**Abstract.** In this paper, we present the first multi-year time series of atmospheric NH<sub>3</sub> ground-based measurements in the Paris region (Créteil, 48.79°N, 2.44°E, France) retrieved with the mid-resolution “Observations of the Atmosphere by Solar absorption Infrared Spectroscopy” (OASIS) ground-based Fourier Transform infrared solar observatory. Located in an urban region, OASIS has previously been used for monitoring air quality (tropospheric ozone and carbon monoxide), thanks to its specific column sensitivity across the whole troposphere down to the atmospheric boundary layer. A total of 4920 measurements of atmospheric total columns of ammonia have been obtained from 2009 to 2017, with uncertainties ranging from 20% to 35%, and are compared with NH<sub>3</sub> concentrations derived from the Infrared Atmospheric Sounding Interferometer (IASI). OASIS ground-based measurements show significant interannual, and seasonal variabilities of atmospheric ammonia. NH<sub>3</sub> total columns over the Paris megacity (12 million people) vary seasonally by 2 orders of magnitude, from approximately 10<sup>15</sup> molecules cm<sup>-2</sup> in winter to 10<sup>17</sup> molecules cm<sup>-2</sup> for spring peaks, probably due to springtime spreading of fertilizers on surrounding croplands.

30

## 1 Introduction

Ammonia ( $\text{NH}_3$ ) is a reactive and volatile chemical species present in the atmosphere as a trace gas. As the main alkaline atmospheric molecule (Behera et al., 2013), it plays a major role in the formation of secondary fine particulate matter of ammonium salts and thus in particle air pollution (Seinfeld and Pandis, 2006).  $\text{NH}_3$  is heterogeneously distributed in the atmosphere, depending on local and regional sources (potentially including agriculture, urban traffic, particle-to-gas conversion, sewage, industrial activities) and sinks (wet and dry deposition, gas-to-particle conversion).

In France, atmospheric ammonia ( $\text{NH}_3$ ) is mainly emitted (more than 94%) by agricultural activities (Ringuelet et al., 2016, Genermont et al., 2018) via livestock waste and urine, manure spreading and the use of synthetic nitrogen fertilizers. Other minor sources exist, including the combustion of biomass and fossil fuels as well as industrial activity. The source related to motor traffic has increased significantly in recent years, due to the increasing use of catalytic (or non-catalytic)  $\text{NO}_x$  reduction systems on light and heavy duty vehicles. These devices use an injection of urea or ammonia and can give rise to  $\text{NH}_3$  emissions (Chang et al., 2016). The urban area corresponding to the Paris city and its suburbs is the second largest megacity in Europe with more than 12 million people. Ammonia emissions in the Paris region reached nearly 11 kilotons in 2014 of which 93% are attributed to agricultural activities, with a negligible contribution of livestock (DRIEE, 2017). The Paris megacity is located at the administrative region Île-de-France, which includes 49% of agricultural land, with particularly strong activity in the eastern half of the territory. Île-de-France agriculture is mainly dedicated to crops, in particular cereals (with a dominance of wheat), which occupy 67% of the cultivated area. This sector is described as an agricultural belt, with 59% in the Seine-et-Marne department. Urban traffic in the Paris region is estimated to be responsible for 5% of ammonia emissions and industry for 2% (DRIEE, 2017).

Atmospheric ammonia concentrations vary to a large degree during the day, since the atmospheric lifetime of  $\text{NH}_3$  is rather short, on the order of hours to a few days (Galloway et al., 2003; Lutsch et al., 2016; Van Damme et al., 2018). Wet and dry depositions dominate the atmospheric sink of this inorganic compound.  $\text{NH}_3$  is also a gaseous precursor of fine particulate matter ( $\text{PM}_{2.5}$ , particles of an aerodynamic diameter less than  $2.5 \mu\text{m}$ ). As the main alkaline molecule in the atmosphere, it reacts rapidly with sulfuric ( $\text{H}_2\text{SO}_4$ ) and nitric ( $\text{HNO}_3$ ) acids in the atmosphere to form ammonium sulfate or ammonium nitrate (Behera et al., 2013). These ammonium salts may represent more than 50% of the  $\text{PM}_{2.5}$  fraction, during peaks of spring air pollution, periods of fertilizer application by agriculture. Concentrations of ammonium nitrate in Île-de-France in the 2009/2010 period can be simulated by the CHIMERE chemistry-transport model with only a small bias ( $<20\%$ , Petetin et al., 2016). However, comparisons of the precursors' concentrations measured during the FRANCIPOL campaign (May 2010 to February 2011) show an overestimation of nitric acid and an underestimation of ammonia by the CHIMERE model (Petetin et al., 2016). These differences appear to stem in part from the uncertainties associated with ammonia emissions. They suggest large uncertainties in the emissions of the precursors of ammonium nitrate over the Paris region.

