15 **Abstract**

16 The aerosol optical characteristics in the urban area of Rome were retrieved over a period of 7 years  
17 from March to September 2010-2016. The impact of aerosol single scattering albedo (SSA), optical  
18 depth (AOD), estimated at 400 nm, and Ångström exponent on the ultraviolet (UV) index has been  
19 analyzed. Aerosol optical properties are provided by a PREDE-POM sun-sky radiometer of the  
20 ESR/SKYNET network and the UV index values were retrieved by a Brewer spectrophotometer both  
21 located in Rome. Chemical characterization of urban PM<sub>10</sub> (particulate matter 10 micrometers or less in  
22 diameter) samples, collected during the URBan Sustainability Related to Observed and Monitored  
23 Aerosol (URBS ROMA) intensive field campaign held in summer 2011 in the same site, was performed.  
24 PM macro-components were grouped in order to evaluate the contribution of the main macro-sources  
25 (SOIL, SEA, SECONDARY INORGANIC, ORGANICS and TRAFFIC). Their contributions were  
26 assumed not substantially changed in the other years under study, due to the general stable conditions  
27 during summer seasons in Rome, as reported by the literature. The modulation of their concentration,  
28 according to theoretical calculations, is expected to strongly affect the absorption capability of the  
29 atmosphere over Rome. The surface forcing efficiency, provided by the decreasing trend of UV index  
30 with AOD, which is the primary parameter affecting the surface irradiance during clear sky conditions  
31 in Rome, was found very significant, probably masking the dependence of UV index on SSA and  
32 Ångström exponents. Moreover it was found greater for larger particles and with a more pronounced  
33 slope at the smaller solar zenith angle. In Rome large particles are generally less absorbing since related

34 to the presence of SOIL and SEA components in the atmosphere. The former contribution was found  
35 much higher in summer months because of the numerous episodes of Saharan dust transport  
36

## 37 **1. Introduction**

38 The aerosol influence on the incoming and outgoing solar radiation is a widely studied topic because of  
39 its relation with the Earth's radiative balance and climate. The aerosol influence on ultraviolet (UV)  
40 solar irradiance is also very important, particularly in urban areas, nevertheless still uncertain because  
41 in this wavelength region the columnar absorbing and scattering properties of suspended particles are  
42 not deeply inspected as in the visible spectral range. The aerosol capability of absorbing UV radiation  
43 has important implications for tropospheric photochemistry, human health, and agricultural productivity  
44 (Dickerson et al., 1997; He and Carmichael, 1999; Castro et al., 2001; Casasanta et al., 2011; Mok et  
45 al. 2018).

46 The aerosol single scattering albedo (SSA), that is the ratio of the aerosol scattering to extinction  
47 coefficient, representing an index of the aerosol absorption capability, and the optical depth (AOD), are  
48 important radiative parameters to determine the aerosol effect on the UV irradiance at the surface.

49 Reuder and Schwander (1999) demonstrated that more than 80% of the aerosol effect on surface UV  
50 radiation due to increasing turbidity of the atmosphere can be estimated through aerosol optical depth  
51 and single scattering albedo.

52 UV absorption by aerosol, characterized by low SSA values at wavelengths shorter than 400 nm, is  
53 commonly attributed to organic aerosols that absorb predominantly in the UV region and show a stronger  
54 wavelength dependence than a purely black carbon absorption (Kirchstetter et al., 2004). Also mineral  
55 components shows a significant absorption in the UV region, as highlighted by Meloni et al. (2006).

56 Martins et al. (2009) indicated that the absorption efficiency of urban aerosol is considerably larger in  
57 the UV than in the visible and is probably linked to the absorption by organic aerosol. Similarly, an  
58 enhancement of aerosol absorption at UV wavelengths was observed in urban cities such as Rome, Italy  
59 (Ialongo et al., 2010) and Athens, Greece (Kazadzis et al., 2016), especially in winter.

60 di Sarra et al. (2002), Panicker et al. (2009), and Antón et al. (2011), among others, have shown that an  
61 increase of AOD induces a reduction of the UV index (UVI), an effective parameter to quantify the  
62 potentially harmful effects of UV radiation. These studies suggested that a unit increase in aerosol  
63 optical depth at about 400 nm may produce a significant decrease of UVI which depends on the solar  
64 zenith angle and aerosol properties, and may exceed 50%.

65 This work is aimed at determining for the first time the effect of aerosol optical properties retrieved in  
66 Rome on UV radiation, evaluating the role of SSA, AOD and Ångström exponent. The dataset covers  
67 the period from March to September of 7 years, from 2010 to 2016. Only Spring and Summer periods

68 were selected, when solar zenith angles (SZA) smaller than  $40^\circ$  and then higher values of UVI can be  
69 analyzed. For  $SZA > 40$ , as in winter time, the uncertainty on the irradiances measured by the Brewer  
70 increase due to effects as straight light interference (Bais and Zerefos, 1996) and angular response error  
71 (Antòn et al., 2008). Therefore an enhancement of the estimated error of UV index, which is about 4-  
72 5%, (Schmalwieser et al., 2017) is also expected. This could affect the identification of its variation  
73 caused by aerosol effect, because the UV index is low at  $SZA > 40$  and shows a little range of variability  
74 during the day. Aerosol optical properties were provided by a PREDE-POM sun-sky radiometer of the  
75 ESR/SKYNET ([www.euroskyrad.net](http://www.euroskyrad.net)) network, and the UV index values were measured by a Brewer  
76 spectrophotometer.

