathbf{x}_s = \mathbf{x}_a + \mathbf{A}(\mathbf{x}_L - \mathbf{x}_a) \quad (6)$$

Where \mathbf{x}_s is the smoothed lidar profile, \mathbf{x}_a is the MAX-DOAS retrieval a-priori profile and \mathbf{x}_L is averaged lidar profile. \mathbf{x}_s represents the (noise-free) vertical profile that the MAX-DOAS retrieval would produce if \mathbf{x}_L was the true atmospheric profile given the variable sensitivity of the MAX-DOAS retrieval with altitude. The deviation of \mathbf{x}_s from \mathbf{x}_L at each altitude depends on \mathbf{x}_a and the sensitivity of the MAX-DOAS to the atmosphere at that altitude. MAX-DOAS sensitivity to the true atmospheric state decreases with increasing altitude (Frieß et al., 2006) with typical height resolutions of ~200 m at lower altitudes, increasing to ~700 m at higher altitudes. Therefore, the smoothing is generally expected to smooth the true profiles towards lower altitudes. Also, even if the two instruments viewed the same air mass, the retrieved and smoothed profiles are expected to differ at least slightly due to two factors. The first factor is the retrieval noise $\mathbf{G}\boldsymbol{\varepsilon}$, which is unknown since the true measurement error $\boldsymbol{\varepsilon}$ is unknown. \mathbf{G} is the gain matrix, which describes the retrieval's sensitivity to the measurements. The true smoothed profiles would be described using the following Eq. (7):

$$\mathbf{x}_{retrieved} = \mathbf{x}_a + \mathbf{A}(\mathbf{x}_{true} - \mathbf{x}_a) + \mathbf{G}\boldsymbol{\varepsilon} \quad (7)$$

The second factor is that lidar vertical profiles observed straight up, measured only above 100 m a.g.l. and are the least sensitive close to the surface. The 0-100 m a.g.l. extinction in the lidar profiles was assumed to be equal to the average extinction measured between 100-200 m a.g.l. but the vertical profiles may have been variable below 150 m a.g.l.

Field Code Changed

Field Code Changed

Uncertainty in the lidar vertical profiles is greatest in the lowest 150 m a.g.l., introducing uncertainty into the smoothed lidar profiles.

Error bars on the MAX-DOAS AODs, VCDs and mixing ratios shown in figures were obtained from the optimal estimation retrieval. Error bars on the lidar and AERONET AODs are the standard error of the temporally averaged values since these instruments have a finer time resolution than the MAX-DOAS retrievals. Error bars on the active-DOAS mixing ratios are the root sum square errors of the standard error of the averaged values and the average error reported by the respective DOASIS retrievals. Error bars on the Pandora VCDs are root sum square errors of the standard error of the average values and the reported instrumental precision. Deming fit linear regressions were performed using the Monte Carlo method, which included the errors on the x and y data, with the “linfitxy” function in MATLAB (Browaeys, 2017). The Aug 23 and Sep 03 AERONET and Pandora data were also correlated with MAX-DOAS and lidar data by subtracting 30 minutes from the Oski-Ôtin data to account for the time of air mass transport between the Fort McKay South and Oski-Ôtin given the wind-speeds.

Field Code Changed

3 Results and Discussion

This paper discusses results from largely cloud-free days when industrial plumes were observed (Aug 23, Sep 03, Sep 04, Sep 06, Sep 07) and one day with clean conditions (Sep 05). Nine days are not discussed due to the presence of clouds most of the day.

Vertical profiles of wind speed and -direction measured by the windRASS are shown in Figures 2 and 3, respectively. A summary of wind conditions and pollution levels for each day is shown in Table 3.

Aug 23 exhibited the greatest enhancements in aerosol and trace gas pollution during the study. Wind-directions in the morning were North to East-North-East and South-East to South-South-West in the afternoon. Winds were relatively low-speed with minimal wind shear. The pollution enhancement periods were associated with Southerly (S) winds, suggesting that air-masses rich in industrial emissions originated from the Syncrude and Suncor mining areas south of the sites (Fig. 1). The pollution enhancements impacted both sites (AMS 13 and Oski-Ôtin).

Sep 03 exhibited moderate pollution levels. Pollution data is only presented from 11:00 onwards due to the presence of clouds before this time. Wind-directions varied from South-East to South-South-West with occasional South-West to North-West winds. Significant wind-shear was observed in the vertical profiles of wind. The pollution enhancements impacted both sites.

Sep 04 exhibited moderate pollution levels. Wind-directions were frequently South to South-Easterly with intermittent periods of South-West and North-West winds. Significant wind shear was observed: wind-directions tended to rotate clockwise from South-South-East near the surface to North-East as altitude increased. The limited afternoon wind data suggest North-West winds. Wind speeds were low to moderate, tending to increase with altitude. The pollution enhancements impacted both sites.

Sep 05 exhibited the cleanest conditions and greatest wind-speeds during the study. Winds were West-South-West to Westerly. Both sites were impacted by air-masses that passed over boreal forests.

Sep 06 exhibited low to moderate pollution enhancements in the morning with low pollution conditions in the afternoon. Winds were North to North-Easterly but varied over time and with altitude. Wind-speeds tended to be low at the surface but moderate to large at higher altitudes; significant wind-shear was present. Fort McKay South was impacted by emissions from facilities north of the sites: Shell Jackpine and Muskeg River Mines, CNRL Horizon, and Imperial Oil.

Sep 07 exhibited moderate to low pollution. Winds-directions were South-South-East during the morning and South-West to South-South-West during the afternoon. Significant wind shear was observed in the lowest 400 m a.g.l. between 9:00 and 11:00 and during the afternoon around 16:00. Different air-masses may have impacted the two sites.

10 3.1 Inter-comparisons of MAX-DOAS aerosol retrievals with lidar and AERONET data

The AODs from the MAX-DOAS, lidar and AERONET sun photometer instruments exhibited similar temporal trends on Aug 23, Sep 03, Sep 04, Sep 05 and Sep 07 (Figs. 4-9 (a)). Note that the measured and optimal estimation modelled O_3 dSCDs showed good agreement for all these days with linear regression slopes of 0.99 and $R^2=0.91-0.98$ (Table S10). The MAX-DOAS AODs were statistically different from the lidar and AERONET AODs for approximately half the data, even when the two sites experienced the same air-masses. This result is expected based on three factors: 1) the different vertical extents of the atmosphere observed by the instruments, 2) temporal variability in the lidar S-ratio, and 3) the limited sensitivity of the MAX-DOAS measurements at higher altitudes. These factors will be discussed below to evaluate the performance of the MAX-DOAS AOD retrievals under various atmospheric conditions.

20 3.1.1 Impact of Instrumental Vertical Sensitivity on AOD

AERONET AODs were generally significantly greater than MAX-DOAS and lidar AODs, except during the greatest pollution events (Figs. 4-9 (a)). During the low-pollution day of Sep 05, AERONET AODs reached a maximum of 0.15 ± 0.00 while maximum MAX-DOAS AODs were 0.08 ± 0.01 (Fig. 4(b)). On Sep 05 the MAX-DOAS and AERONET AODs had a slope of linear correlation of 1.04 ± 0.08 ($R^2=0.77$) but had a linear intercept of $-0.08 \pm 0.01 \text{ km}^{-1}$. This negative intercept can be attributed to aerosol loading above the boundary layer that was observed by the sun photometer but not by the MAX-DOAS. This result is expected because the AERONET sun photometer observed aerosol extinction throughout the entire column (tropospheric and stratospheric) while the MAX-DOAS and smoothed lidar profiles observed up to 4 km. Further, the MAX-DOAS retrieved and smoothed lidar profiles likely only ~~captured-represented enhancements-aerosol extinction~~ below 2 km because of the exponentially decreasing a-priori profiles used and the decreasing sensitivity of the MAX-DOAS retrieval with increasing altitude (see Supplement Section 8 for explanation of their a-priori shape and scale height choice). The MAX-DOAS and smoothed lidar AODs are, therefore, expected to be significantly smaller than the

Formatted: Subscript

Formatted: Superscript

AERONET AODs when the aerosol extinction in the boundary layer was “clean” and contributed a small fraction to the total tropospheric extinction (e.g., Fig. 10; Aug 23_9:10). MAX-DOAS AODs were also significantly smaller than AERONET AODs even under moderately polluted conditions when the magnitudes of the aerosol extinction remained enhanced compared to background above the boundary layer. For example, on Sep 04 the extinctions between the boundary layer top and 4 km could be relatively large, ~1/3 the near-surface extinctions (Figs. 10_& 15 (a) & S9 (a)), leading to much smaller MAX-DOAS AODs than AERONET AODs (Fig. 6(a)). Note that increasing the scale height of the Sep 04 a-priori profile from 0.6 to 1.2 km only slightly increased the MAX-DOAS AODs with a linear regression slope of 1.14±1.13 and intercept=0±0 km⁻¹ (Table S21 & Figs. S17 & S24. The AODs from both a-priori profiles were ~50% of the AERONET AOD values, an expected result since a significant contribution to the total AOD was expected to be present >3 km (Table S21, Fig. S9 (a)). Aerosol loadings can be non-trivial in the free troposphere since fine mode particles can remain in the atmosphere for days (Zhong and Zaveri, 2017). Dust and smoke are aerosol types that are transported most efficiently to the free troposphere from the boundary layer compared to other types. Once in the free troposphere, aerosols have much longer residence times of aerosols are much longer in the free troposphere compared to within the boundary layer. Therefore, enhanced loading of the dust and smoke aerosols present in the free troposphere in the AOSR may be due to local sources since dust and smoke are emitted by the industrial activities and biomass burning, but they also could be transported long distances (e.g., originating from fires in British Columbia). Forest fire smoke has been observed above the boundary layer by airborne lidar measurements in AOSR (see Figures 12 and 13 and discussion of elevated forest fire plumes in Aggarwal et al. (2018)). Therefore, the aerosol extinction above the boundary layer in the AOSR could contribute to a significant fraction of the total atmospheric AOD on certain days depending on the emission and transport of aerosols. Globally, Bourgeois et al. (2018) found that the monthly averaged fractional contribution of the free troposphere extinction to the total AOD obtained from satellite observations was greater in northern mid-latitudes (25%) compared to southern mid-latitudes (13%), attributed to the larger number of emission sources and convection activity. While monthly average contribution was 25%, the contribution likely varies significantly on a day to day basis, particularly in a region such as the AOSR that has numerous emission sources, locally and upwind. The lidar measurements indicate that the contribution of the AOD above 2 km can vary significantly as indicated by a comparison of- aerosol extinction vertical profiles from Sep 04 and Aug 23 (Fig. S9). These results indicate that the ratio of the MAX-DOAS AODs to AERONET AODs depends on the location of the aerosol extinction within the tropospheric profile. The use of simple linear regressions to evaluate the performance of MAX-DOAS AOD retrievals using sun photometer AODs may be appropriate only when the aerosol extinction in the boundary layer dominates the total tropospheric AOD.

3.1.2 Impact of S-ratio Variability on Lidar AODs

MAX-DOAS AODs significantly exceeded the smoothed lidar AODs during the most polluted periods (Fig. 4(b)). This result is unexpected, given that the instruments’ AODs should ideally be equal when the instruments observed the same

airmasses. However, the deviation can be explained by variation in the lidar S-ratio. The S-ratio of 25 steradians (sr) appears accurate during relatively clean periods (e.g., Sep 05, Aug 23 morning) but an underestimation under the industrially polluted conditions of the afternoon of Aug 23 (Figs. 4(b) & 12). Modeled S-ratios for Aug 23 were 21-28 sr during the low pollution morning and 36-44 sr during the peak pollution enhancement at ~16:50 (Table 4). The morning S-ratios were calculated using the refractive indices of toluene or kaolinite based on the dominance of organic particles and dust in the region during background atmospheric conditions (Fig. 11 (a)). The afternoon S-ratios were modelled using the refractive index of sulphate particles based on the significant enhancement in sulphate particle loading (Fig. 11 (a)). Increased loading of sulphate particles tends to increase the S-ratio. Note that the 16:50 S-ratios were greater than the morning S-ratios for all refractive indices because the particle size distribution of the industrial plume (fine-mode dominated) increased the S-ratio. The modelled variability in the S-ratio is supported by lidar measurements in the AOSR in 2018 that allowed determination of temporal and vertical variability in the S-ratio (Strawbridge et al., 2018). Measured S-ratios ranged from 20 to 60 sr within the boundary layer at Oski-Ôtin in 2018 (Fig. S6).

Based on these results, lidar vertical profiles of aerosol extinction were retrieved using an S-ratio of 44 sr for the extinction below the free troposphere after 14:30 on Aug 23. As shown in Figure 4 (a), the updated lidar AODs are in more reasonable agreement with the MAX-DOAS and AERONET AODs compared to the original lidar AODs shown in 4(b). The linear regression of the MAX-DOAS and updated lidar AODs has a slope of 1.15 ± 0.02 with an intercept of -0.01 ± 0.02 ($R^2 = 0.97$) instead of 2.18 ± 0.03 for the original lidar AODs ($R^2 = 0.97$) (Table S3). Modelling S-ratios using particle data measured at the near-surface appears to be valid during Aug 23 because the vertical profile was relatively well mixed. A well-mixed boundary layer was indicated by the similarity in temporal trends between the Active-DOAS mixing ratios and MAX-DOAS VCDs and between the AODs and the surface particle loading (Figs. 4 (g, h) & 11 (a)). However, if the distribution of particles in space is inhomogeneous, this method cannot be used to determine the S-ratio of the total boundary layer.

Results from Sep 03 and Sep 06 illustrate that near-surface measurements of particles properties can be invalid for modelling the total column S-ratio due to complex vertical profiles of particles. Despite near-surface enhancements in sulphate particles (Fig. 11) and SO₂ mixing ratios observed by Active-DOAS (Fig. 5(f)), the MAX-DOAS and lidar AODs were very similar after 11:30-17:00 on Sep 03 (Fig. 5(a)). The MAX-DOAS and Pandora SO₂ VCDs were moderate compared to the enhancements on Aug 23, suggesting that the sulphate enhancements were confined mainly near the surface after 11:30. Due to wind-shear, the near-surface air (<200 m a.g.l.) was often impacted by industrial pollution from the south while the air at higher altitudes was impacted by less polluted regions (North-West and Northerly winds), particularly around 14:00 (Fig. 3 (b)). Thus, the S-ratio of 25 sr was representative of the total boundary layer after 11:30 despite sulphate enhancements at the surface, leading to similar magnitudes of MAX-DOAS and lidar AODs. S-ratios modelled using the near-surface measurements of particles during the afternoon of Sep 03 would have overestimated the S-ratio within the total boundary layer.