Monitoring the atmospheric concentrations of  $\text{NH}_3$  is essential for improving air quality models, as well as for quantifying the fluxes characterizing the nitrogen cycle. The measurement of atmospheric ammonia concentrations is not subject to

regulation (in the sense of the European Directives) and is really challenging for several reasons: (i) High temporal and spatial dependence of ambient concentration levels (Allen et al., 1988; Sutton et al., 1998); (ii) Rapid conversion of  $\text{NH}_3$  between gaseous, particulate and aqueous phases (Warneck, 1988); (iii) Measurement artefacts due to  $\text{NH}_3$  reactivity with sampling and measurement systems:  $\text{NH}_4^+$ - $\text{NH}_3$  conversion, adsorption on surfaces, etc. (Sutton et al., 2008; Von Bobruzki et al., 2010). This is why there are only a few measuring stations for which atmospheric ammonia concentrations are measured with a time resolution finer than a month. Most of the existing observation networks are designed to evaluate long-term trends and are therefore based on sampling techniques accumulating during several weeks (passive samplers, denuders or liquid bubblers) and off-line analysis in the laboratory.

Other in situ methods enable to estimate surface atmospheric concentrations of  $\text{NH}_3$  (e.g. by cavity ring-down spectroscopy (CRDS) techniques (Sun et al., 2015)) or even in the lower atmosphere (airborne campaigns (Leen et al., 2013, Shephard et al., 2015, Sun et al., 2015)). Hourly measurements are very rare at present, and are mainly available during intensive short-term measurement campaigns and are limited to a small number of measurement sites of several established networks such as the European Monitoring and Evaluation Programme (EMEP) (EMEP/EEA, 2016) used by the French Centre interprofessionnel technique d'études de la pollution atmosphérique (CITEPA) (CITEPA, 2015) or the Dutch National Air Quality Monitoring Network (LML: Landelijk Meetnet Luchtkwaliteit) of the Netherlands (Volten et al., 2012).

An innovative and very promising alternative for monitoring atmospheric ammonia is infrared remote sensing. This approach exploits the ammonia absorption spectral signatures of thermal infrared radiation measured by Fourier transform infrared spectroscopy (FTIR) instruments. These methods are free from sampling problems and are noticeably less influenced by local sources than in situ observations. Current or until very recent space-based  $\text{NH}_3$  data are available from the IASI sounder (Infrared Atmospheric Sounding Interferometer, onboard the Metop satellites, Clerbaux et al., 2009; Clarisse et al., 2009), TES (Tropospheric Emission Spectrometer embedded on the Aura satellite, Shephard et al., 2015, TES's mission was ended in January 2018, after nearly a 14-year career of discovery), CrIS (Cross-track Infrared Sounder embedded in the Suomi National Polar-Orbiting Partnership satellite, Shephard and Cady-Pereira, 2015 ; Dammers et al., 2017), TANSO/FTS (Thermal And Near-infrared Sensor for carbon Observation-Fourier Transform Spectrometer on the Greenhouse Gases Observing SATellite (GOSAT), Someya et al., 2019) and AIRS (Atmospheric Infrared Sounder, Warner et al., 2016, here, a grating spectroscopy instrument installed on the Aqua satellite). These measurements allow the retrieval of total columns of  $\text{NH}_3$ , vertically integrated concentrations between the Earth's surface and the top of the atmosphere. In particular for the IASI instrument, observation processing algorithms have evolved considerably in recent years (Van Damme et al 2014, 2015; Whitburn et al. 2016), a data product that we call hereafter  $\text{NH}_3$ -IASI. These currently available satellite data also feature indicators of the quality of the space-based observations and retrievals, and have been validated (Dammers et al., 2016). Even though the observations from space remain complex due to the weak absorption of this species, the availability of a global distribution of  $\text{NH}_3$  twice a day (for example over Europe) is an important achievement. In addition, the high-resolution FTIR solar stations of the Network for the Detection of Atmospheric Composition Change (NDACC) measure, from the ground, the total ammonia columns but are also capable of providing information on its vertical