77

## 78 **2. The site and Instruments**

79

80 Rome is a large urban site, with about 3 million inhabitants, located 25 km east of the Tyrrhenian Sea,  
81 in the middle of an undulating plain. The atmosphere is affected by urban emissions as well as by semi-  
82 rural particulates and, especially during the summer season, by sea breeze and long-range desert dust  
83 advection from the Saharan region (e.g., Ciardini et al., 2012).

84 Long term measurements of aerosol physical and optical properties, columnar ozone content and UV  
85 irradiance (290 -325 nm) are carried out in Rome, on the roof of the Physics Department of Sapienza  
86 University ( $41.9^\circ\text{N}$ ,  $12.5^\circ\text{E}$ ; altitude 60 m) at the Laboratory of Geophysics. This site is located in the  
87 central sector of the city.

88 Aerosol properties are retrieved by the observations taken in clear sky conditions by the sun-sky  
89 radiometer PREDE/POM model 01, (hereafter called POM). It is a narrow band filter photometer able  
90 to perform measurements of direct solar and diffuse sky irradiances at selected wavelengths (315, 400,  
91 500, 675, 870, 940 and 1020 nm) and at 24 scattering angles, in the range  $[0 - 180^\circ]$  in the almucantar  
92 geometry. The 315 and 940 nm channels are used to retrieve ozone and water vapour columnar content,  
93 whereas the other ones provide information on aerosols. The time resolution is 1 minute for direct  
94 irradiance and 10 minutes for diffuse irradiances. This instrument is part of the European Skynet  
95 Radiometer network (ESR, Campanelli et al., 2012; [www.euroskyrad.net](http://www.euroskyrad.net)) that is a regional subnetwork  
96 of SKYNET (Takamura et al., 2004); it has been operating in Rome since 2010 up to present. Calibration  
97 is performed monthly by the Improved Langley method (Campanelli et al., 2007), a well-tested “on-  
98 site” procedure that allows to frequently check the instrument status.

99 UV irradiance and total ozone content have been measured since 1992 at Rome by the Brewer Mk IV  
100 spectrophotometer No.067. This instrument is also operating by the Physics Department of Sapienza  
101 University at the Laboratory of Geophysics in Rome and is part of a European Brewer Network

102 (EUBREWNET). The Brewer Mk IV is a single monochromator spectrophotometer specifically  
103 designed to retrieve through a well-defined data processing (Siani et al., 2018) the total column ozone  
104 by measuring solar direct irradiances at selected UV wavelengths in the ozone absorption spectrum (Kerr  
105 et al., 1981). The accuracy of direct-sun measurements of total ozone taken with a well-maintained  
106 Brewer spectrophotometer is 1% (Vanicek, 2006). The performance of the Brewer instrument for UV  
107 measurements was controlled every two years till 2014 through intercomparisons to the traveling  
108 reference QASUME UV spectroradiometer operated by Physikalish Meteorologisches Observatorium  
109 Davos/ World Radiation Centre. The mean ratio of Brewer integrated solar UV irradiances to QASUME  
110 is within +3% (see <https://www.pmodwrc.ch/en/world-radiation-center-2/wcc-uv/>). After that the UV  
111 calibration has been carried out by IOS using 1000w lamps which are traceable to the QASUME  
112 reference spectroradiometer (Siani, et al., 2013). The Brewer also measures global spectral irradiances  
113 from 290 nm to 325 nm with a spectral resolution of about 0.5 nm at 0.5 nm steps. UV spectral scans  
114 are performed at Rome every 30 min throughout the day. The SHICrivm algorithm, used to obtain the  
115 biologically effective UV irradiance as explained in the section 3, compensates for the missing  
116 contribution of wavelengths longer than 325 nm. Based on considerations for similar corrections in the  
117 Brewer operating software (Fioletov et al., 2004), we estimate an uncertainty <2% in the UV index value  
118 for solar zenith angles <70° due to this extrapolation.

119  
120 To complete the characterization of aerosol properties at Rome during summer, results from an intensive  
121 field campaign (URBan Sustainability Related to Observed and Monitored Aerosol – URBS ROMA,  
122 Campanelli et al., 2012 ) conducted in the period June – July 2011 in the same location and aimed to  
123 determine the aerosol direct radiative effect at the surface, were used. Particulate matter 10 micrometers  
124 or less in diameter (PM<sub>10</sub>) mass concentrations were collected by using a dual channel sampler (HYDRA  
125 Dual Sampler, FAI Instruments, Fonte Nuova, Rome, IT) equipped with Teflon membrane filters and  
126 quartz fiber filters on the two channels. PM<sub>10</sub> mass concentration was measured on Teflon filters by  
127 gravimetry using an automated microbalance.

128 The elastic Lidar of the Sapienza University was also operative simultaneously with the other  
129 instruments and, in this study, it was used to discriminate days affected by desert dust.

130 Finally, during the period under analysis, the cumulated precipitation measured at the station Roma  
131 Macao of the Ufficio Idrografico e Mareografico of Rome, less than 1 km far from the Department of  
132 Physics of Sapienza University, was also used.