Similarly, near-surface measurements of particles would not represent the total boundary layer on Sep 06 due to an elevated industrial plume. The MAX-DOAS NO₂ VCDs remained enhanced while the Active-DOAS mixing ratios rapidly decreased

Field Code Changed

from ~7 ppb to ~1 ppb (Fig. 8(g)). The MAX-DOAS AODs approached the AERONET AODs around noon (Fig. 8(a)), maximizing around the time that the lidar observed elevated vertical profiles of aerosol extinction. These results suggest that elevated plumes from the industrial facilities to the north of Fort McKay South (Fig. 1) increased the S-ratios at higher altitudes. S-ratios modelled using the surface data during this time, therefore, would have underestimated the average S-ratio within the boundary layer.

These results suggest that the MAX-DOAS retrievals of AODs performed well when the vertical extent of instrumental viewing and S-ratio variability are considered.

3.1.3 Comparison of MAX-DOAS Vertical Profiles of Aerosol Extinction with Averaged and Smoothed Lidar Vertical Profiles

MAX-DOAS vertical profiles of aerosol extinction are compared to averaged and smoothed lidar vertical profiles in Figures 12 to 18.

Smoothing alters the shape and magnitude of the averaged lidar profiles in several ways. Smoothing the averaged lidar profiles generally “compresses” the profiles by vertically attributing extinction at higher altitudes to lower altitudes (compare panels (a) and (b) in Figs. 12-18). This result is expected due to the decreasing sensitivity of the MAX-DOAS retrieval with increasing altitude apparent in the averaging kernels (Fig. S7). The smoothing also replaces lidar aerosol extinction above ~1.5 km a.g.l. with the (small) a-priori extinction values because the MAX-DOAS measurements have little information content at high altitudes (Fig. S7). This effect is apparent when comparing the Sep 03 averaged and smoothed lidar profiles above 1.5 km a.g.l. (Fig. 14). Profiles that were relatively uniform within a few hundred meters of the surface can sometimes be smoothed into apparently elevated profiles because the averaging kernel attributes much of the extinction from altitudes aloft to one altitude bin closer to the surface. For example, the averaging kernels for the Sep 04 14:10 retrieval for altitudes 0.55 to 1.25 km peak at 0.45 km rather than at their respective height (Figs. S7 & S8). Conversely, the smoothing can transform vertically narrow and distinctly elevated profiles near the surface into exponentially decreasing profiles due to the limited vertical resolution of the retrieval (see the 9:30 profile in Fig. 17). Therefore, interpretation of the retrieved MAX-DOAS profiles must account for the effects of smoothing on the true atmospheric profiles.

On Aug 23, the MAX-DOAS and smoothed lidar vertical profiles (S-ratio = 25 sr) exhibited similar temporal trends and vertical enhancements within the boundary layer (Fig. 12). The magnitudes of aerosol extinctions were consistent between the smoothed lidar and MAX-DOAS vertical profiles in the morning, supporting the hypothesis that the S-ratio of 25 sr was appropriate for “clean” periods. In contrast, the MAX-DOAS extinctions exceeded the smoothed lidar extinctions in the afternoon (Fig. 12). Using an S-ratio of 44 sr within the afternoon plume (discussed in 3.1.2) resulted in smoothed lidar profiles consistent with the MAX-DOAS profiles (Fig. 13). While temporal trends and overall magnitudes were similar, MAX-DOAS retrievals tended to exhibit more distinctly elevated profiles than the smoothed lidar profiles. The use of a constant S-ratio within the plume may have caused the lidar profiles to appear more vertically uniform than the true profiles since S-ratios can maximize where extinction peaks (Fig. S6). Also, the MAX-DOAS viewing geometry observed air masses

south of the field site, closer to industrial sources, where the vertical profiles may have been less well-mixed. Finally, MAX-DOAS measurement errors can be mapped into the retrieved profile, leading to uncertainties, but are probably only important at higher altitudes where the measurements contain little information content. Deviations in the MAX-DOAS profiles from the smoothed lidar profiles after 17:00 can be attributed to reduced light levels and the longer retrieval time, reducing signal-to-noise ratio and the probability of the viewed airmasses changing significantly within the time required to capture the measurements for the retrieval, respectively.

For the Sep 03, Sep 04 and Sep 07 (morning) comparisons, the MAX-DOAS retrieved profiles generally captured the same temporal and vertical trends in extinction enhancements as the smoothed lidar profiles, but the lidar extinctions were smaller than the MAX-DOAS extinctions (Figs. 14, 15, & 18). The S-ratio of 25 sr probably underestimated the true values given the presence of sulphate particles (Fig. 11 (b, c, f)) and enhanced SO₂ VCDs (Figs. 5(b), 6(b) & 9(b)). On Sep 05 the S-ratio of 25 sr is expected to be appropriate due to the clean conditions. The magnitudes of the MAX-DOAS extinctions were unexpectedly greater than the smoothed lidar extinctions but were generally equal within error (Fig. 16). The Sep 06 MAX-DOAS aerosol retrievals appear noisier than the smoothed lidar profiles (Fig. 17). The elevated plumes present in the MAX-DOAS retrievals but not in the lidar profiles may be related to an increased S-ratio due to the impact of plumes from north (Fig. 8 (g)). On Sep 07 the MAX-DOAS aerosol extinction profiles were of greater magnitude and different in vertical profile shape compared to the smoothed lidar profiles after 12:00. The deviation can be attributed to significant wind-shear and rapid temporal variation in the wind profiles after 12:00 (Figs. 2(f) & 3(f)). Aerosol extinction magnitudes varied by up to a factor of five within 10 minutes in the afternoon (Fig. S11). These conditions violate two assumptions of the MAX-DOAS retrievals: low horizontal inhomogeneity and that the spectra measured during the retrieval time observed the same airmass. Although the MAX-DOAS retrievals of AOD were consistent with the smoothed lidar AODs, the temporal and vertical resolutions of the MAX-DOAS retrievals were insufficient to retrieve accurate vertical profile shapes. The afternoon MAX-DOAS vertical profile retrievals are, therefore, not expected to represent the true atmospheric state.

3.2 Evaluation of MAX-DOAS Trace gas Retrievals

3.2.1 Comparison of MAX-DOAS and Pandora Trace gas VCDs

The MAX-DOAS and Pandora SO₂ and NO₂ VCDs exhibited similar temporal trends over the four days of comparison, except during the afternoon of Sep 07 (Fig. 4(c, d); (b, c) in Figs. 5, 6 & 9).

On Aug 23 the MAX-DOAS and Pandora VCDs were strongly correlated ($R^2 > 0.80$) with linear regression slopes of 1.55 ± 0.07 and 2.20 ± 0.07 for SO₂ and NO₂ VCDs, respectively (Table S4). Greater trace gas enhancements were also observed near the surface at Fort McKay South compared to Oski-Ôtin through in-situ measurements by the Wood Buffalo Environmental Association (WBEA) (Wood Buffalo Environmental Association, 2019) (Fig. S12) with slopes of the linear regressions of 1.42 ± 0.05 ($R^2=0.91$) and 1.93 ± 0.07 ($R^2=0.61$) for SO₂ and NO₂, respectively (Table S2). The strong correlations between the trace gas measurements between the sites indicate that the same airmass impacted both sites but that

Field Code Changed

a more central (higher concentration) portion of the plume impacted Fort McKay South or significant horizontal dilution of the plume occurred during transport.

The NO₂ VCDs had a slope of the regression greater than that of the in-situ NO₂ measurements (Table S2). NO_x may have been lost at a faster rate near the surface during transport due to deposition to the surface (e.g., the boreal forests). Transport times between the sites were relatively long (~30 minutes) on this day due to low wind-speeds below 600 m a.g.l. (Fig. 2). NO_x is lost through surface deposition and photochemical conversion to HONO and HNO₃ (Finlayson-Pitts et al., 2003; Wojtal et al., 2011). HONO might be subsequently released as NO and OH, but the HNO₃ loss will be virtually permanent.

On Sep 04 the MAX-DOAS and Pandora VCDs exhibited similar temporal trends and were often equal within error (Fig. 6(b, c)). The slopes of the linear correlations of the SO₂ and NO₂ VCDs were 1.10±0.33 ($R^2=0.51$) and 0.95±0.07 ($R^2=0.85$), respectively (Table S6). The greater variability in SO₂ between the sites compared to NO₂ is consistent with the in-situ data between Fort McKay South and the WBEA Bertha Ganter site (Fort McKay North; 57.189428, -111.640583) with $R^2=0.7$ and 0.92 for SO₂ and NO₂, respectively (Table S6) (Wood Buffalo Environmental Association, 2019). SO₂ plumes are more localized in the AOSR, originating mostly from large industrial stacks and fewer sources compared to NO₂ (Zhang et al., 2018) (Tables S1 & S2). Note that when MAX-DOAS SO₂ VCDs were significantly greater than Pandora SO₂ VCDs around noon, the SO₂ mixing ratios at Fort McKay South were approximately double those at the Bertha Ganter (Fort McKay) site (Fig. S12). These results suggest that the MAX-DOAS performed well in retrieving accurate VCDs of SO₂ despite the weaker linear correlation with the Pandora VCDs. The two sites appear to have largely experienced the same air-masses within a small temporal period (<20 minutes) due to higher wind-speeds relative to Aug 23 and Sep 03 (Fig. 2 (a, c)). Higher wind speeds likely reduced the maximum enhancements in trace gas VCDs compared to Aug 23 and Sep 03 due to greater dispersion. Wind shear on Sep 04 (Fig. 3 (c)) may also have transported only certain altitudes of the elevated plumes from south of Fort McKay South to the sites. In contrast, wind shear on Aug 23 was limited within 500 m a.g.l. (Fig. 3(a)).

On Sep 03 and Sep 07, the MAX-DOAS and Pandora VCDs demonstrated weak linear correlations ($R^2 < 0.2$) (Tables S5 and S9).

The Sep 03 VCD correlations are inconclusive due to the limited number of data points and relatively little variation in the Pandora VCDs. The MAX-DOAS VCDs tended to be higher than the Pandora VCDs. Unlike on Aug 23, an examination of the in-situ data between sites is not helpful due to the significant wind-shear on Sep 03 and the presence of elevated plumes. Based on the good agreement between the MAX-DOAS and Pandora VCDs on Sep 04 with similar VCD magnitudes, the apparent overestimation could be due to different air-masses experienced by the two sites.

Field Code Changed

Field Code Changed

Field Code Changed

On Sep 07 the MAX-DOAS were similar to the Pandora trace gas VCDs before 13:30 but were much larger after (Fig. 9 (b, c)). The deviation of the MAX-DOAS VCDs is an expected result given the rapid spatial and temporal variation in the wind profiles (discussed in 3.1.3). Errors of the trace gas retrievals can be expected to be even greater than the aerosol retrieval errors because the retrieved aerosol profiles were used as forward model parameters in the trace gas retrieval. The afternoon

MAX-DOAS trace gas retrievals on Sep 07 are not expected to represent the true atmospheric state. Note that the strength of correlation between the measured and optimal estimation modelled dSCDs of the trace-gases was weaker for the retrievals from Sep 07 (slopes = 0.9 and $R^2 = 0.67-0.74$) compared to Aug23 (slopes = 0.99 and $R^2 = 0.97-0.98$) and Sep 04 (slopes = 0.97-9.88 and $R^2=0.91-0.98$) (Table S11). These statistical results are consistent with the good performance of the trace-gas retrievals on Aug 23 and Sep 04 compared to relatively poor performance on Sep 07.

Inter-comparisons of the Pandora and MAX-DOAS VCDs show that the MAX-DOAS retrievals of trace gas VCDs performed well under low to moderate wind-speeds and when vertical profiles of pollution were relatively constant within the retrieval period.

3.2.2 Comparison of MAX-DOAS 0-100 m Retrieval with Active-DOAS Mixing Ratios

The 0-100 m a.g.l. MAX-DOAS trace gas retrievals are shown with the Active-DOAS mixing ratios in Figures 4 (e, f) and Figures 5-9 (d, e). The MAX-DOAS retrievals generally captured the Active-DOAS temporal trends but tended to overestimate the magnitudes. The MAX-DOAS retrieval yields an estimate of the average concentration within the 0-100 m layer, which is larger than the surface value in case of uplifted layers. Therefore, in-situ near-ground instruments, such as Active-DOAS, are required when accurate surface mixing ratios are required.

The MAX-DOAS retrievals were most consistent with the Active-DOAS measurement during the late afternoon of Aug 23 (Fig. 4 (e, f)). SO_2 was at its highest levels and assumed to be relatively well-mixed within the boundary layer based on the similarity in the temporal trends in SO_2 VCDs and surface mixing ratios (Fig. 4 (g)) and the uniformity of the lidar vertical profiles <1 km a.g.l. (Fig. 13 (a)). The mixing ratios were equal within error during the morning and after 14:00 with some differences in the early afternoon that may be due to the different viewing geometry. On days other than Aug 23, the uncertainty in the surface retrieval is often too high for reliable comparison when the near-surface when SO_2 and NO_2 were <20 ppb and <10 ppb, respectively. Overall, the MAX-DOAS retrievals of 0-1000 m performed well, considering the frequently complex vertical profiles observed during the study.

3.2.3 Temporal trends of MAX-DOAS Trace gas VCDs and Active-DOAS Mixing Ratios

Active-DOAS mixing ratios are shown with MAX-DOAS VCDs in Fig. 4(g, h) and in Figs. 5-9 (f, g). The VCDs and mixing ratios exhibited similar temporal trends on Aug 23, Sep 04-06 (Fig. 4(g, h); Figs. 6 & 7 (f, g)), but not on Sep 03 and Sep 07 ((f, g) in Figs. 5 & 9). The similar temporal trends in VCDs and mixing ratios observed on Aug 23 are consistent with the limited vertical wind-shear and low to moderate wind-speeds, as discussed previously. In contrast, the ratio of VCDs to

Formatted: Space Before: 12 pt

Formatted: Superscript

Formatted: Superscript

Formatted: Superscript

5 mixing ratios sometimes varied even during short periods on Sep 04 and Sep 06. If the boundary layer is well-mixed, the Active-DOAS mixing ratios and MAX-DOAS VCDs are expected to have similar temporal trends during short periods since the boundary layer is expected to be effectively constant. On Sep 04, the temporal trends were very similar until ~13:30, when the rapid decrease in trace gas mixing ratios was not reflected in the VCDs (Fig. 6 (f, g)), indicating elevated pollution plumes that are apparent in the lidar measurements (Fig. S7 (a)). These observations are a testament to the ability of MAX-DOAS to observe elevated pollution plumes not detectable at the surface. The differences in the short-term trends in VCDs and mixing ratios are consistent with the wind profile data around 13:30 on Sep 04, which indicates Westerly to Northwesterly wind directions <300 m a.gl. that are expected to result in relatively clean air near the surface (Fig. 3(c)). Although measurements of the wind profiles above ~250 m a.gl. were unavailable, southerly winds aloft are suggested by the trace gas VCDs remaining enhanced until ~15:00. While significant enhancements of trace gas near the surface tend to contribute to enhanced VCDs, the opposite may not always occur: elevated plumes that cause enhanced VCDs may not result in large surface mixing ratios (Fioletov et al., 2016). The observations in this study indicate that elevated enhancements may also result from vertical wind shear. Techniques for estimating emissions from industrial facilities must account for the possibility that different vertical portions of plumes can be transported in different directions. Such complex pollution conditions require pollution monitoring techniques such as MAX-DOAS that can detect elevated pollution plumes. In addition to being able to observe elevated plumes that are under-sampled by in-situ, ground instruments, MAX-DOAS can be used to estimate emissions when deployed using the mobile-MAX-DOAS technique (Davis et al., 2019).