distribution (Dammers et al., 2015). Spectroscopic measurements from the ground have been used for decades in the validation of satellite measurements. The diurnal variability is observed directly from the ground, with a temporal resolution of a few minutes. The high temporal resolution of these ground-based solar measurements can help to understand the nature of ammonia sources, especially in urban environments where there is a crucial lack of observations of this short-lived and spatially highly disperse pollutant. A better knowledge of NH<sub>3</sub> emissions and associated atmospheric processes thus requires extended observational networks able to assess high temporal and spatial variabilities of the atmospheric content of ammonia. Such networks are still to be built, especially in France where NH<sub>3</sub> measurements are extremely rare.

In this study, we present the first multi-year time series of atmospheric NH<sub>3</sub> ground-based measurements over a European megacity (Paris), retrieved with the moderate-cost mid-resolution OASIS (Observations of the Atmosphere by Solar absorption Infrared Spectroscopy) FTIR solar observatory located in the Paris suburbs (Créteil, France). Given its good sensitivity to surface pollutant concentrations, it has been used previously for monitoring urban pollution (tropospheric ozone and carbon monoxide) (Viatte et al., 2011; Chelin et al., 2014). A total of 4920 measurements of NH<sub>3</sub> total columns have been obtained between 2009 and 2017, with uncertainties ranging from 20% to 35% (one standard deviation) using the retrieval code PROFFIT (Hase et al., 2004) adapted for our medium spectral resolution and based on the NDACC stations' methodology. The data are compared with NH<sub>3</sub> concentrations from IASI measurements for verifying consistency with the NH<sub>3</sub>-OASIS retrievals.

The paper is organized as follows. First, we present in detail the NH<sub>3</sub>-OASIS data by describing the site, the retrieval strategy and uncertainties (Section 2). A comparison between the NH<sub>3</sub>-OASIS columns and the NH<sub>3</sub>-IASI satellite data is provided in Section 3.1, while Section 3.2 gives the atmospheric NH<sub>3</sub> time-series focusing on seasonal variability. Finally, in Section 3.3, we examine the correlation between atmospheric ammonia measured by OASIS and surface PM<sub>2.5</sub> concentrations at a daily scale.

## **2 Ground-based FTIR NH<sub>3</sub> data: description and characterization**

### **2.1 The FTIR-OASIS observatory**

The OASIS ("Observations of the Atmosphere by Solar Infrared Spectroscopy", 48.79° N, 2.44° E, 56 m above sea level) observatory is located in the Paris region, which is a European megacity (12 million inhabitants) surrounded by a large rural region and relatively flat terrain (Figure 1). It routinely performs solar absorption measurements since 2009 under clear-sky conditions, using a mid-spectral resolution spectrometer (BRUKER Vertex 80, with a spectral resolution of 0.06 cm<sup>-1</sup>, maximum optical path difference of 12 cm). In order to carry out air quality research, we have assessed the capability of a medium-resolution FTIR solar absorption spectrometer for monitoring pollutants, especially O<sub>3</sub> and CO. We have demonstrated that OASIS is able to continuously monitor tropospheric ozone over Créteil with good accuracy and sufficient information content (Viatte et al., 2011). A 5-year analysis of ozone in the lower troposphere and carbon monoxide has also

been made (Chelin et al., 2014). Given the moderate cost and compactness of OASIS, deployment of analogous systems nearby or in large megacities might be useful in support of satellite and air quality studies in other regions of the world.