133

### 134 **3. Methodology**

135

136 The POM normalized radiance (that is the ratio between the solar diffuse radiance and direct solar  
137 irradiance) is inverted using the Skyrad4.2 pack (Nakajima et al., 1996), which is an official computer  
138 code of the SKYNET network. Signals from the channels centered at the wavelengths of 400, 500, 675,  
139 870, and 1020 nm are analyzed in order to determine AOD, SSA, and Ångström exponent (Ang), the  
140 latter obtained by using all the wavelengths. In addition, the Ångström exponent is also calculated from  
141 the AOD at 400 and 500 nm ( $Ang_{400-500}$ ) to infer the AOD wavelength dependence in the spectral range  
142 closest to the UV region. Cloud screening and quality check of the retrieved inversions are also  
143 performed. The cloud screening is based on the direct solar irradiance variability in 3 minute time  
144 interval, as explained in Estelles et al. (2012). The quality check of SSA and AOD at 400 nm ( $SSA_{400}$ ,  
145 and  $AOD_{400}$ , respectively), that is the POM shortest wavelength used in this analysis, is based on the  
146 results from the most recent literature on Skyrad pack. Hashimoto et al. (2012) performed numerical  
147 tests on the  $SSA_{400}$  retrievals using the Rstar-6b radiative transfer code (Nakajima and Tanaka, 1986)  
148 and Skyrad pack (versions 4.2 and 5.0) inversions. The simulation of an atmosphere contaminated by  
149 both dust-like and water insoluble aerosols brought to  $SSA_{400}$  values of about 0.70. Simultaneously  
150 values varying between 0.71-0.75 were retrieved testing a cirrus contamination case by enhancing the  
151 coarse mode for simulating the presence of ice particle types (cirrus particles model of the World Climate  
152 Programme report, Deepak and Gerber, 1983). Following these results,  $SSA_{400}$  values lower than 0.70  
153 were rejected in this study because considered unrealistic, but it should be taken into account that values  
154 between 0.71 and 0.75 could contain information on both dust presence and cirrus-cloud contamination.  
155 Hashimoto et al. (2012) also demonstrated that the SSA retrieval by Skyrad4.2 pack is problematic, since  
156 sometimes SSA tends to be unnaturally close to unity, irrespectively of the AOD. Therefore, inversions  
157 where  $SSA_{400}$  assumed values  $\geq 0.99$  were also rejected. In this work we used only SSA at 400 nm as  
158 absorption estimation parameter, because the comparison against retrievals from other versions of the  
159 Skyrad code showed good agreement at this wavelength and discrepancies at the others.

160  
161 The UVI was introduced in Canada in 1992 (Fioletov, 2010) to represent the potentially harmful effects  
162 of UV radiation in a simple form. UVI is a unit-less quantity determined by multiplying the erythemally  
163 weighted UV irradiances (in  $W\ m^{-2}$ ) over the range 280-400 nm by  $40\ m^2W^{-1}$  (Cost -713, 2000). UVI  
164 values are grouped into exposure category expressing the risk for unprotected skin to Sun exposure.  
165 Typically at mid-latitudes, UVI values at noon vary from 0 to 10, but highest UVI values (a peak of  
166 12.3 at Plateau Rosà, 3500 m a.s.l., in Valle d'Aosta Region, Italy) were experienced at high altitude  
167 (e.g., Casale et al., 2015) and lower latitude sites.

168 Spectral UV irradiances, measured by the Brewer spectrophotometer in clear sky conditions (no clouds  
169 over the sun) selected according to Alexandrov et al. (2004) methodology, were used to retrieve UV

170 index values. The spectral irradiances were processed using the SHICrvm software (version 3\_075) to  
 171 obtain the biologically effective UV irradiance by weighting the solar irradiances with a function (action  
 172 spectrum) representing the effectiveness of UV radiation to produce the erythematous response in the skin  
 173 (C.I.E., 1998). The SHICrvm software was also applied to check for any spectral wavelength shift and  
 174 spectral anomalies (Slaper et al, 1995) in the UV data. In addition, since the Brewer MKIV  
 175 spectrophotometer measures spectral irradiances up to 325 nm, the non-measured part of the UVA  
 176 spectrum needed for the calculation of UVI was also extrapolated by the same software.

177 Total ozone values ( $O_3$ ) from direct-sun measurements were generated by using Brewer Processing  
 178 Software, applying the rejection criteria on ozone values less than 100 DU and greater than 500 DU  
 179 (Siani et al., 2018). Yet, individual total ozone values were discarded when standard deviation is above  
 180 2.5 DU and ozone air mass is above 3.5 (The Ozone air mass is defined as the ratio of the actual ozone  
 181 path length taken by the direct solar beam to the analogous vertical ozone path when the Sun is overhead  
 182 from the surface to the top of the atmosphere).

183  
 184 To discern the dependence of UVI only on aerosol characteristics, the UVI dependence on the solar  
 185 zenith angle ( $\theta$ ), ozone content, and orbital parameters (varying Earth-Sun distance) must be taken into  
 186 account. Therefore, firstly the UVI was corrected for the variation of the Earth-Sun distance and values  
 187 were reduced to the mean Sun-Earth distance (Madronich, 1993). Secondly, only data at two values of  
 188  $\theta$ ,  $30^\circ$  and  $40^\circ$ , were selected. This criterion excludes winter data, when the solar zenith angle is always  
 189 higher than  $40^\circ$  in Rome. Thirdly, the UVI dependence on total  $O_3$  has been removed. This correction  
 190 has been implemented using the Radiation Amplification Factor (RAF) and scaling the UVI to the total  
 191 diurnal ozone average value measured during the day with the lowest  $AOD_{400}$  recorded in the entire  
 192 dataset (303 DU on September 2, 2014). Infact the effect of ozone on the erythematous UV irradiance may  
 193 be described as suggested by Madronich (1993) and Booth and Madronich (1994):

$$194 \quad \frac{E^*}{E} = \left( \frac{O_3}{O_3^*} \right)^{RAF}, \quad (1)$$

195 where  $E$  and  $E^*$  are two UV irradiances observations, and  $O_3$  and  $O_3^*$  their corresponding total ozone  
 196 amounts.