Field Code Changed

Field Code Changed

3.2.4 MAX-DOAS Retrievals of Vertical profiles of SO₂ and NO₂

20 MAX-DOAS retrievals of vertical profiles of SO₂ and NO₂ are shown in Figure 19. Unlike the aerosol profiles, co-located measurements of the trace gas vertical profiles were generally not available. The magnitude and vertical location of the pollution were highly dependent on wind direction and wind shear. The greatest trace gas enhancements occurred under South-South-Easterly wind-directions (Figs. 3 & 19) where pollution originated from the greatest sources of SO₂ and NO₂ to the South (Fig. 1; Tables S1 & S2). The MAX-DOAS retrievals performed well in terms of the profile shapes expected based on the wind profiles or evidence of elevated plumes. For example, trace gas pollutants in the MAX-DOAS retrievals were confined largely to <200 m on the mornings of Sep 04 and Sep 07 (Fig. 19 (c) & (f)) as expected from the wind-shear (Fig. 3). The elevated profiles of SO₂ on Sep 03 before noon and during the afternoon of Sep 04 are consistent with the results discussed previously.

30 Aircraft measurements of trace gases on Sep 03 allow some comparison of the MAX-DOAS retrieved profiles. A vertical profile of SO₂ measured during an aircraft spiral ascent at ~14:27 in the vicinity of Fort McKay South (Fig. 20) is consistent in magnitude and shape with the MAX-DOAS retrieved vertical profile for 11:00-11:20 (Fig. 20). The MAX-DOAS 11:10 profile was used for comparison because it appears to have observed the same plume as the aircraft spiral. Although these two profiles cannot be directly compared due to the differences in time and vertical resolutions, the aircraft profile indicates

that the magnitudes and elevated shape of the MAX-DOAS profiles of SO₂ are reasonable. The elevated SO₂ plumes measured by the aircraft and MAX-DOAS could have originated from upgrader stacks at either the Syncrude or Suncor facilities south of Fort McKay South. The aircraft also passed over Fort McKay South at 16:32, measuring 30 ppb of SO₂ and 5 ppb of NO₂ at 395 m a.g.l. The MAX-DOAS retrieval for 16:20-16:40 had maximum SO₂ values of 57 (\pm 19) ppb at 5 350 m and maximum NO₂ values of 10 (\pm 5) ppb at 650 m. Note that the Active-DOAS measured 20 (\pm 0.1) ppb of SO₂ and 4.3 (\pm 0.1) ppb of NO₂ near the surface. These measurements, therefore, suggest that elevated plumes were present and that the MAX-DOAS retrieved magnitudes are reasonable.

3.3 Advantages of MAX-DOAS

MAX-DOAS has an advantage over the zenith lidar technique in detecting aerosol extinction since lidar retrievals cannot 10 detect close to the surface due to challenges with signal overlap (Zieger et al., 2011). Quantifying aerosol extinction from lidar measurements also requires additional knowledge (i.e., the S-ratio) (Wagner et al., 2004), as has been highlighted in this paper. The advantage of the MAX-DOAS over the sun photometer (in direct-sun viewing mode) is the ability to determine vertical profiles of pollutants versus only total columns. The MAX-DOAS is complementary to Active-DOAS and other point-source measurements when pollution within the boundary layer is vertically inhomogeneous (see 3.2.3). While 15 surface level, local measurements of pollutants are often important for applications such as health exposure studies, they may fail to provide the full picture of the total boundary layer pollution. Such in-situ measurements provide highly localized information with little information about elevated plumes that may mix down to the surface down-wind. MAX-DOAS allows remote sensing of airmasses over longer path-lengths, even if plumes are elevated. The MAX-DOAS method is advantageous over satellite measurements when plumes are localized and can provide more information on near-surface 20 trends.

3.4 Limitations of the Inter-Comparisons in this Study

A limitation to validating the MAX-DOAS AODs against lidar and sun photometer data was the different viewing geometry and slightly different locations. Also, Angstrom exponents used to convert the lidar extinctions to the MAX-DOAS retrieval wavelength would ideally be measured at Fort McKay South. Application of a single S-ratio modelled from particle 25 measurements from the near-surface to the entire lidar vertical profile can introduce errors since the S-ratio may vary vertically (see 3.1.2 and Fig. S6). The S-ratio can be significantly non-uniform with altitude when the vertical profile is composed of layers of anthropogenic (urban, biomass burning), and/or biogenic aerosols or mixtures of them. Even if a layer is well-mixed, the lidar ratio can change with height if the vertical profile of relative humidity is non-uniform (Weitkamp, 2005). 30 The MAX-DOAS trace gas VCDs should ideally be compared with a co-located Pandora instrument given the possibility of horizontal inhomogeneity between the sites. Validation of the MAX-DOAS 0-100 m retrieval using the Active-DOAS

Field Code Changed

Field Code Changed

Field Code Changed

mixing ratios was complicated by the lowest viewing elevation angle observing 5 m above the Active-DOAS light path. The MAX-DOAS “surface” retrieved values are only expected to be equal to the Active-DOAS values when the air masses were well-mixed within 0-100 m a.g.l. A more thorough validation of the MAX-DOAS near-surface retrievals could be achieved with trace gas measurements at multiple heights within 100 m a.g.l. from a tall tower.

5 4 Summary

In this study, data from a diverse range of instruments have allowed an expansive characterization of the MAX-DOAS retrievals of aerosol extinction, NO₂ and SO₂. The retrievals performed well at capturing the aerosol loading within the boundary layer. The exception was under conditions of rapid variation in the vertical profiles of pollutants during the retrieval period. The ratio of the MAX-DOAS to sun photometer AODs depended on the vertical location of the aerosol extinction within the atmospheric column. Direct inter-comparisons of AODs between instruments must account for the relative spatial extents observed. The comparison of MAX-DOAS and lidar data combined with S-ratio modelling indicated that accurate S-ratio values are essential to retrieve accurate profiles of aerosol extinction from lidar measurements when particle composition or size distribution varies significantly temporally or spatially. Direct comparison of MAX-DOAS and lidar AODs should be made with caution when knowledge of the S-ratio value(s) is limited. S-ratios can be estimated from measurements of particle size distribution and composition using Mie scattering modelling. However, near-surface measurements of particles should only be used to model S-ratios when the boundary layer is well mixed. Lidar extinction profiles should ideally be determined using a technique that accounts for the vertical and temporal variation in the S-ratio such as in [Strawbridge et al. \(2018\)](#). When the S-ratio variability was accounted for, the results of this study indicate that the MAX-DOAS retrievals of aerosol extinction performed well compared to the smoothed lidar results.

Comparisons of averaged and smoothed lidar profiles of aerosol extinction indicated that the vertical sensitivity of the MAX-DOAS retrievals smoothed the true atmospheric profiles towards the surface. This smoothing can transform vertical profiles that are relatively uniform within the boundary layer into apparently elevated profiles and vice versa. This shape change depends on the location of extinction within the true vertical profile and the averaging kernel matrix of the retrieval. Interpretation of the shape of the MAX-DOAS vertical profiles must account for the instrument’s sensitivity to the true vertical profile (i.e., the averaging kernel matrix).

MAX-DOAS retrievals of NO₂ and SO₂ VCDs performed well in comparison to the Pandora VCDs. The exception was when the aerosol retrievals were inaccurate due to rapidly varying vertical profiles. This was an expected result since the aerosol retrievals are used as forward model parameters in the trace gas retrieval. The MAX-DOAS trace gas retrievals within 0-100 m a.g.l. captured the temporal trends observed by the Active-DOAS measurements, but the MAX-DOAS mixing ratios were statistically greater than the Active-DOAS values, particularly when SO₂ and NO₂ were <20 ppb and <10 ppb, respectively. Differences between the instruments’ values can be attributed to variability in the trace gas profiles within 150 m a.g.l. The MAX-DOAS observed elevated enhancements of pollution undetected by ground-based techniques such as

Field Code Changed

the Active-DOAS, perhaps its greatest asset. Pollution enhancements at surface-level did not always coincide with total boundary layer enhancements, and vice versa, due to elevated plumes and/or significant wind-shear. The MAX-DOAS vertical profiles of trace gases were consistent with the profiles expected based on the wind direction and -shear conditions. Aircraft measurements of SO₂ near Fort McKay South on Sep 03 indicated that the magnitudes and elevated shape of the retrievals were reasonable.

A major advantage of the MAX-DOAS technique is the ability to simultaneously retrieve total columns and vertical profiles of trace gases and aerosol extinction in the boundary layer and the lower troposphere from spectral measurements without requiring ~~prior~~ knowledge of the ~~aerosol size distributions or compositions or the vertical profiles of trace gases~~. These advantages are important in industrial regions where the vertical profiles of pollutants vary temporally and spatially, and in-situ monitoring can under-sample plumes. In the AOSR and similar industrial regions, a full understanding of the air quality conditions requires instruments, such as MAX-DOAS, capable of observing the total boundary layer on a horizontal scale of a few kilometers, in addition to traditional in-situ instruments.

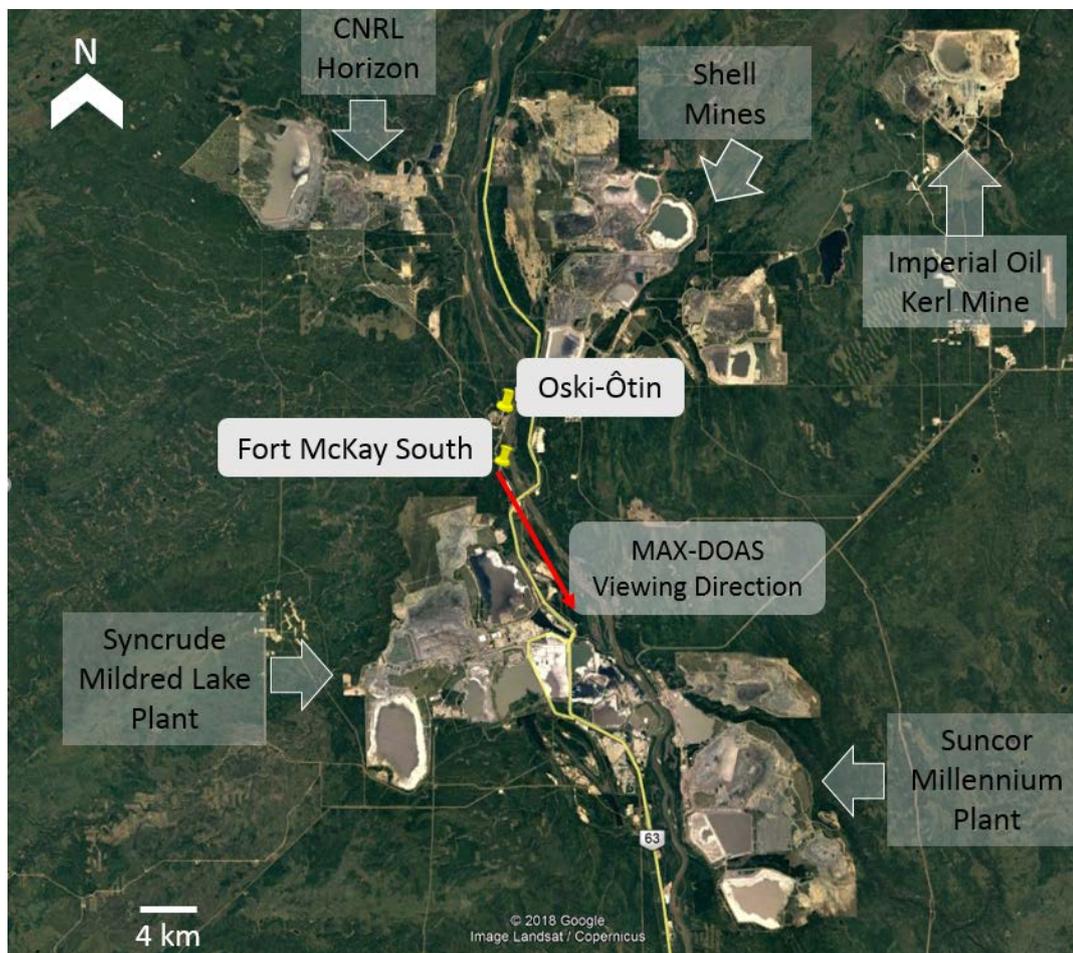

Figure 1 Location of field sites Fort McKay South and Oski-Ôtin and major industry sources.