The observatory comprises an automatized cupola (Sirius 3.5 “School Model” observatory, 3.25 m high and 3.5 m in diameter) in which the upper part (a dome equipped with a mobile aperture) rotates to track the sun. The alt-azimuthal solar tracker in OASIS is the A547N model manufactured by Bruker Optics, using bare gold-coated mirrors which are less sensitive to corrosion and pollution than the original Al mirrors. Infrared solar absorption spectra are nominally recorded on a deuterated-triglycine-sulfate (DTGS) detector using a potassium bromide (KBr) beamsplitter, in order to cover the spectral region from 700 to 11000  $\text{cm}^{-1}$  (0.9 to 14.3  $\mu\text{m}$ ) without any optical filter, so that column abundances of many different atmospheric trace gases can be retrieved simultaneously.

## 10 **2.2 Ground-based $\text{NH}_3$ retrievals**

The ammonia spectral signatures used in this study are observed in the 10.6  $\mu\text{m}$  spectral region and belong to the  $\nu_2$  vibrational band (Dhib et al., 2007). To achieve a sufficiently high signal-to-noise ratio, each spectrum is produced by co-adding 30 scans at the highest spectral resolution, resulting in one interferogram recorded over a period of approximately 10 min. Each coadded interferogram is Fourier-transformed for obtaining a spectrum without further numerical apodization (i.e. unapodized/boxcar apodization). Carbonyl sulfide (OCS) cell measurements are regularly performed to verify the alignment of the instrument (Chelin et al., 2014). Ammonia absorption lines from the  $\nu_2$  vibrational band are also used for satellite-based estimates (Clarisse et al., 2009; Whitburn et al., 2016) and in the first retrievals of ammonia from high-resolution ground-based NDACC FTIR stations (Dammers et al., 2015). Atmospheric transmission spectra from two spectral microwindows are used in this work (926.3-933.9  $\text{cm}^{-1}$  and 962.5-970  $\text{cm}^{-1}$ ). They are slightly larger than those for the Bremen and Lauder NDACC stations (Dammers et al., 2015) because of the coarser spectral resolution of OASIS atmospheric spectra (0.06  $\text{cm}^{-1}$ ). The choice of using large microwindows aims at retrieving  $\text{NH}_3$  abundances from the intensity contrast between the target gas signature and the surrounding continuum. We account for this last one by fitting an empirical background polynomial function with respect to wavelength, with four degrees of freedom. The main interfering species in these windows are  $\text{H}_2\text{O}$ ,  $\text{CO}_2$ ,  $\text{O}_3$ , which are simultaneously retrieved together with  $\text{NH}_3$ . Minor interfering species are  $\text{HNO}_3$ ,  $\text{SF}_6$ ,  $\text{C}_2\text{H}_4$ , and CFC-12. Figure 2 shows an example of a measured spectrum on the 21 March 2012 with contributions of all main species, here calculated using the spectral atlas of Meier et al. (Meier et al., 2004). The strong spectral signatures of ammonia are seen in both microwindows, even when observed with the medium spectral resolution of the Vertex 80 spectrometer. Note that the  $\text{NH}_3$  concentrations of this day were particularly higher than on average, resulting in very strong  $\text{NH}_3$  features.

30 The retrievals are performed using the PROFFIT 9.6 code (Hase et al., 2004) widely used by the NDACC community to retrieve trace gases from high-resolution FTIR measurements, but adapted for the medium resolution. The software is capable of including spectral channeling in the fitting process and for the estimation of error budgets. Channeling is caused by the presence of optical resonators as e.g. filters or windows, in the measurement beam. Here, the ability of the code to

handle spectral channeling in the fit is of relevance, because we intend to quantify a minor absorber and some channeling was detected in the measured spectra. For this purpose, the channeling frequency is determined from a Fourier transform of the residual of an auxiliary fit. A neighbouring spectral section containing few absorption lines and wide enough to encompass many cycles of the channeling signal is selected for this purpose. For the chosen frequency, a sine and a cosine amplitude are subsequently included in the fit of the  $\text{NH}_3$  target windows. Daily temperature and pressure profiles for the meteorological variables are obtained from the Goddard Space Flight Center NCEP (National Center for Environmental Prediction). For radiative transfer calculations, profiles at 44 altitude levels, from 50 m up to 70 km, are set. Spectroscopic data are taken from the HITRAN 2008 database (which does not include ad-hoc changes on line parameters added in HITRAN 2012, Rothman et al., 2009), except for  $\text{CO}_2$  lines from the HITRAN 2012 database (Rothman et al., 2013). As for satellite retrievals and in consistency with the moderate spectral resolution of OASIS, we derive total columns of  $\text{NH}_3$  from each radiance spectrum. A scaling factor of a climatological vertical profile of  $\text{NH}_3$  is adjusted in order to minimize the difference between measured and simulated spectra, so the degree of freedom for the ammonia retrievals is 1. As the radiance values are rather small below  $1000 \text{ cm}^{-1}$ , a quality criterion was introduced selecting only spectra with a signal-to-noise ratio higher than 30, as measured between 960 and  $990 \text{ cm}^{-1}$  covering lines of a weak  $\text{CO}_2$  band. Figure 3 shows a measured spectrum (black line), the corresponding simulated spectrum (red line) and the difference between observation and simulation (blue line) in both microwindows. The fits are excellent with a standard deviation of 2% in both microwindows.