197 Similarly, it is possible to apply the above relationship to UVI:

$$198 \quad UVI^* = UVI \left( \frac{\langle O_3 \rangle}{O_3^*} \right)^{RAF}, \quad (2)$$

199 where  $\langle O_3 \rangle$  is the diurnal ozone average value,  $O_3^*$  is the diurnal ozone average value during the day  
 200 with the minimum average  $AOD_{400}$ , and RAF is assumed to be equal to 1.25, according to di Sarra et al.  
 201 (2002). di Sarra et al. 2002 (Figure 8) retrieved values of RAF after correcting for the influence of co-  
 202 varying aerosol optical depth. They retrieved values between 1.0 and 1.2 at  $30^\circ$  and  $40^\circ$  solar zenith

203 angle when considering all aerosol conditions. As discussed in the paper, these values are affected by  
204 different processes (the wavelength dependence of the aerosol sensitivity, the interdependence between  
205 ozone and aerosol, possibly through increased ozone absorption following enhanced scattering by  
206 aerosols, ozone and aerosol vertical distributions). The values of 1.25 was derived from UVSPEC  
207 radiative transfer model calculations where the aerosol amount was kept fixed. This value is also in  
208 agreement with various other determinations of the ozone RAF (e.g., De Luisi and Harris, 1983;  
209 McKenzie et al., 1991; Kerr and McElroy, 1993). However a sensitivity study of UVI\* on RAF variation  
210 from 1 to 1.25 has been performed over all the dataset showing an average decreasing of UVI\* of about  
211 1.4% that is within the declared uncertainty of 4-5%, (Schmalwieser et al., 2017).

212 To point out the possible effect of aerosol optical characteristics measured at 400 nm on UVI\*, AOD<sub>400</sub>,  
213 SSA<sub>400</sub>, Ang and Ang<sub>400-500</sub> were analyzed as function of UVI\* at the two fixed solar zenith angles, taking  
214 estimations of aerosol parameters and UVI\* within  $\pm 5$  minutes.

215

216 Chemical characterization of the collected PM<sub>10</sub> dust, during the URBS campaign, was carried out  
217 according to the method reported in Perrino et al. (2009). Briefly, elements were determined on Teflon  
218 filters by X-ray fluorescence (XRF); then the filters were water-extracted and analyzed for their ionic  
219 content by ion chromatography (IC); elemental and organic carbon (EC and OC) were detected on quartz  
220 filters by thermo-optical analysis (NIOSH-QUARTZ temperature protocol). This overall analytical  
221 procedure allows the determination of each individual component typically accounting for more than  
222 1% of the PM<sub>10</sub> mass (macro-components: Si, Al, Fe, Na, K, Mg, Ca, chloride, nitrate, sulfate,  
223 ammonium, elemental carbon, organic carbon) and to obtain the mass closure.

224 PM<sub>10</sub> macro-components can be grouped into five clusters to estimate the contribution of the main  
225 macro-sources: SOIL, SEA, SECONDARY INORGANICS, ORGANICS, and TRAFFIC. Details about  
226 the algorithms are reported in Perrino et al. (2014). The contribution of SOIL was calculated by adding  
227 the concentration of elements (as metal oxides) generally associated with mineral dust: Al, Si, Fe, the  
228 insoluble fractions of K, Mg, and Ca (calculated as the difference between XRF and IC determinations),  
229 calcium and magnesium carbonate (calculated as the sum of soluble calcium multiplied by 1.5 and  
230 soluble magnesium multiplied by 2.5); SEA was estimated from the sum of Na<sup>+</sup> and Cl<sup>-</sup>, multiplied by  
231 1.176 in order to take into account minor sea-water components; SECONDARY INORGANICS were  
232 calculated as the sum of non-sea-salt sulphate, nitrate, and ammonium; the contribution of road  
233 TRAFFIC was estimated by adding elemental carbon to an equivalent amount multiplied by 1.1 in order  
234 to consider the contribution of primary organic matter that can be adsorbed on particles surface; the  
235 remaining organic carbon, multiplied by 1.6 to take into account non-C atoms, constituted the  
236 ORGANICS and included both secondary organic species and primary components.

237 During the same campaign, the presence of Saharan dust over Rome was detected by manually  
238 inspecting the Lidar Backscatter ratio at 532 nm. Days showing aerosol above the Boundary layer, and

239 the simultaneously check of the Hysplit (Draxler et al., 1998) back-trajectories (bringing airmass from  
240 Saharah reagions), were classified as “dusty”.

241

242 Finally to help the understanding of the possible different effects of PM<sub>10</sub> macro-components  
243 concentration on the atmosphere over Rome, the imaginary parts of refractive index of each fundamental  
244 materials in the Rstar model, were taken as reference. Rstar is a radiative transfer model (Nakajima and  
245 Tanaka 1986) able to simulate the radiation fields in the atmosphere-land-ocean system at the  
246 wavelength range 0.17 – 1000 μm. Eight fundamental materials (water, dust-like, sea salt, volcanic ash,  
247 yellow sans, ice, water-soluble, soot and 75%H<sub>2</sub>SO<sub>4</sub>) are considered to assemble a three component  
248 internal mixture for each of the ten particles model types (Water, dust-like, volcanic-ash, rural, urban,  
249 yellow sand, ice, soot, 75%H<sub>2</sub>SO<sub>4</sub>, sea spray, tropo). In this study the refractive indexes for sea salt, soot  
250 and dust-like fundamental materials were taken as reference.