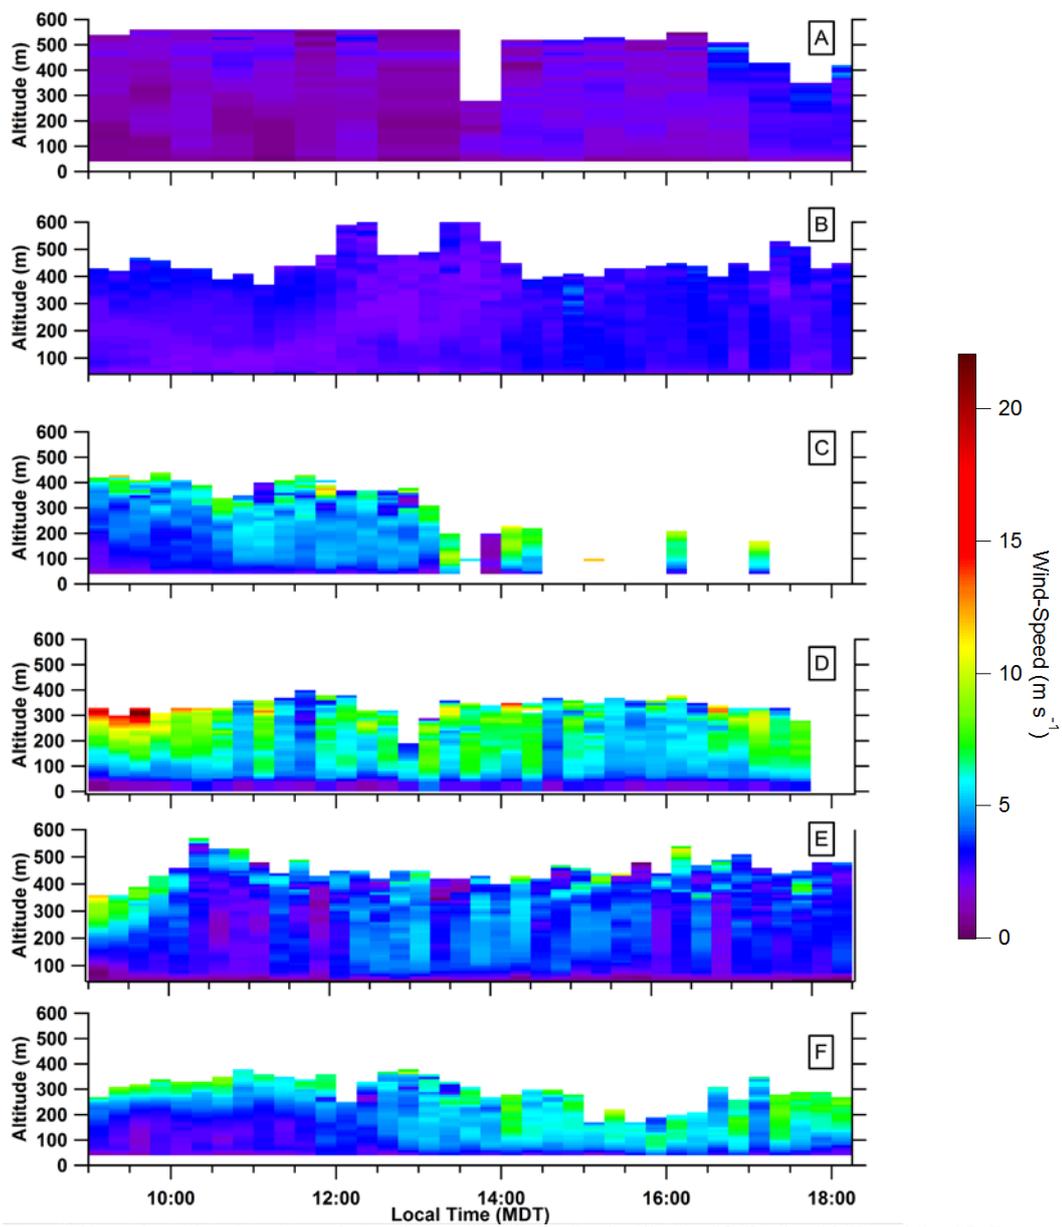

Figure 2 Vertical profiles of wind speed: Aug 23 (A), Sep 03 (B), Sep 04 (C), Sep 05 (D), Sep 06 (E), and Sep 07 (F).

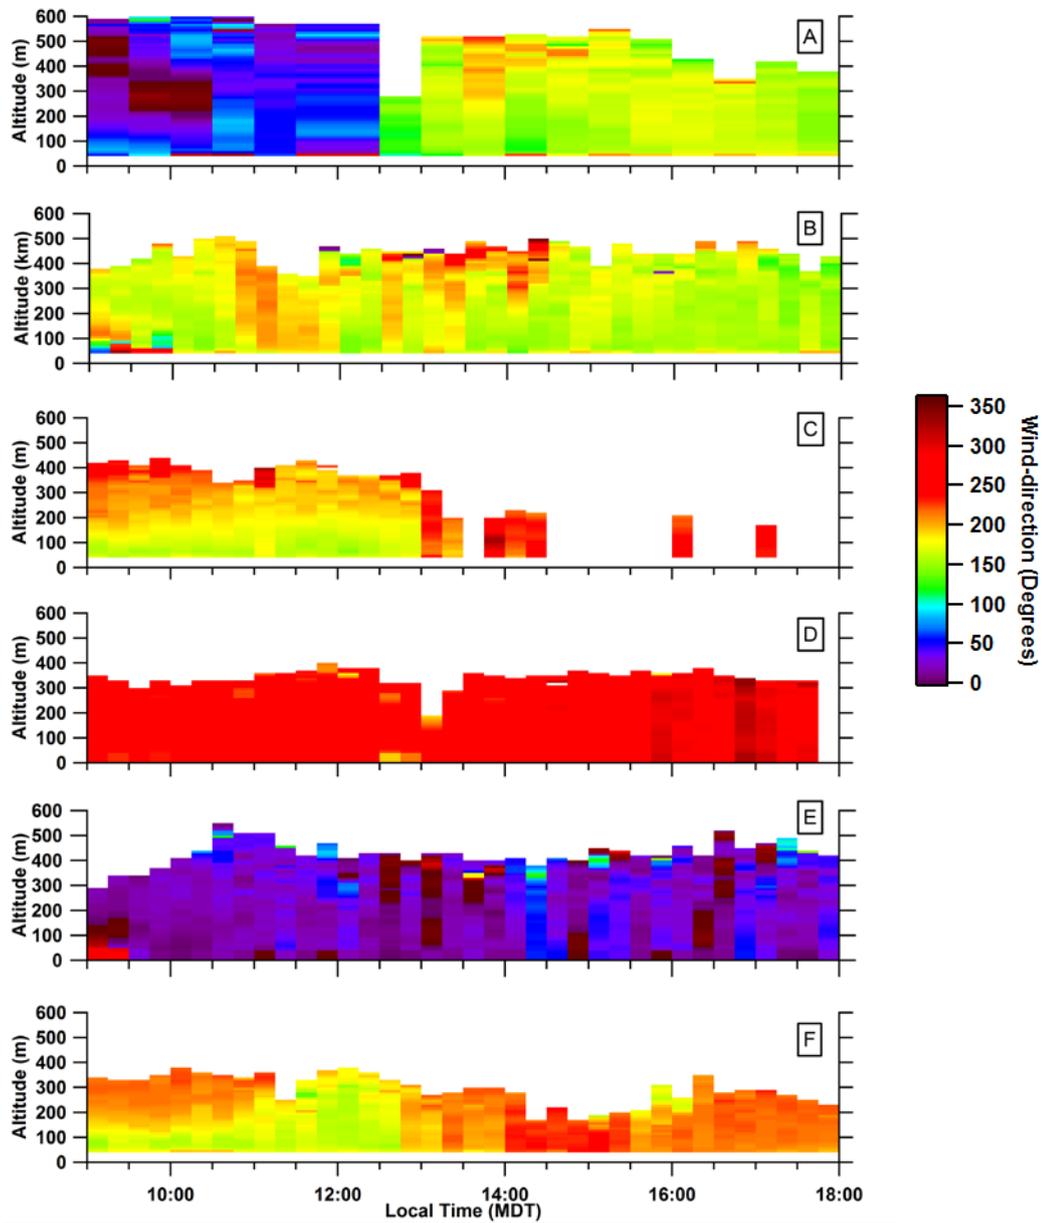

Figure 3 Vertical profiles of wind direction: Aug 23 (A), Sep 03 (B), Sep 04 (C), Sep 05 (D), Sep 06 (E), and Sep 07 (F).

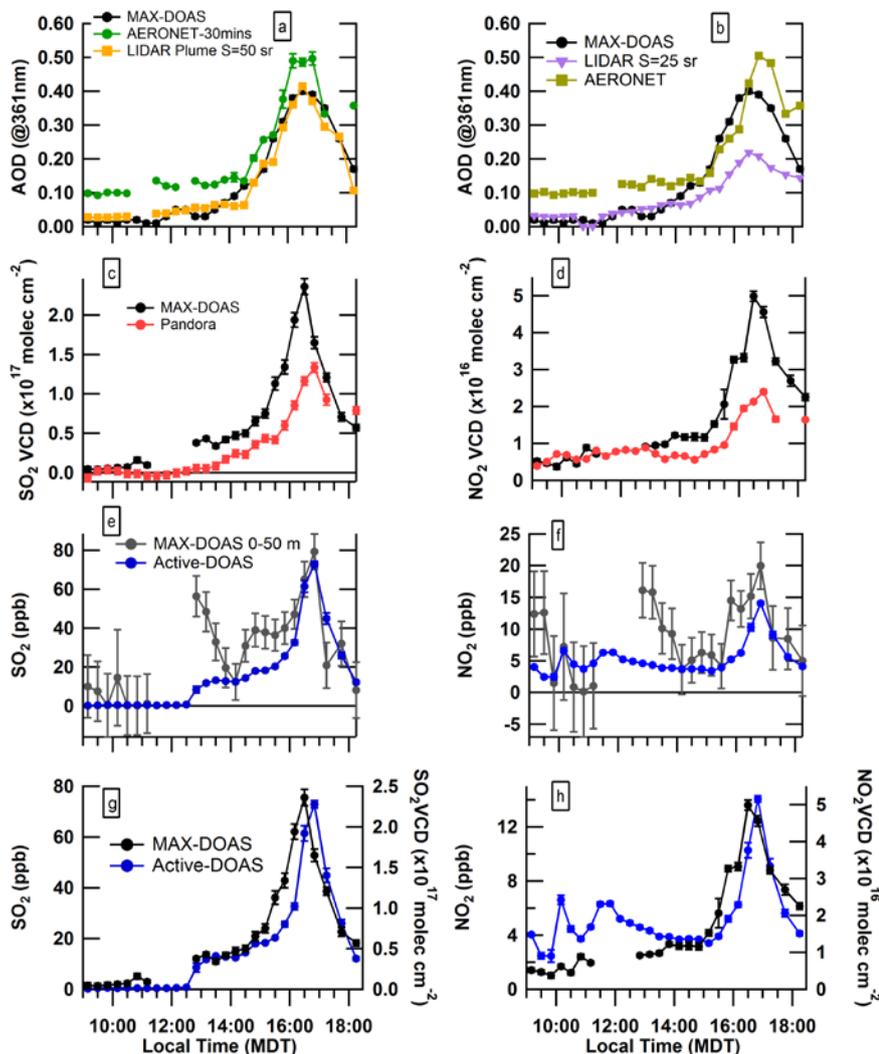

Figure 4 Aug 23 AODs from MAX-DOAS, lidar (S-ratio=44 sr >14:30), and AERONET (-30 mins.) (a); AODs from MAX-DOAS, lidar (S-ratio = 25 sr), and AERONET (b); MAX-DOAS and Pandora SO₂ VCDs (c); MAX-DOAS and Pandora NO₂ VCDs (d); MAX-DOAS 0-100 m and Active-DOAS SO₂ mixing ratios (e); MAX-DOAS 0-100 m and Active-DOAS NO₂ mixing ratios (f); MAX-DOAS VCDs and Active-DOAS mixing ratios of SO₂ (g); and MAX-DOAS VCDs and Active-DOAS mixing ratios of NO₂ (h). MAX-DOAS error bars were obtained from the optimal estimation retrieval. Error bars on the lidar and AERONET AODs are the standard error of the temporally averaged values. Error bars on the Pandora VCDs and Active-DOAS mixing ratios are root sum square errors of the standard error from temporal averaging and the instrumental precision and the DOASIS retrieval error, respectively. See section 2.3.3 for details.