### 2.3 A priori profiles and uncertainty

A climatological a priori profile of  $\text{NH}_3$  that assumes vertically homogenous  $\text{NH}_3$  concentrations (0.1 ppb) in the troposphere is taken from the MIPAS project (Remedios et al., 2007). The a priori profiles of the interfering species ( $\text{H}_2\text{O}$ ,  $\text{CO}_2$ ,  $\text{O}_3$ ) are taken from the Whole Atmosphere Community Climate Model (WACCM version 6) (Chang et al., 2008). We consider the posteriori errors calculated by PROFFIT 9.6. This calculation is based on the error estimation method by Rodgers (2000). For the uncertainty in the  $\text{NH}_3$  line parameters, we assume values as stated in the HITRAN 2008 database (Rothman et al., 2009). We assume a conservative value of 20% for the integrated intensities and of 10% for the pressure broadening coefficients. The total errors are dominated by uncertainties in the spectroscopic parameters, and are equivalent to those estimated by Dammers et al. (2015) for a high resolution ground-based station at Bremen (Germany). Table 1 summarizes the results of total errors according to the different ammonia total columns, which vary from 20% to 35%. Another a priori was tested with higher concentrations of  $\text{NH}_3$  in the atmospheric boundary layer (with fixed concentrations up to 900 m then decreasing  $\text{NH}_3$  concentrations until 4 km). Using this a priori profile reduces the mean squared difference between measured and simulated spectra by about 60%. However, both retrievals with homogenous and sloped a priori profiles show rather similar results, with the same relative evolution in time and differences in absolute terms in the order of magnitude of the total column retrieval error (the use of the sloped a priori profile increases the retrieved  $\text{NH}_3$  abundances by 20% with respect to that using an homogenous a priori).

## 3 Results

### 3.1 Seasonal variability of NH<sub>3</sub> ground-based data

Figure 4 shows the multi-year time series of NH<sub>3</sub> total columns derived from FTIR ground-based OASIS measurements retrieved from all the 4920 available spectra in 2009–2017, resulting from 234 measurement days. Table 2 gives a summary of statistics of the retrieved NH<sub>3</sub> measurements versus the four seasons. Individual measurements with an overall mean total column of  $0.84 \cdot 10^{16}$  molecules NH<sub>3</sub> cm<sup>-2</sup> and a standard deviation of  $0.86 \cdot 10^{16}$  molecules NH<sub>3</sub> cm<sup>-2</sup> indicate a large variability in the observations. They highlight peak abundances in spring (March-April-May), more precisely in March. The amplitude of the spring peaks varies throughout the years, with maxima in March 2012, reaching about  $9 \cdot 10^{16}$  molecules NH<sub>3</sub> cm<sup>-2</sup>. The occurrence of the highest NH<sub>3</sub> concentrations in March is particularly noticeable: all measurements are above  $2 \cdot 10^{16}$  molecules NH<sub>3</sub> cm<sup>-2</sup>, which corresponds to the mean of data plus one standard deviation over the springtime period (March/April/May). They are measured for this calendar month, for almost every year (2011 (2 days), 2012 (11 days), 2014 (6 days), 2015 (4 days), 2016 (4 days) and 2017 (1 day)). March 2012 is therefore a month particularly polluted in terms of atmospheric NH<sub>3</sub>. In addition to many days with more than  $2 \cdot 10^{16}$  molecules NH<sub>3</sub> cm<sup>-2</sup>, a peak reaching the quadruple of that threshold on March 21, 2012, represents the maximum retrieved ammonia total column.