251

#### 252 **4. Results**

253 The analyzed dataset covers the period March – September from 2010 to 2016 (for the last year the series  
254 end in August). Figure 1 shows monthly averages of SSA<sub>400</sub>, AOD<sub>400</sub>, and Ångström exponent for the  
255 period under examination. Annual means (calculated over the 7 months under study) of SSA<sub>400</sub> vary  
256 between a minimum value of 0.84±0.08 (observed in 2016) and a maximum of 0.97±0.03 (observed in  
257 2015). A comparison against AERONET retrievals obtained from measurements taken in TorVergata, a  
258 semirural area 14 km south east of the town, is also shown in Figure 1 (red points). The AERONET  
259 inversion, performed according to Dubovik and King (2000), is able to retrieve aerosol optical properties  
260 from Sun and sky radiance measurements. In this study we used level 1.5 data and Version 3 inversion  
261 algorithm (Giles et al., 2019). Although the two sites are slightly different in terms of atmospheric  
262 particles optical properties and the wavelength used for AOD, SSA and Ångström differs (380, 440 and  
263 440-870 nm, respectively), the agreement between the AERONET and SKYNET properties is mostly  
264 within the SKYNET standard deviations. This is true also in the 3 common months of 2016 when a  
265 large decreasing trend in SSA is visible in both the sites. The decrease is even stronger from March to  
266 May, however, we are not able to identify the reason for this enhanced aerosol absorption. Differently  
267 in summer 2014 a stronger absorption in TorVergata is observed respect to Rome. Di Ianni et al. (2018),  
268 in a long term analysis of AERONET TorVergata data from 2001 to 2017, showed this period starting  
269 in Autumn 2013 and ending in Autumn 2014 as an anomalous one in terms of absorption and turbidity  
270 of the atmosphere over the site. AOD<sub>400</sub> annual mean values range between a minimum of 0.14±0.06 (in  
271 2014) and a maximum of 0.36±0.10 (in 2015; values higher than 0.3 are measured only in this year for  
272 the period under study). The Ångström exponent varies between 0.56±0.29 (in 2012) and 1.49±0.21 (in

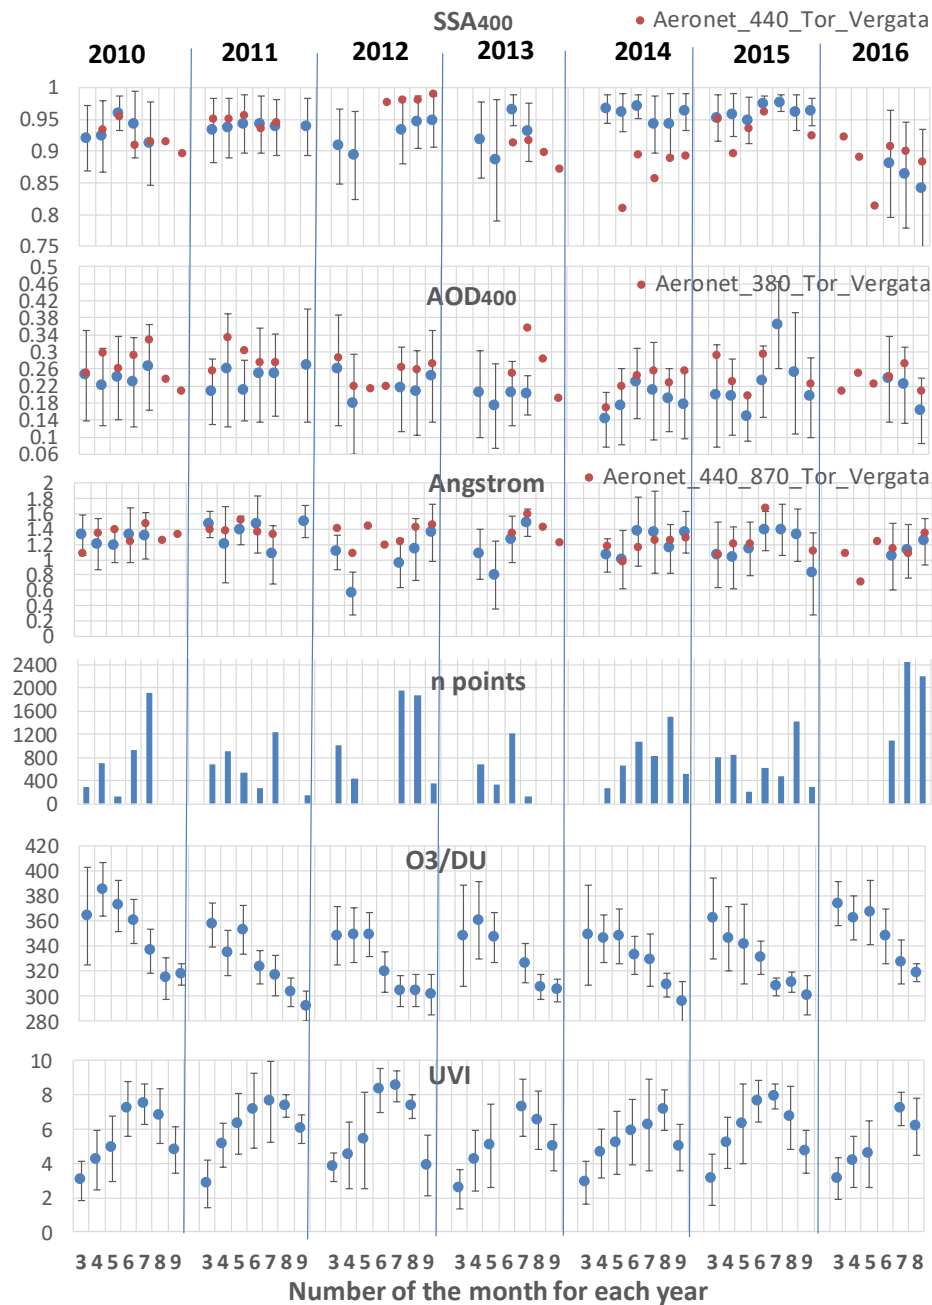

273 2011). The total ozone content values and UVI at local noon are also plotted in Figure.1. The seasonal  
274 ozone behavior is typical of mid-latitude sites, with highest values measured in spring and particularly  
275 in April 2010 (385 D.U. ) and March 2016 (374 D.U.). As expected, UVI has a bell-shape behavior  
276 generally peaked in July.