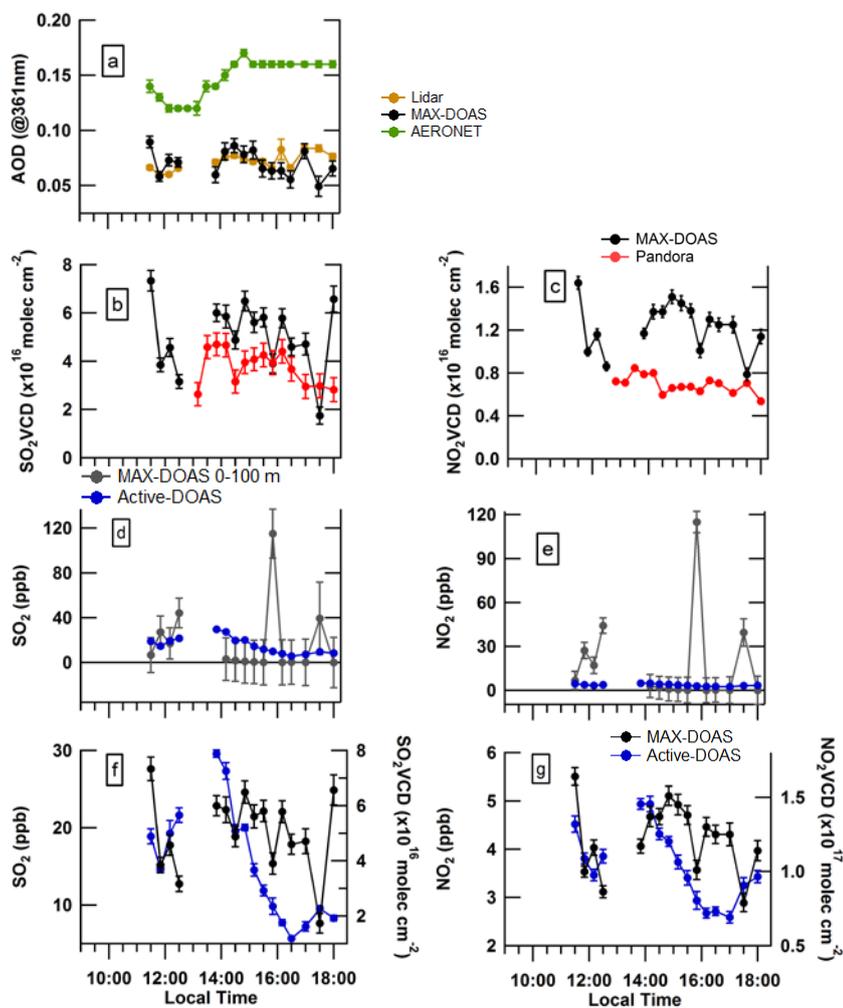

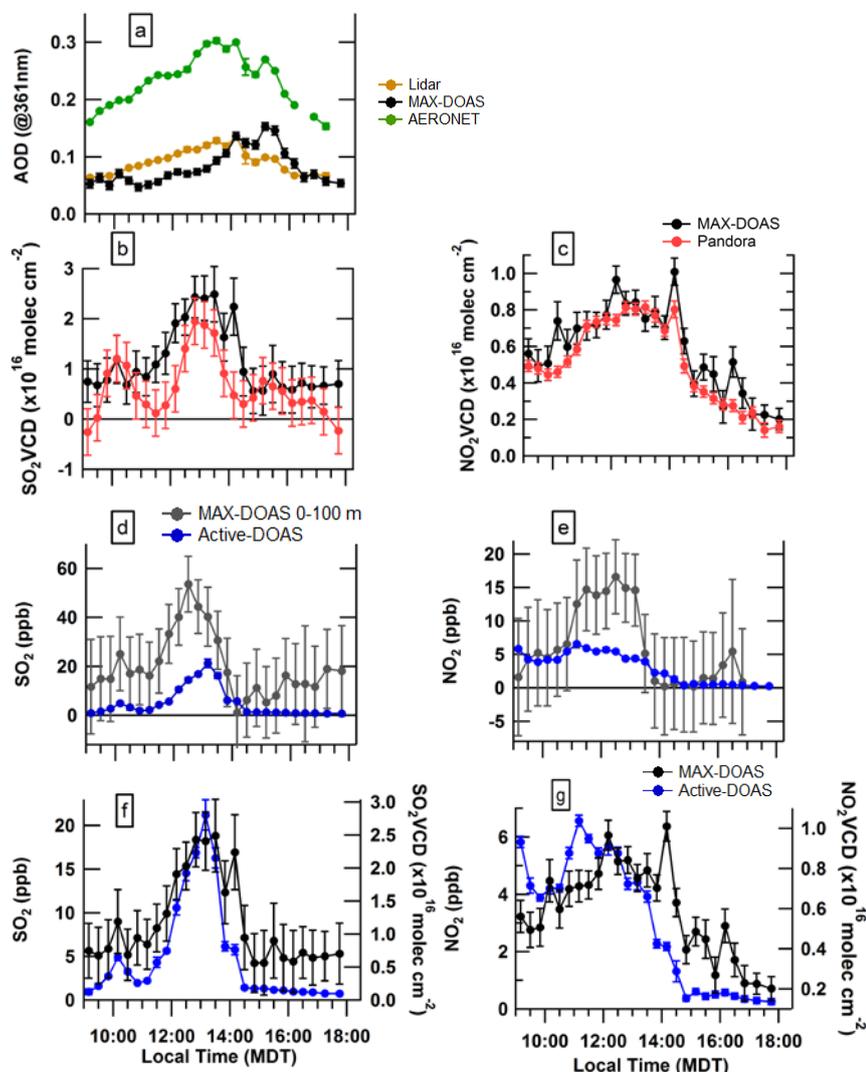

Figure 5 Sep 03 AODs from MAX-DOAS, lidar, and AERONET (a); MAX-DOAS and Pandora SO₂ VCDs (b); MAX-DOAS and Pandora NO₂ VCDs (c); MAX-DOAS 0-100 m and Active-DOAS SO₂ mixing ratios (d); MAX-DOAS 0-100 m and Active-DOAS NO₂ mixing ratios (e); MAX-DOAS VCDs and Active-DOAS mixing ratios of SO₂ (f); and MAX-DOAS VCDs and Active-DOAS mixing ratios of NO₂ (g). MAX-DOAS error bars were obtained from the optimal estimation retrieval. Error bars on the Pandora VCDs and Active-DOAS mixing ratios are root sum square errors of the standard error from averaging and the instrumental precision and the DOASIS retrieval error, respectively. See section 2.3.3 for details.

5 **Figure 6** Sep 04 AODs from MAX-DOAS, lidar, and AERONET (a); MAX-DOAS and Pandora SO₂ VCDs (b); MAX-DOAS and Pandora NO₂ VCDs (c); MAX-DOAS 0-100 m and Active-DOAS SO₂ mixing ratios (d); MAX-DOAS 0-100 m and Active-DOAS NO₂ mixing ratios (e); MAX-DOAS VCDs and Active-DOAS mixing ratios of SO₂ (f); and MAX-DOAS VCDs and Active-DOAS mixing ratios of NO₂ (g). MAX-DOAS error bars were obtained from the optimal estimation retrieval. Error bars on the Pandora VCDs and Active-DOAS mixing ratios are root sum square errors of the standard error from averaging and the instrumental precision and the DOASIS retrieval error, respectively. See section 2.3.3 for details.

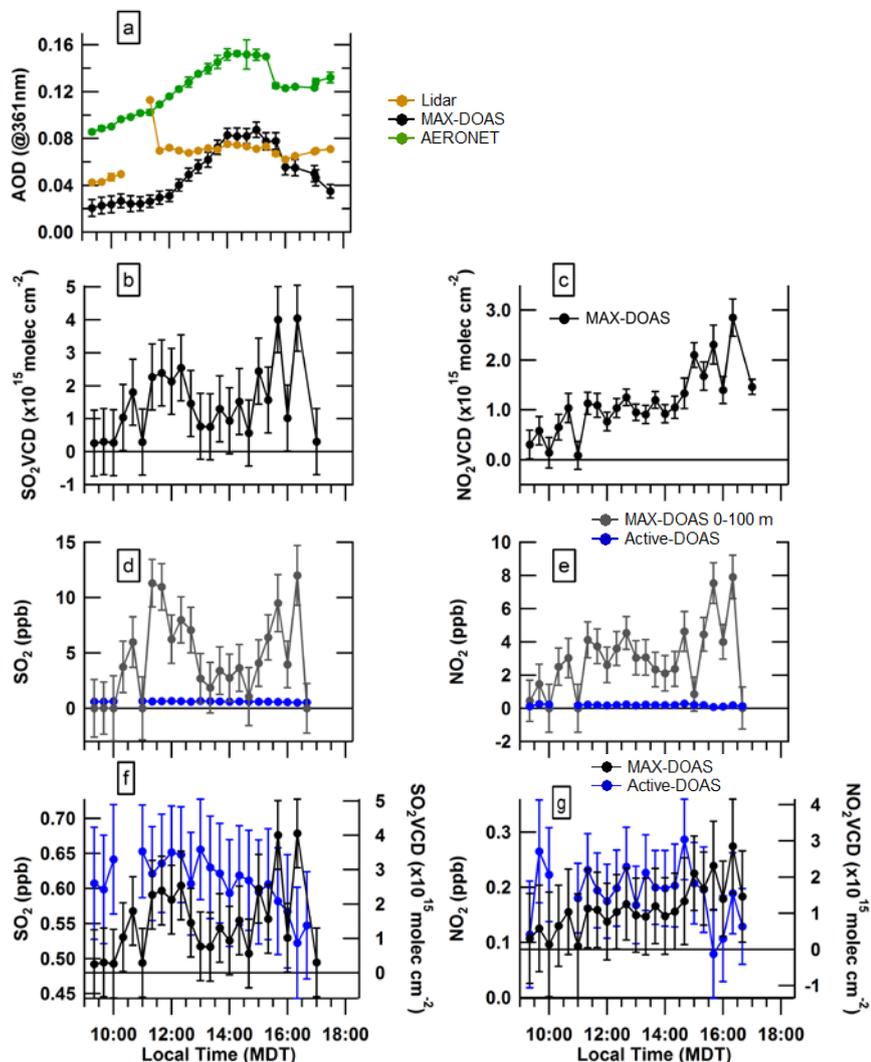

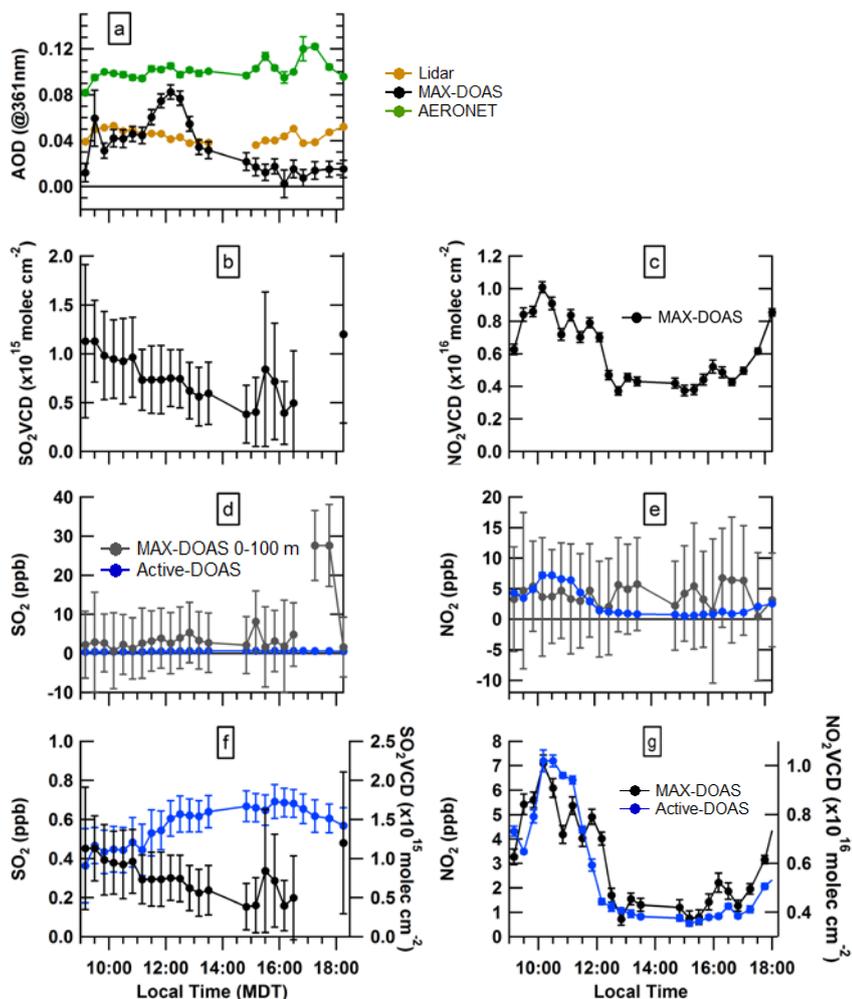

Figure 7 Sep 05 AODs from MAX-DOAS, lidar, and AERONET (a); MAX-DOAS SO₂ VCDs (b); MAX-DOAS NO₂ VCDs (c); MAX-DOAS 0-100 m and Active-DOAS SO₂ mixing ratios (d); MAX-DOAS 0-100 m and Active-DOAS NO₂ mixing ratios (e); MAX-DOAS VCDs and Active-DOAS mixing ratios of SO₂ (f); and MAX-DOAS VCDs and Active-DOAS mixing ratios of NO₂ (g). MAX-DOAS error bars were obtained from the optimal estimation retrieval. Error bars on the lidar and AERONET AODs are the standard error of the temporally averaged values. [Error bars on the Active-DOAS mixing ratios are root sum square errors of the standard error from averaging and the DOASIS retrieval error. See section 2.3.3 for details.](#)

5 **Figure 8** Sep 06 AODs from MAX-DOAS, lidar, and AERONET (a); MAX-DOAS SO_2 VCDs (b); MAX-DOAS NO_2 VCDs (c); MAX-DOAS SO_2 0-100 m and Active-DOAS SO_2 VCDs (b); MAX-DOAS NO_2 VCDs (c); MAX-DOAS SO_2 0-100 m and Active-DOAS SO_2 mixing ratios (d); MAX-DOAS NO_2 0-100 m and Active-DOAS NO_2 mixing ratios (e); MAX-DOAS VCDs and Active-DOAS mixing ratios of SO_2 (f); and MAX-DOAS VCDs and Active-DOAS mixing ratios of NO_2 (g). MAX-DOAS error bars were obtained from the optimal estimation retrieval. Error bars on the lidar and AERONET AODs are the standard error of the temporally averaged values. [Error bars on the Active-DOAS mixing ratios are root sum square errors of the standard error from averaging and the DOASIS retrieval error. See section 2.3.3 for details.](#)

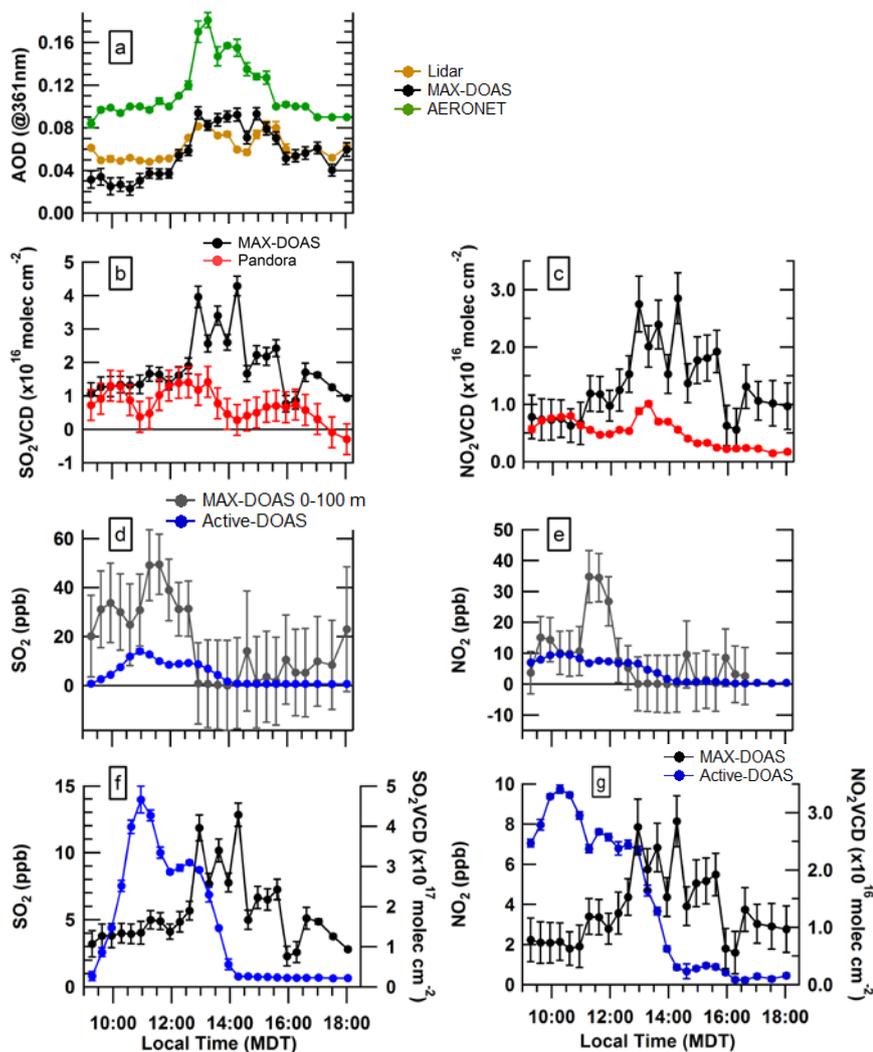

Figure 9 Sep 07 AODs from MAX-DOAS, lidar, and AERONET (a); MAX-DOAS and Pandora SO₂ VCDs (b); MAX-DOAS and Pandora NO₂ VCDs (c); MAX-DOAS 0-100 m and Active-DOAS SO₂ mixing ratios (d); MAX-DOAS 0-100 m and Active-DOAS NO₂ mixing ratios (e); MAX-DOAS VCDs and Active-DOAS mixing ratios of SO₂ (f); and MAX-DOAS VCDs and Active-DOAS mixing ratios of NO₂ (g). MAX-DOAS error bars were obtained from the optimal estimation retrieval. Error bars on the Pandora VCDs and Active-DOAS mixing ratios are root sum square errors of the standard error from averaging and the instrumental precision and the DOASIS retrieval error, respectively. See section 2.3.3 for details.