The seasonal variability is analysed in Figure 5 in terms of monthly averages over the 2009-2017 period. The mean NH<sub>3</sub> column in March is  $1.65 \cdot 10^{16}$  molecules NH<sub>3</sub> cm<sup>-2</sup>, which is two times higher than the overall mean total column over the 4920 measurements in 9 years.

As for many other regions, NH<sub>3</sub> seasonality is well marked, with high values that might be connected with the timing of agricultural manure spreading. As shown by both approaches of Ramanantenasoa et al. (2018) for 2005-2006, mineral fertilizers are mainly used in the Île-de-France region because they are major arable crop (especially cereals) farming areas. They account for 59% of NH<sub>3</sub> emissions according to CADASTRE\_NH3 framework based on the process-based Volt'Air model (Garcia et al., 2011; Garcia et al., 2012). These fertilizers are mostly spread during springtime. In Bremen, NH<sub>3</sub> atmospheric total columns have a similar seasonal cycle with highest levels during spring. The maximum values occur around April, which is consistent with temporal emission patterns for manure application reported for this region (Dammers et al., 2015). Note that for example, highest levels in Bremen were observed during springtime with total columns reaching up to  $9.3 \cdot 10^{16}$  molecules NH<sub>3</sub> cm<sup>-2</sup>, which is close to the maximum peak observed by OASIS in March 2012.

One can observe also in Figure 4 significant concentrations in June (2017), July (2010, 2012, 2013, 2014, 2015 and 2017) and in August 2016, with another threshold of  $1.5 \cdot 10^{16}$  molecules NH<sub>3</sub> cm<sup>-2</sup>, which corresponds roughly to the mean of data plus one standard deviation over the summer time period (June/July/August). This shows a second seasonal peak for the summer period. On the contrary, during winter months (December-January-February) the NH<sub>3</sub> total columns have a pronounced minimum (mean total column of  $0.12 \cdot 10^{16}$  molecules NH<sub>3</sub> cm<sup>-2</sup> and a standard deviation of  $0.12 \cdot 10^{16}$  molecules NH<sub>3</sub> cm<sup>-2</sup>). It is worth noting that fewer observations are available during this season due to frequent overcast conditions.

This evolution during early winter and, to a lesser extent, summer are also observed in the Bremen measurements, emphasizing some similarities between both the Paris and Bremen station environments. Such seasonal behavior is not only found in Europe but also in other megacities as Seoul (Korea), where surface ammonia concentration exhibit higher values during spring and in the warm season (summer), while dropping to a minimum in the cold season (winter) (Phan et al., 2013). One possible explanation is the increased volatility of ammonia in agricultural soils and ammonium particles (in the atmosphere in aqueous or solid phase) under warm meteorological conditions.

### 3.2 Comparison between NH<sub>3</sub>-OASIS and NH<sub>3</sub>-IASI

The validation of the satellite products of IASI (Van Damme et al., 2014) is limited by the scarcity of long-term series of atmospheric ammonia measurements. A first attempt to validate IASI-NH<sub>3</sub> measurements was made with correlative data from surface in-situ and airplane-based measurements (Van Damme et al., 2015). They confirmed consistency between the NH<sub>3</sub>-IASI dataset and the available in-situ observations and showed promising results for validation by using independent airborne data from the CalNex campaign (California Research at the Nexus of Air Quality and Climate Change). Nevertheless, that study was limited by the availability of independent measurements and suffered from representativeness issues for the satellite observations when comparing to surface concentration measurements. Recently, Dammers et al. (2016) reported a first step in the validation of NH<sub>3</sub>-IASI products, comparing ammonia columns with high-resolution FTIR measurements from several NDACC stations around the world. They concluded that IASI reflects similar pollution levels and seasonal cycles as shown by FTIR observations and the best correlation ( $R = 0.83$  and a slope of 0.60) was obtained with the NDACC Bremen station. Bremen is located in the northwest of Germany, which is characterized by intensive agriculture. It is most suitable for comparisons with IASI given the very high atmospheric concentrations of NH<sub>3</sub> observed there. Compared to this work over Bremen, our analysis is the first comparison of ground-based NH<sub>3</sub> measurements performed in a megacity (Paris) with NH<sub>3</sub>-IASI and covers nine years of data. In this study, we consider NH<sub>3</sub> total columns retrieved from the IASI-A instrument (aboard the Metop-A platform) observations along with those retrieved from the IASI-B instrument (aboard the Metop-B platform) observations, IASI-B data being available only for the period from 8 March 2013. Average and median errors of these satellite measurements used in this study are 89% and 60% respectively, which are coherent with uncertainties for most of the NH<sub>3</sub>-IASI data listed in Van Damme et al. (2014 and 2017), because of small absorption features by ammonia observed with the relatively coarse spectral resolution of IASI as compared to ground-based instruments. The sensitivity of IASI retrievals to surface concentrations of NH<sub>3</sub> is also limited, and the time of IASI overpasses (early morning and early evening) are not coincident with the typical early afternoon peaks of NH<sub>3</sub> concentrations.