277 Scatter plots of monthly average  $SSA_{400}$  and UVI versus monthly precipitation (Figure. 2) were  
278 performed in order to check if precipitation can affect on average the optical parameters.

279 The only two parameters showing a slight correlation are  $SSA_{400}$  ( $R=0.30$ ) and UVI ( $R= -0.60$ ),  
280 highlighting that higher precipitation is associated with higher values of SSA (therefore less absorbent  
281 particulate) and with lower UVI values. These correlations among monthly mean values may be  
282 incidental, or due to the combination of different processes. In particular, we may expect that a higher  
283 occurrence of scattered clouds conditions, corresponding to lower UVI values passing the cloud  
284 screening procedure (no cloud over the sun), may be associated with periods with high precipitation  
285 during short-lived weather spring-summer disturbances. Possible effects on  $SSA_{400}$  may be linked to  
286 the possible influence of high humidity conditions, leading to a larger water content in soluble particles.  
287 This is however speculative, and a detailed analysis goes beyond the scope of this paper.

288 During June-July 2011 the chemical analysis of the collected  $PM_{10}$  (Figure 3) measured an average  
289 contribution over the entire mass of about 29% of SOIL, 6% of SEA, 23% of SECONDARY  
290 INORGANIC, 28% of ORGANICS and 9% of TRAFFIC components. During the URBS- ROMA  
291 campaign, the elastic Lidar showed the presence of significant events of desert dust transport, the  
292 strongest observed during the days highlighted in orange in Figure 3. It must be considered that in the  
293 days flagged as “dusty”, dust can remain at a higher level and not measurable at ground (this is the case  
294 of 3 and 18 July). Conversely, sometimes a lot of aerosol is visible at ground level but it was not possible  
295 discriminating the presence of desert dust from the local SOIL component (this is the case of July 2 and  
296 17). The atmosphere over Rome, during summer, can be characterized by a contribution of SEA  
297 comparable with TRAFFIC, or even greater during days with no desert dust advection. The absorption  
298 capability of these two components is very different: in the Rstar radiative transfer model at 413 nm the  
299 imaginary part of marine aerosol refractive index (sea salt) is  $2.42 \times 10^{-8}$ , whereas for soot, that is the  
300 fundamental material characterizing the TRAFFIC component, is  $4.57 \times 10^{-1}$ . The mineral component  
301 (dust-like) has a refractive index of  $7.95 \times 10^{-3}$  at the same wavelength. It is therefore expected that the  
302 modulation of the concentration of the three co-existent materials, can strongly affect the absorption  
303 capability of the atmosphere over Rome.

304

307 Figure 1: Monthly averages of SSA<sub>400</sub>, AOD<sub>400</sub>, Ångström exponent, cumulated precipitation, total O<sub>3</sub>  
 308 and UVI at local noon for each year from 2010 to 2016. The number of points refers to the data used to  
 309 retrieve the aerosol parameters. Error bars are the standard deviation. Red points are AERONET  
 310 retrievals at 440 nm.

311  
 312 Figure 2: monthly average of  $SSA_{400}$  (left) and UVI (right) at local noon versus monthly precipitation  
 313  
 314

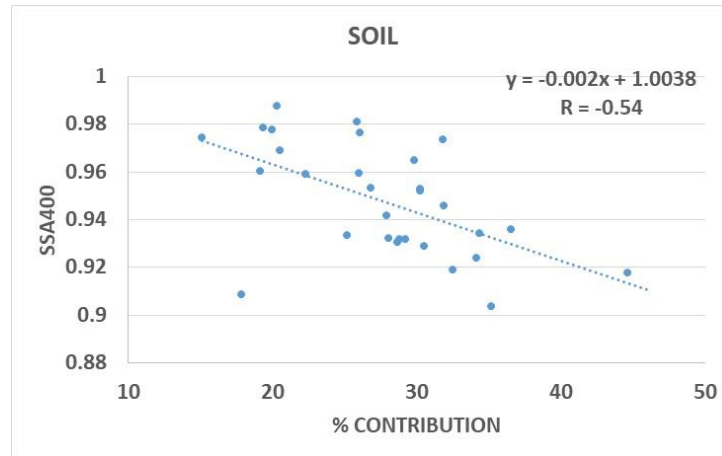

315  
 316 Figure 3: Concentration of the components of  $PM_{10}$  collected in Rome from 21 June to 27 July 2011 as  
 317 derived from chemical analyses. Orange columns represent days affected by the passage of desert dust,  
 318 as measured by Lidar.