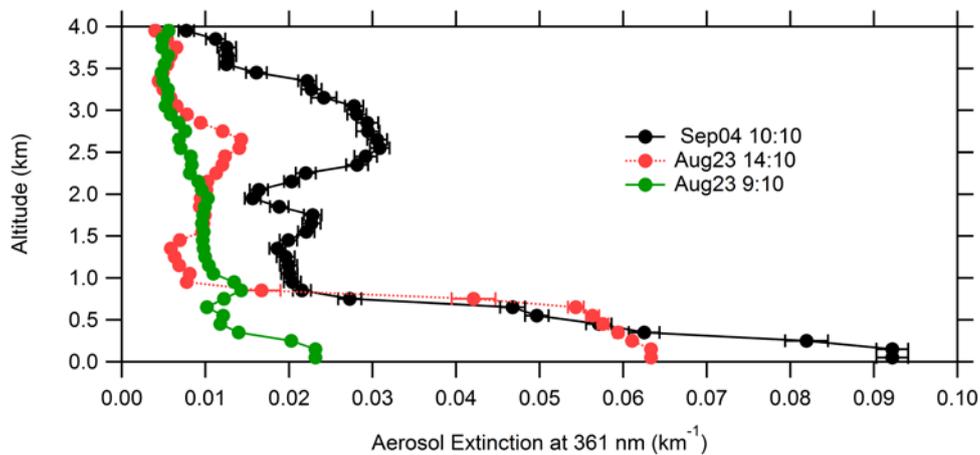

Figure 10 Examples lidar vertical profiles of aerosol extinction (averaged into MAX-DOAS retrieval height intervals and times) on Aug 23 and Sep 04.

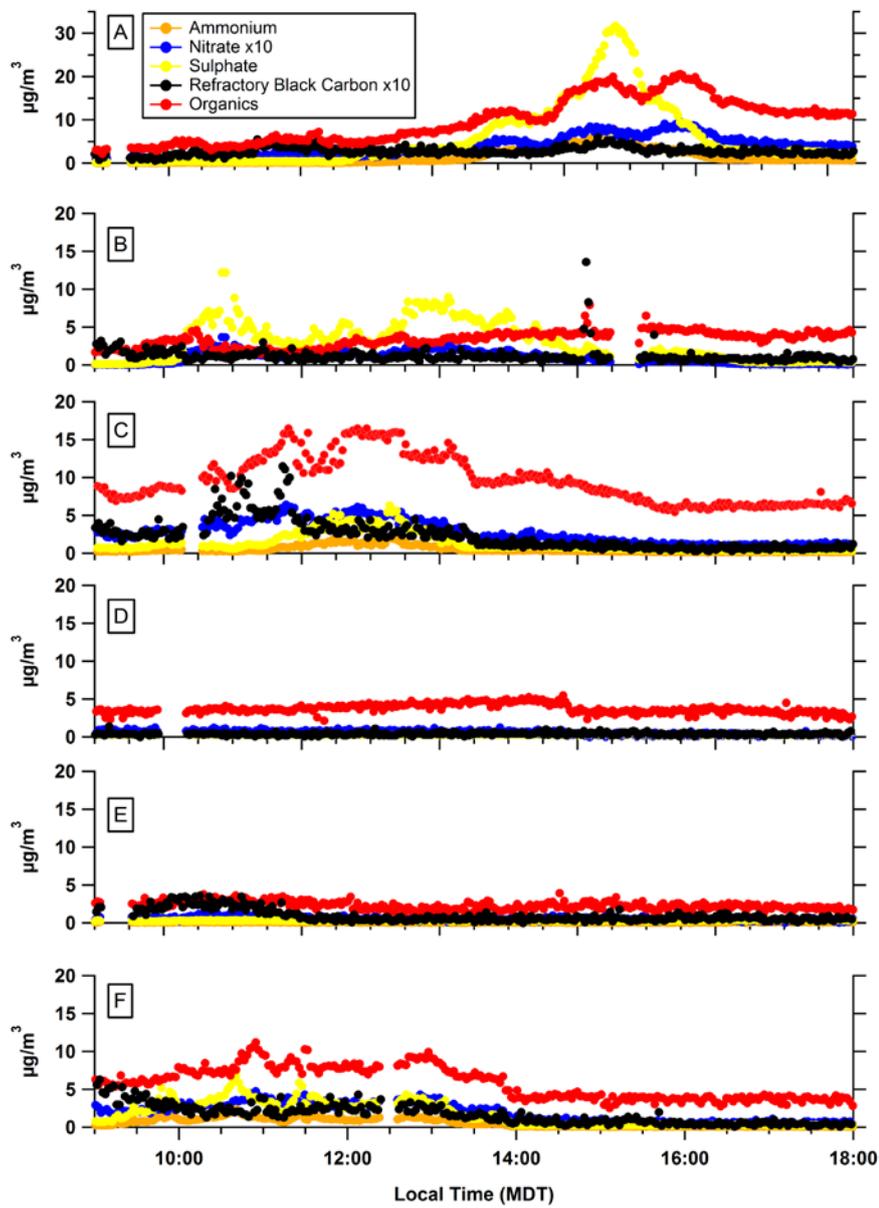

Figure 11 Near-surface particle compositions on Aug 23 (A), Sep 03 (B), Sep 04 (C), Sep 05 (D), Sep 06 (E), and Sep 07 (F). Note different y-axis scale for Aug 23 and that Nitrate and Refractory Black Carbon are shown multiplied by 10.

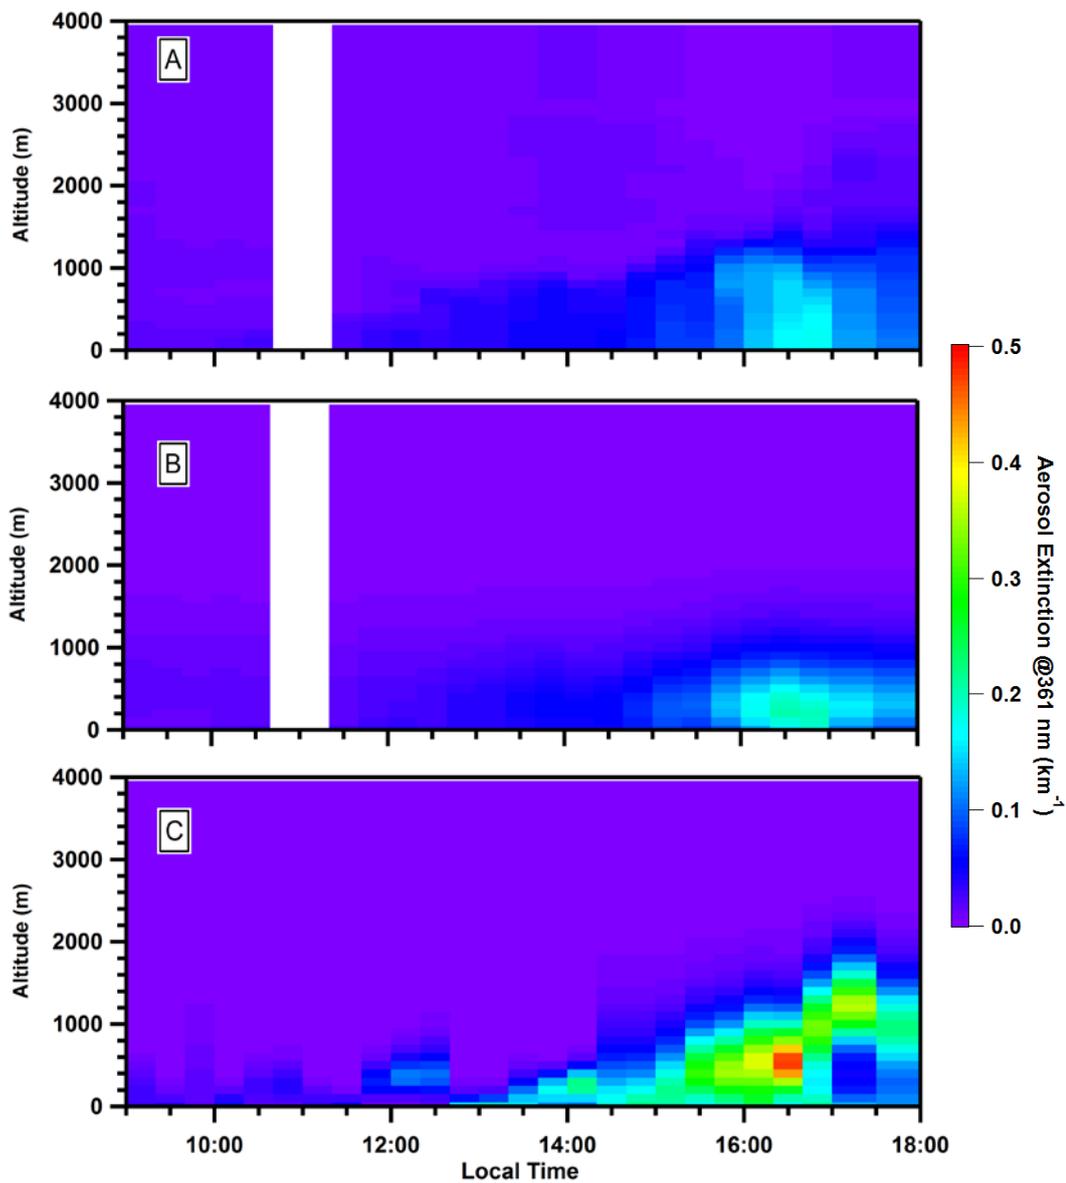

Figure 12 Aug 23 vertical profiles of aerosol extinction (361 nm) from S-ratio=25 sr: averaged lidar (a), smoothed lidar (b), and MAX-DOAS retrieved (c).

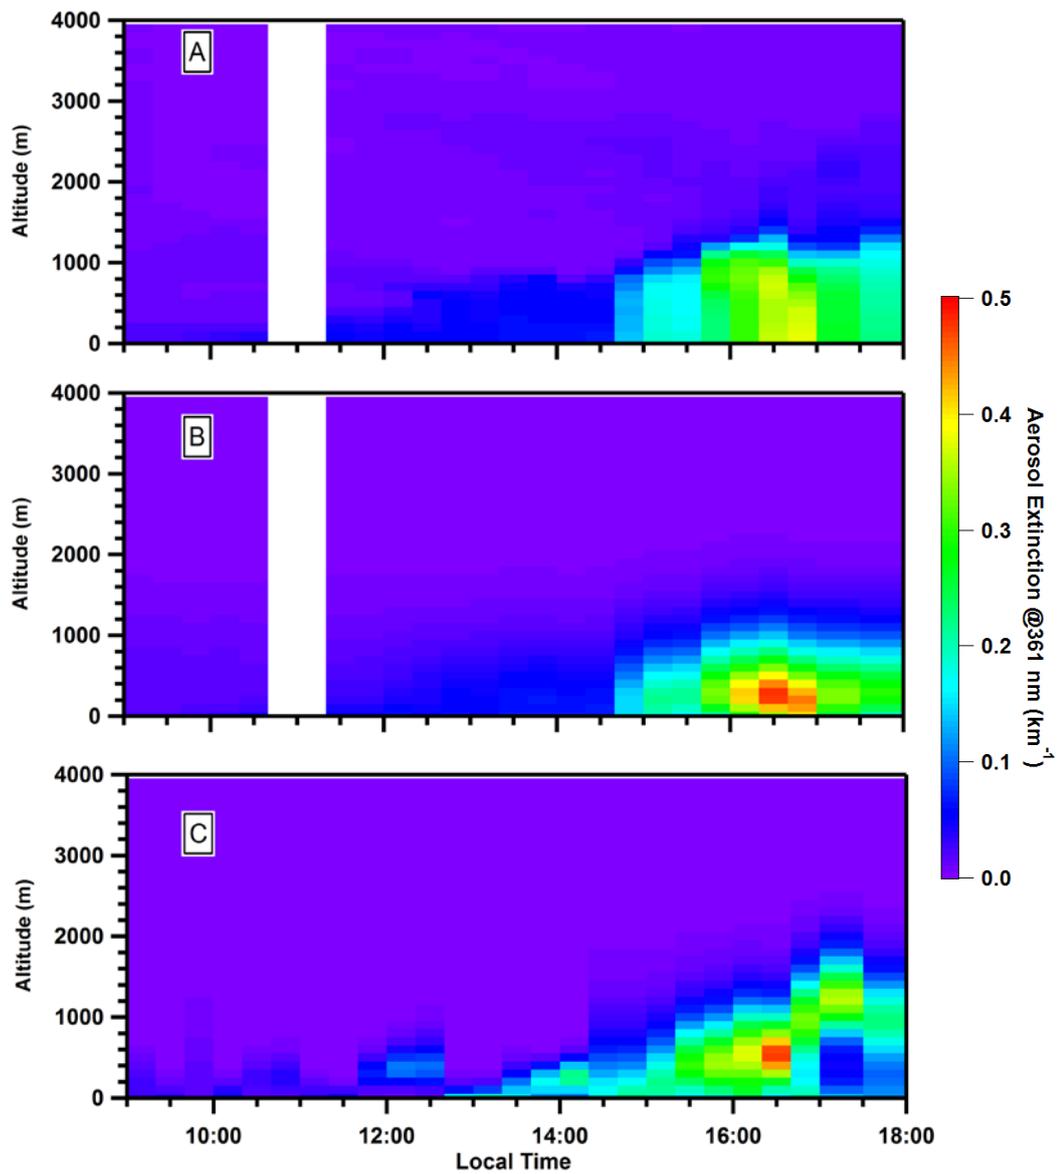

Figure 13 Aug 23 vertical profiles of aerosol extinction (361 nm) from S-ratio=44 sr within the plume >14:30 local time: averaged lidar (a), smoothed lidar (b), and MAX-DOAS retrieved (c).