For the comparison, only morning overpass (AM) satellite observations (i.e. 09:30 local time) are considered here, as they are generally more sensitive to NH<sub>3</sub> owing to more favorable thermal contrast at daytime (Van Damme et al., 2014), and for better temporal coincidence (OASIS observations are only carried out during daytime). The satellite data have a circular footprint of 12 km diameter at nadir and an ellipsoid shaped footprint of up to 20 km×39 km at the outermost angles

(Clarisse et al., 2009). We use raw observations from 1 January 2009 to 31 December 2016, from the most recent version of IASI NH<sub>3</sub> retrievals (the near-real-time neural network retrieval version 2 with reanalysed meteorological inputs called ANNI-NH3-v2.2R, Van Damme et al., 2017).

Note that, the lifetime of atmospheric NH<sub>3</sub> is rather short, on the order of hours not being uncommon (Galloway et al., 2003; Lutsch et al., 2016; Van Damme et al., 2018), up to a few days, due to efficient deposition and fast conversion to particulate matter. Thus, NH<sub>3</sub> concentrations vary strongly as function of emission strengths and meteorological conditions (such as temperature, precipitation, wind, vertical mixing in the atmospheric boundary layer).

In order to minimize differences associated with the temporal variability of NH<sub>3</sub>, we only consider NH<sub>3</sub> measurements from OASIS performed within +/- 30 min with respect to the IASI morning overpass. The spatial coincidence criterion is 15 km between the center of IASI pixels and OASIS. Tests with wider coincidence criteria (50 km and +/- 90 minutes) do not show significant differences (similar correlations are obtained despite a greater number of coincidences). We also exclude NH<sub>3</sub>-IASI data with relative errors higher than 100%, except those with absolute errors lower than  $5 \cdot 10^{15}$  molecules cm<sup>-2</sup>

Figure 6 shows a scatterplot comparison between NH<sub>3</sub>-OASIS and NH<sub>3</sub>-IASI data. We obtain a very good correlation of  $R = 0.79$  and a slope of 0.73 for a total of 52 coincidences. These results are similar to those from a comparison between a ground-based FTIR at Bremen and NH<sub>3</sub>-IASI look-up table version:  $R = 0.83$  and a slope of 0.60 for a total of 53 coincidences (Dammers et al., 2016) and NH<sub>3</sub>-IASI neural network version:  $R = 0.67$  and slope of 0.96 for 802 coincidences from several ground-based FTIR stations (Dammers et al., 2017). Here for Paris, we used stricter spatiotemporal collocation criteria for the comparison, as we have more data than the Bremen study. For this correlation, we calculated the absolute differences (AD) between satellite (y axis) and FTIR-OASIS NH<sub>3</sub> total columns (x axis), which are defined here as:

$$AD = (NH_3-IASI) \text{ column} - (NH_3-OASIS) \text{ column} \quad (1)$$

The average of the absolute differences is  $-0.78 \cdot 10^{15}$  molecules cm<sup>-2</sup>, with a root mean squared error (RMSE) equal to  $4.86 \cdot 10^{15}$  molecules cm<sup>-2</sup> and a standard deviation of error (STDE) equal to  $4.84 \cdot 10^{15}$  molecules cm<sup>-2</sup>. This reveals a very good consistency between NH<sub>3</sub>-IASI and NH<sub>3</sub>-OASIS, this last one being analyzed during 9 years (2009-2017) in section 3.1.