319  
 320 A statistical analysis of daily means of  $SSA_{400}$ ,  $AOD_{400}$  and Ångström exponent with the percentage  
 321 contribution of each chemical component, has been performed in order to connect optical properties and  
 322 chemical analysis. In fact, assuming that the in situ measurements are representative of the entire column,  
 323 their variation affects particles refractive index and particles dimensions, and consequently their  
 324 absorption capability and Ångström exponent. Scatter plot of  $SSA_{400}$  versus the SOIL component  
 325 (Figure 4) shows a slight negative correlation ( $R = -0.54$ ), whereas no other correlation is visible for the  
 326 other components and other optical and physical parameters. This result underlines that in situ

327 measurements may not provide information correlated with the columnar properties, because optical and  
328 physical properties at the ground may differ from those of the entire column. Therefore, both information  
329 must be used complementarily for understanding the radiative effects of such a mixture of different  
330 components.

331

332

333 Figure 4. Behaviour of  $SSA_{400}$  versus the percentage contribution of SOIL component as retrieved during  
334 the URBS campaign.

335

336 Assuming that relations between aerosol composition and their optical properties, measured during  
337 summer 2011, are comparable in the last years, they can be considered as representative of the summer  
338 period 2010-2016 studied in this paper. This assumption is supported by the general presence of stable  
339 conditions during summer seasons in Rome, characterized by both SOIL source as the most consistent  
340 contribution to the  $PM_{10}$  mass and a constant contribution of sea breeze (Perrino et al., 2015).

341 In order to point out the possible effect of aerosol optical characteristics measured at 400 nm on  $UVI^*$ ,  
342 the  $AOD_{400}$ ,  $SSA_{400}$ ,  $Ang$ , and  $Ang_{400-500}$ , were analyzed as function of  $UVI^*$ , at the two selected values  
343 of solar zenith angle. Figure 5 shows the frequency distributions of the number of measurements for  
344 each of the two angles.  $\theta=30^\circ$  is more representative of the warmest months, whereas  $40^\circ$  covers a wider  
345 period.

Figure 5: Number of measurements available for each zenith angle.

346

347

348

349 The dependency of  $UVI^*$  on  $AOD_{400}$ ,  $SSA_{400}$ ,  $Ang$  and  $Ang_{400-500}$  for  $30^\circ$  and  $40^\circ$  solar zenith angles are  
 350 shown in Figure 6, colored for different values of  $SSA_{400}$  or  $AOD_{400}$ . A clear linear decreasing trend of  
 351  $UVI^*$  when increasing  $AOD_{400}$  is evident. The slope in these graphs corresponds to the  $UVI^*$  radiative  
 352 forcing efficiency, i.e., the change in  $UVI^*$  produced by a unit change in AOD. The slope is more  
 353 pronounced at the smaller solar zenith angle, as already found by previous studies (di Sarra et al., 2008;  
 354 Antón et al., 2011). No clear dependence of  $UVI^*$  on  $SSA_{400}$  or on Ångström exponents can be noticed.  
 355 If existent, it is expected to be masked by the dependency on AOD, which is the primary parameter  
 356 affecting the surface irradiance.

357 To investigate in more detail, the entire dataset was divided in three groups of  $Ang_{400-500}$ , below 0.8,  
 358 between 0.8 and 1.7, and above 1.7, and in two groups of  $SSA_{400}$ , smaller and larger than 0.85,  
 359 respectively. The values separating the different groups were determined according to the frequency  
 360 distributions of the two variables for the entire investigation period, shown in Figure 7. Scatter plots and  
 361 linear fits of  $UVI^*$  versus the two variables, for each group, were performed and points with a distance  
 362 greater than  $2\sigma$  from the regression line (nout), with  $\sigma$  the standard deviation of the residuals, were  
 363 rejected.

364 The dependence of  $UVI^*$  on AOD for the three classes of  $Ang_{400-500}$  is shown in Figure 8, colored for  
 365 different values of  $SSA_{400}$ , and in Table I. The slope is generally larger for smaller values of  $Ang_{400-500}$ ,  
 366 similarly to what found by Antón et al. (2011). At  $30^\circ$  the other two classes of  $Ang_{400-500}$  have a very  
 367 similar slope, differing of 0.15 that is below its uncertainty estimation from the fit. Conversely at  $40^\circ$  an  
 368 intermediate value of the slope is found for  $Ang_{400-500} \geq 1.7$ ; this value appears essentially driven, for  
 369 both the zenith angles, by cases with low SSA and low AOD, which might be attributed to a possible  
 370 influence from combustion particles characterized by small size and high absorption (see, e.g., Pace et  
 371 al., 2005). A similar dependency on the Ångström exponent was found by di Sarra et al. (2008) when

372 considering the forcing efficiency over the whole shortwave spectral range. The smallest slope is  
373 associated to the  $0.8 < \text{Ang}_{400-500} \leq 1.7$ , range which is characterized by a larger mixture of absorption  
374 capabilities.

375 The Ångström exponent in Rome varies between about 0.5 and 1.8 (Figure 7), with a typical range of  
376 variability of 1.3. The estimated effect of the Ang variability can be determined by considering the slope  
377 difference among the different values of Ang, which is of the order of 1.5 at  $30^\circ$  solar zenith angle (from  
378 Table I). The corresponding change of UVI\* is about 2 (from Figure 6, plot of UVI\* vs  $\text{Ang}_{400-500}$ ).