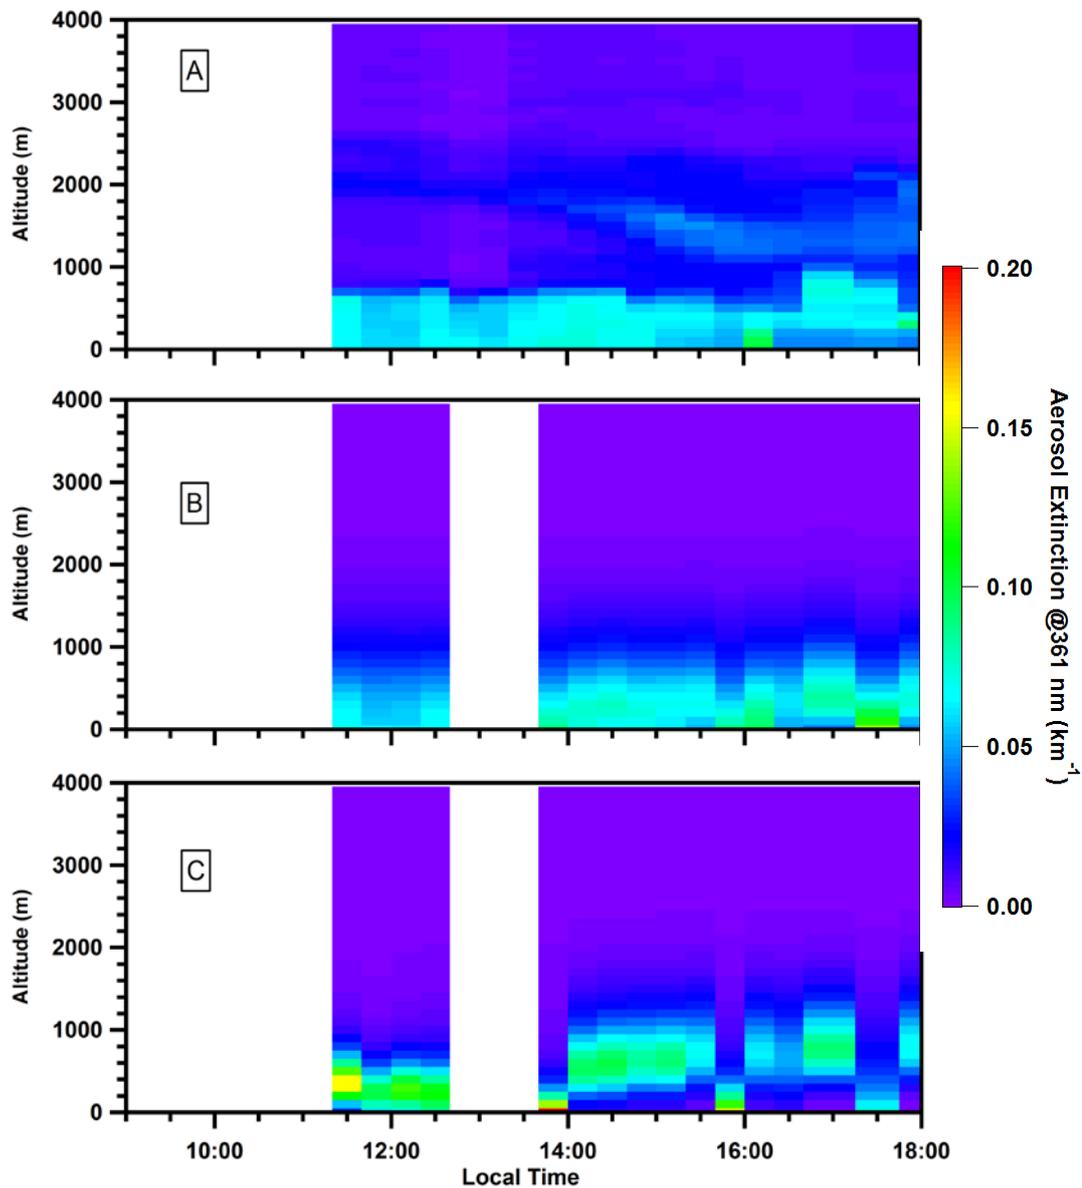

Figure 14 Sep 03 vertical profiles of aerosol extinction (361 nm) from averaged lidar (a), smoothed lidar (b), and MAX-DOAS retrieved (c).

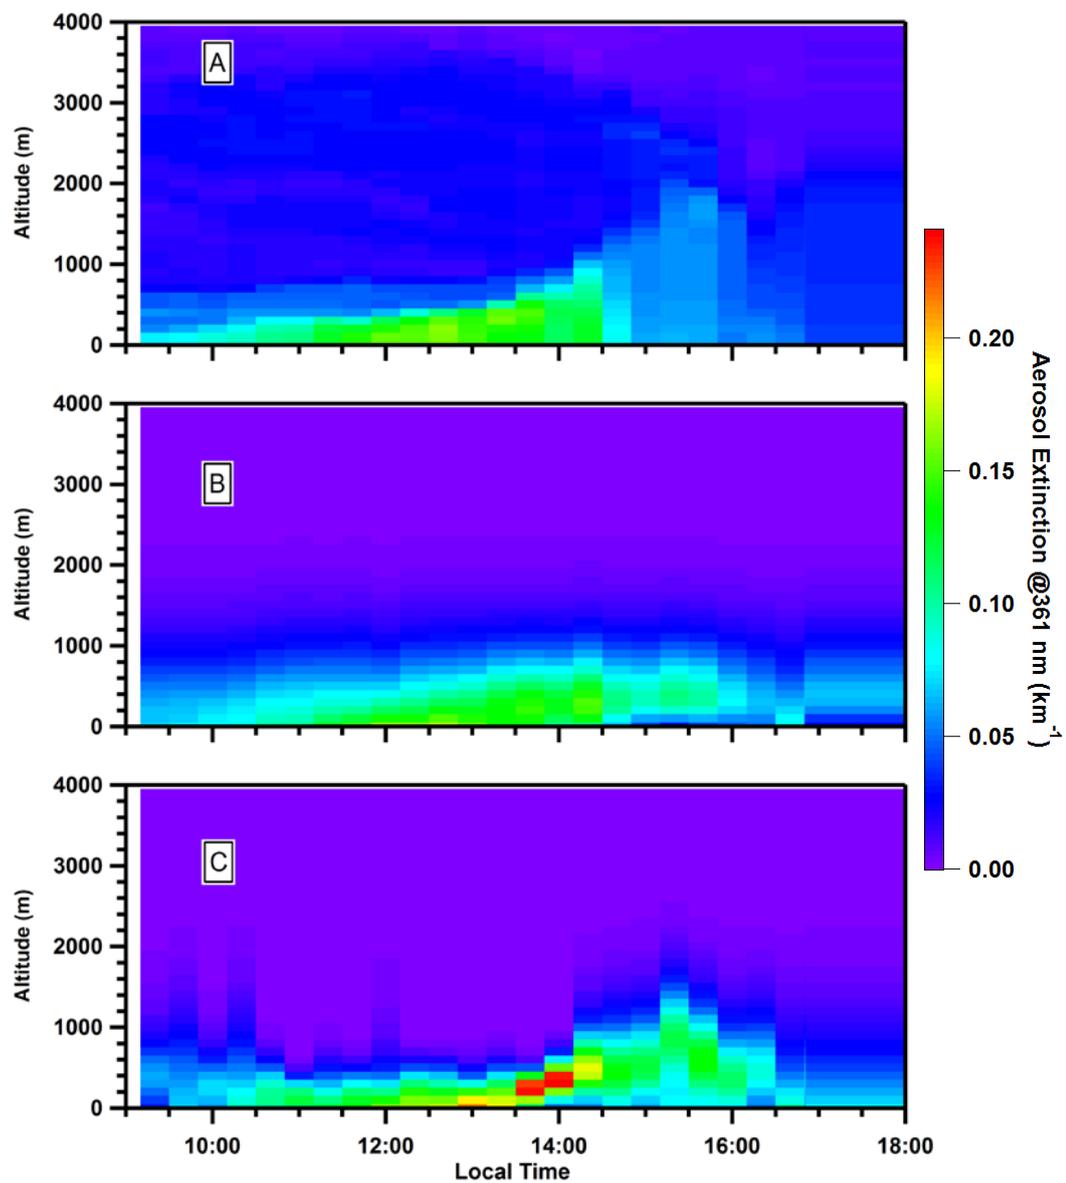

Figure 15 Sep 04 vertical profiles of aerosol extinction (361 nm) from averaged lidar (a), smoothed lidar (b), and MAX-DOAS retrieved (c).

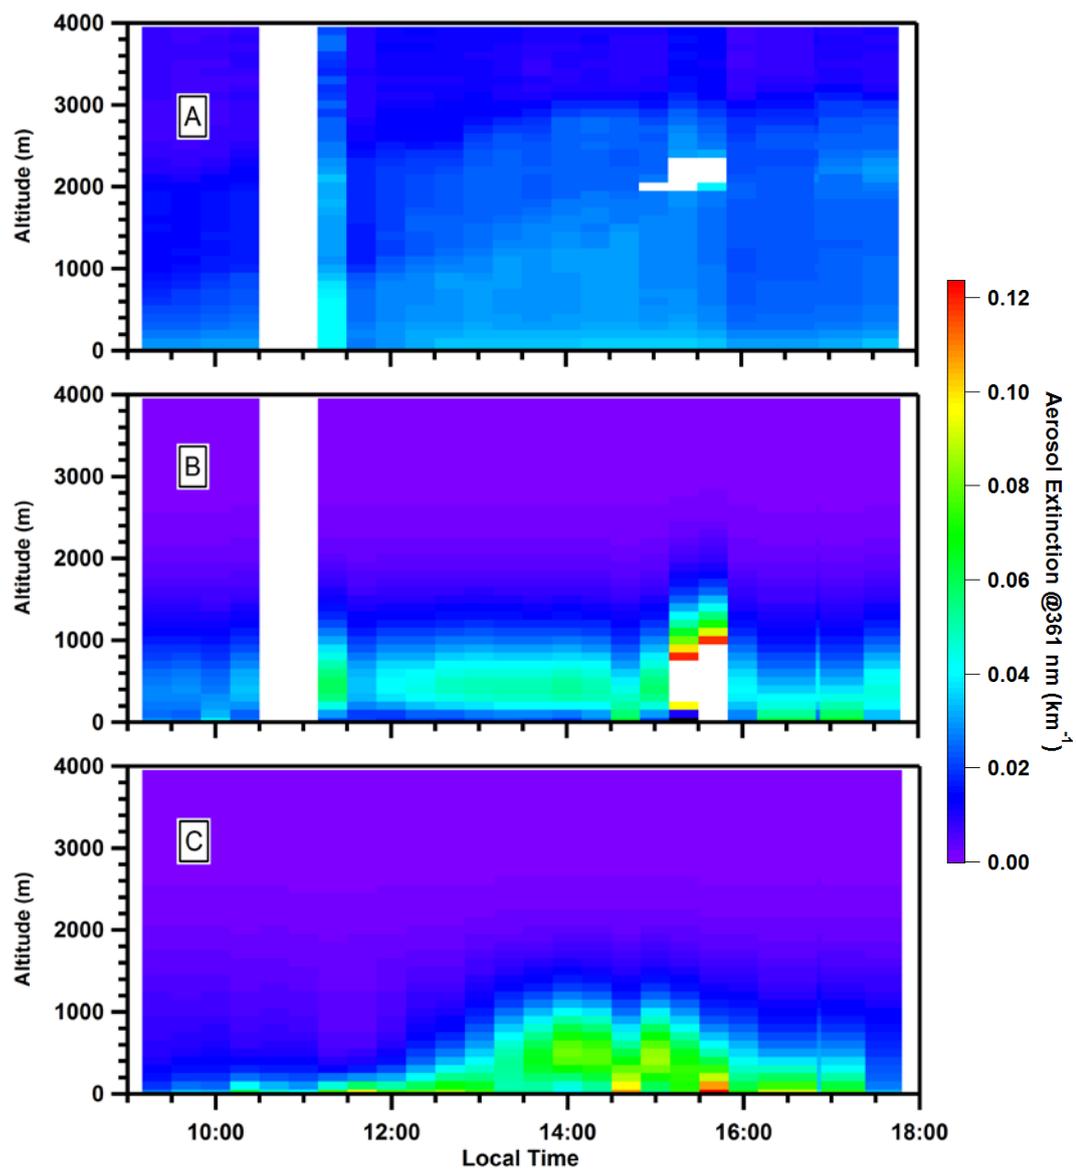

Figure 16 Sep 05 vertical profiles of aerosol extinction (361 nm) from averaged lidar (a), smoothed lidar (b), and MAX-DOAS retrieved (c). Omitted data in the afternoon were measurements of cirrus clouds.