379 Figure 9 shows the scatter plots of UVI\* vs  $\text{AOD}_{400}$  for  $\text{SSA}_{400} < 0.85$  (left side) and  $\text{SSA}_{400} \geq 0.85$  (right  
380 side), with a colour scale for different values of the Ångström exponent at the two zenith angles. For  
381 solar zenith angles  $30^\circ$  (Table II) the slope of UVI\* versus  $\text{AOD}_{400}$  is larger for  $\text{SSA}_{400} \geq 0.85$ , increasing  
382 of about 67% going from -1.77 to -2.96. This increase is significant, since it is greater than the  
383 uncertainty of the estimated slope. For solar zenith angles  $40^\circ$  the increase is about 9%, going from -  
384 1.42 to -1.55, but in this case it is comparable with the estimated uncertainties of the slope, varying from  
385 15% for  $\text{SSA}_{400} < 0.85$ , to 7% for  $\text{SSA}_{400} \geq 0.85$ . This result is opposite to what Antòn et al. (2011) found  
386 in Granada, Spain, where, as expected, stronger aerosol absorption leads to a large surface forcing  
387 efficiency.

388 Looking at the UVI\* versus  $\text{AOD}_{400}$  or the UVI\* versus  $\text{SSA}_{400}$  scatter plots in Figure 6 it is evident that  
389 for both solar zenith angles (but mostly at the smaller one) less absorbing particles (higher  $\text{SSA}_{400}$ )  
390 correspond to higher  $\text{AOD}_{400}$ . This is also confirmed by the mean and median  $\text{AOD}_{400}$  values calculated  
391 over all the years in the months analyzed in Rome (Table III) with the additional information that higher  
392  $\text{AOD}_{400}$  are also characterized by greater particles ( $\text{Ang}_{400-500} < 0.8$ ). This is probably due to the presence  
393 of SOIL and SEA salt in the atmosphere, as highlighted during URBS.

394 As shown in Figure 7, SSA varies between about 0.75 and 1.0, for a variability range of 0.25. The slope  
395 difference among the different values of SSA is about 1, and a rough estimate of the corresponding  
396 change of UVI\* is of about 0.25. This value is much smaller than the expected effect produced by Ang  
397 that is a change of about 2. Thus, it is very likely that the effect of variations of single scattering albedo  
398 may be masked by concomitant changes of Ang. This could also explain the different result respect to  
399 Antòn et al., 2001. In fact in Rome a greater surface forcing efficiency was found for larger particles  
400 that generally are less absorbing since related to the presence of SOIL and SEA components in the  
401 atmosphere. Those components are probably less influential in Granada, Spain, where the Antòn et al.,  
402 2001 analysis was performed.

438

### 439 5. Conclusions

440 The aerosol optical characteristics in the urban area of Rome were retrieved for a period of 7 years, in  
 441 the months from March to September 2010-2016. The impact of SSA, AOD at 400 nm, and Ångström  
 442 exponent on the UV index has been analyzed. The evolution of UVI\*, which is the measured UV index  
 443 corrected for total ozone changes and scaled at the mean Sun-Earth distance, was studied with respect  
 444 to AOD<sub>400</sub>, SSA<sub>400</sub>, and Ångström exponent calculated using all the wavelengths (Ang) and only 400  
 445 and 500 nm. Data at two fixed values of the solar zenith angle were selected in order to point out the  
 446 possible effect of aerosol optical characteristics measured at 400 nm on UVI\*.

447 A clear linear decreasing trend of UVI\* when increasing AOD<sub>400</sub> was found, with a more pronounced  
 448 slope at the smaller solar zenith angle, as already shown by previous studies. The dependence of UVI\*  
 449 on SSA<sub>400</sub> and Ångström exponents is probably masked by the dependency on AOD, which is the  
 450 primary parameter affecting the surface irradiance. The entire dataset was also analyzed separately for  
 451 different absorption properties (by fixing a threshold value for SSA<sub>400</sub>) and for different aerosols  
 452 dimensions (by fixing threshold values for Ang<sub>400-500</sub>). The surface forcing efficiency, provided by the

453 decreasing trend of UVI\* with AOD<sub>400</sub>, was found greater for larger particles. In Rome these particles,  
454 having small Ångström exponent values, are generally less absorbing since related to the presence of  
455 SOIL and SEA components in the atmosphere. Moreover the former contribution is much higher in  
456 summer months (as highlighted from the chemical characterization of suspended particulate matter over  
457 Rome during the URBS ROMA intensive field campaign held in 2011) because of the numerous  
458 episodes of Saharan dust transport. The result is that the effect of the Angstrom exponent on the incoming  
459 UV radiation could mask the dependence on the SSA.

460 The general behavior observed for the five macro-sources (SOIL, SEA, SECONDARY INORGANIC,  
461 ORGANICS and TRAFFIC) during summer 2011 has been assumed not substantially changed in the  
462 last years, and the variations in the absorption capability of the atmosphere over Rome were attributed  
463 to the different absorption characteristics of the macro-components and their modulation of  
464 concentration in the atmospheric mixture. The assumption that the five macro-sources have not changed  
465 in the last years is supported by the general presence of stable conditions during summer seasons in  
466 Rome, characterized by a constant contribution of sea breeze during daytime. The SOIL source  
467 represents the most consistent contribution to the PM mass because the more aridity of soil during  
468 summer period lead to a higher resuspension of crustal-origin components operated by wind and  
469 vehicular traffic (Perrino et al., 2015). The stability of this situation supports the assumption we did.  
470 Many studies have been performed on the chemical analysis of the PM components, but always related  
471 to short periods. In fact, it is impossible studying the PM chemical composition for a very long period  
472 as the one considered in this study.

473  
474 A better understanding of the impact of aerosol optical properties in Rome on UVI\* can be done in the  
475 next future using measurements of direct and diffuses solar radiation at 340 nm, instead of 400, available  
476 at the ESR Rome site from 2018. Also the use of different versions of the Skyrad code (as version 5.0  
477 or A) can improve the retrieval of the SSA wavelength dependence, making possible the calculation of  
478 the Absorption Ångström Exponent for a better characterization of the absorption properties.