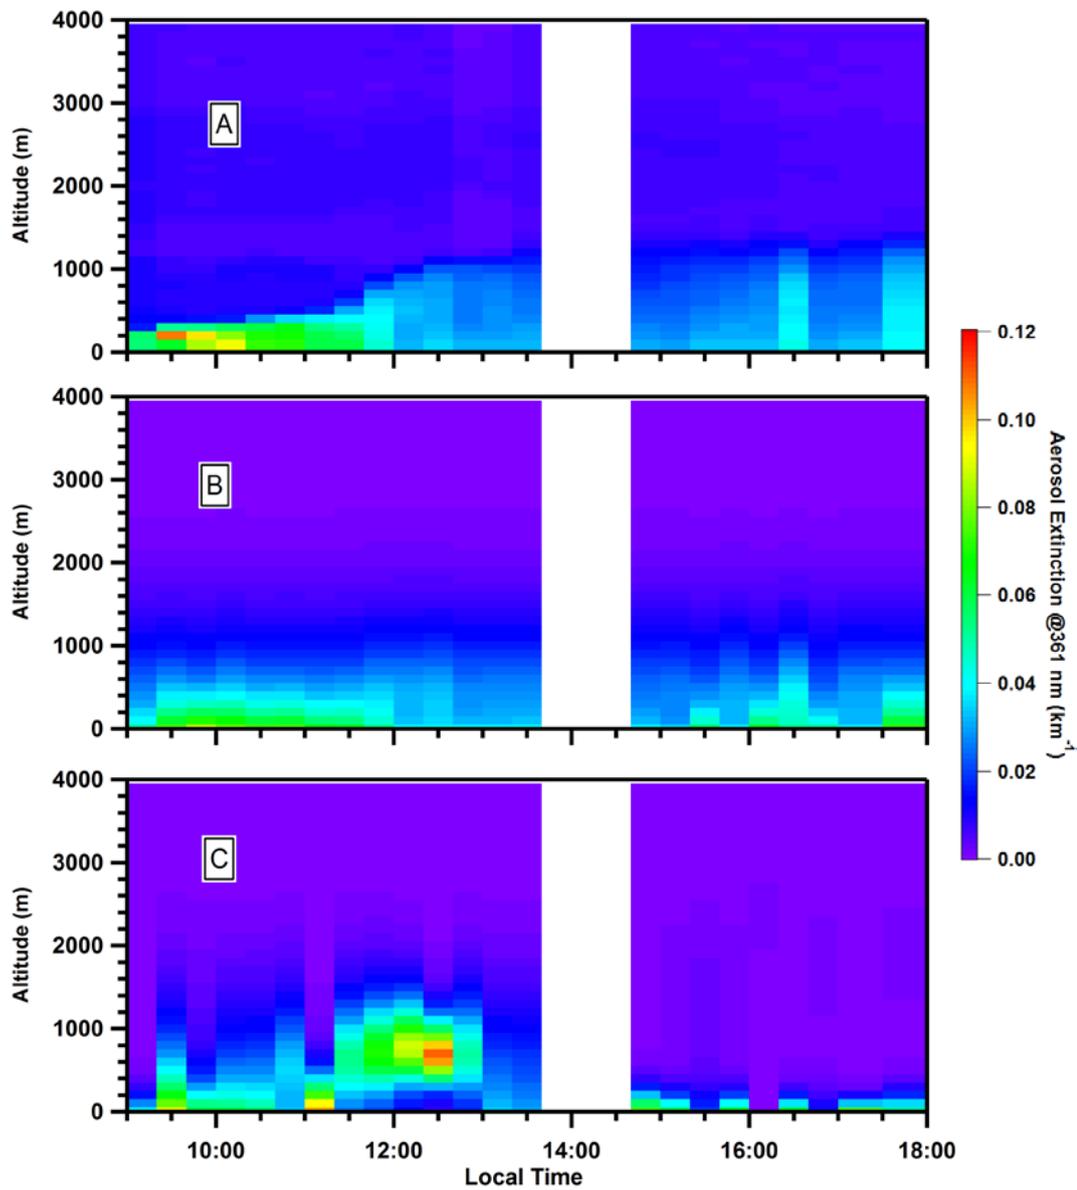

Figure 17 Sep 06 vertical profiles of aerosol extinction (361 nm) from averaged lidar (a), smoothed lidar (b), and MAX-DOAS retrieved (c).

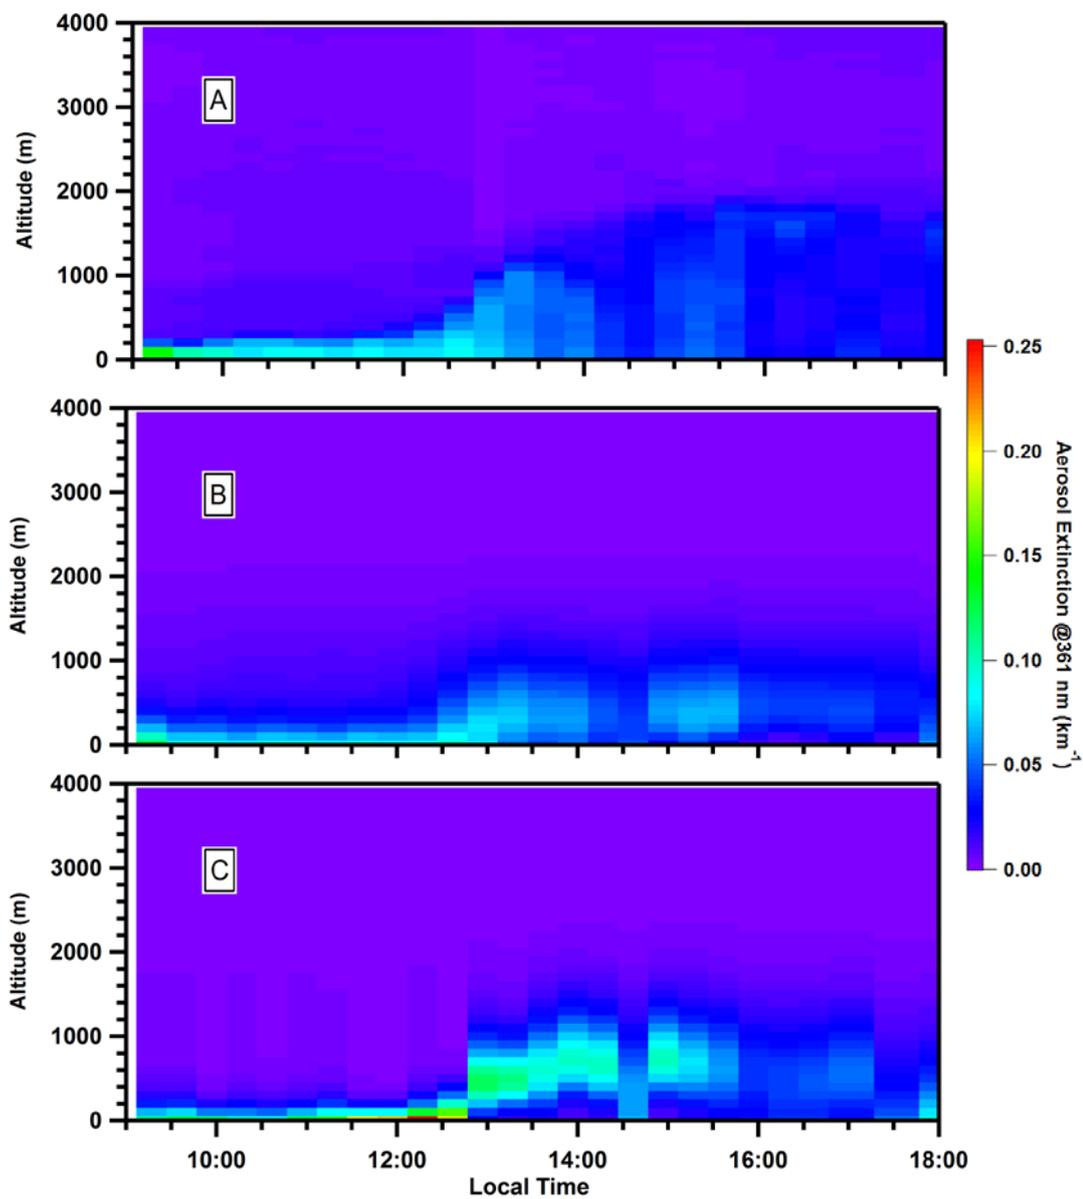

Figure 18 Sep 07 vertical profiles of aerosol extinction (361 nm) from averaged lidar (a), smoothed lidar (b), and MAX-DOAS retrieved (c).

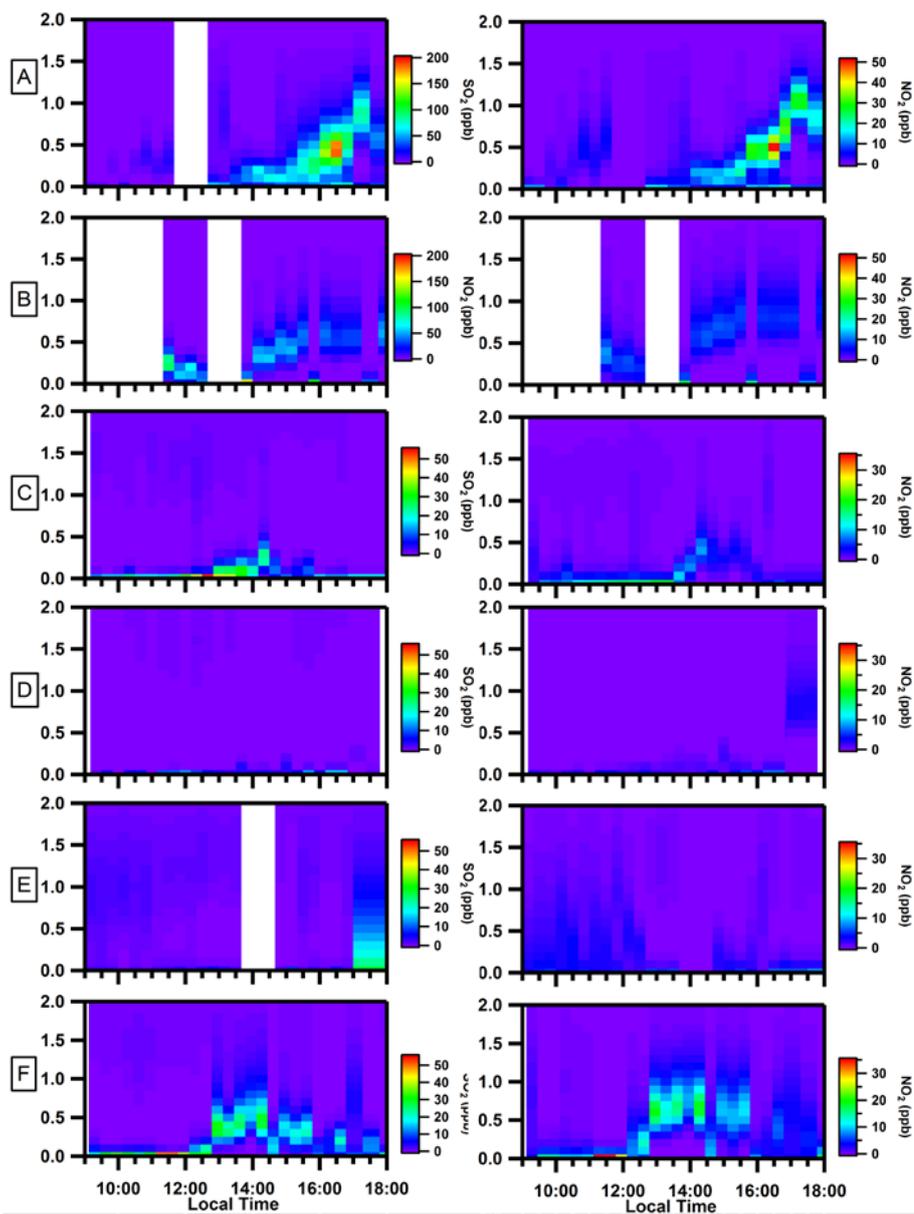

Figure 19 MAX-DOAS vertical profiles of SO₂ (left column) and NO₂ (right column): Aug 23 (A), Sep 03 (B), Sep 04 (C), Sep 05 (D), Sep 06 (E), and Sep 07 (F). Note the different colour scale maximum for Aug 23 and Sep 03.

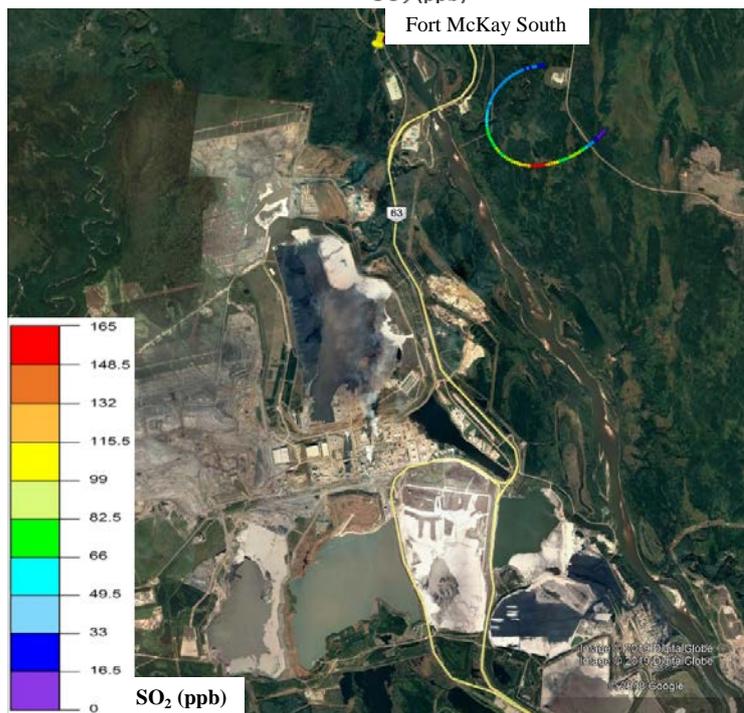

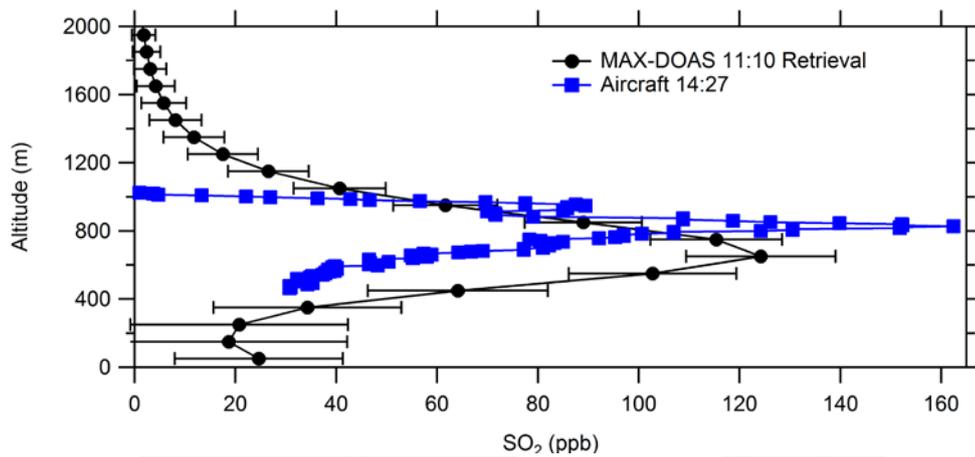

Figure 20 Sep 03 vertical profiles of SO₂ (ppb) from an aircraft spiral measurement (14:26-14:28 local time) and MAX-DOAS retrieved SO₂ vertical profile (local time 11:10). Aircraft spiral shown in Google Earth plot (bottom).