We further investigate the representativeness of the OASIS site for the Île-de-France region by comparing NH<sub>3</sub>-OASIS data with that from IASI at different distances from the ground-based site. We use 15-km-wide rings (Figure 7) centered on the OASIS observatory and increasing the minimal distance ( $d_{min}$ ) of the rings from OASIS observatory with a 1-km step. The 15-km width of the rings is chosen to minimize the impact of ammonia spatial variability and to consider a sufficient number of coincidences for statistics. The minimal distance ( $d_{min}$ ) varies from 0 km up to 400 km. Figures 8 and 9 show respectively the correlation and regression slope as a function of  $d_{min}$  using a maximum allowed sampling time difference of 30 min. The numbers on the right axis of each of the figures show the number of coincident observations used in the comparison. An increasing  $d_{min}$  shows a decreasing correlation (blue lines) and a changing slope (increasing with distance up to 120 km, then decreasing). One can distinguish three different regimes in the plot of Fig. 8. For  $d_{min}$  between 0 and 12 km, highest

correlations are seen with  $R$  varying from 0.84 down to 0.57, then between 12 km and 120 km,  $R$  is around 0.6 despite lots of noise and then we get decreasing correlations for  $d_{min}$  between 120 km and 400 km. This comparison underlines that measurements from OASIS observatory provide information about atmospheric  $\text{NH}_3$  variability on a regional scale, up to 120 km away from the site, but might also be affected by more local processes and/or emissions.

- 5 For  $d_{min}$  between 0 and 12 km, regression slopes vary between 0.73 and 0.81 revealing an underestimation of observed columns by IASI compared to OASIS (Fig. 9), already mentioned by Dammers et al. (2016) when evaluating IASI with some high resolution NDACC stations. This underestimation may be explained by IASI's lower sensitivity to surface ammonia concentrations, due to the coarse spectral resolution and weak thermal contrast between the surface and the lower troposphere and to the spatial heterogeneity of ammonia within the IASI footprint. The regression slope increases until 120
- 10 km for  $d_{min}$  and decreases beyond. This might be linked to the fact that the main surrounding agricultural regions (e.g. Picardie and Champagne) are located until about 120 km away from OASIS, and therefore  $\text{NH}_3$  sources (Clarisse et al., 2019; Van Damme et al., 2018), and these sources are more heterogenous beyond this distance.

### 3.3 Vertical distribution of sensitivity of the $\text{NH}_3$ -OASIS approach

- 15 As mentioned in section 2.2, the  $\text{NH}_3$ -OASIS dataset presented in Figs. 4, 8 and 9 is derived from a scaling factor retrieval scheme whose state vector only has one scalar value associated with the  $\text{NH}_3$  abundance. Therefore, this approach does not provide an averaging kernel matrix as optimal estimation or Tikhonov schemes do, but only a single value of degrees-of-freedom (DOF) without any information on the vertical distribution of the retrieval sensitivity. In order to estimate the vertical sensitivity to  $\text{NH}_3$  provided by OASIS measurements, we have performed a few tests using a  $\text{NH}_3$  profile retrieval
- 20 scheme applied to OASIS spectra with a Tikhonov-Phillips regularization (as similarly implemented for ozone profiles by Viatte et al., 2011). Figure 10 presents examples of averaging kernel diagonals for  $\text{NH}_3$  profile retrievals based on OASIS spectra measured on 13 March 2014, at different times of the day and thus different solar zenith angles (SZA). We remark that OASIS measurements may provide information on the abundance of  $\text{NH}_3$  located around 500 m, with maximum sensitivity for smaller solar zenith angles corresponding to thicker air masses (occurring in the early morning or late
- 25 afternoon). These OASIS averaging kernel diagonals peak at similar altitudes as those estimated by Dammers et al. (2017) for a high spectral resolution Fourier Thermal Infrared spectrometer at the Pasadena site (peaking around 940 hPa, thus approximately at 600 m above sea level). These altitudes are typically located within the atmospheric boundary layer during springtime and summer, at mid-latitudes where most of the atmospheric  $\text{NH}_3$  column variability is expected to occur. Additional tests (not shown) using different spectroscopic databases (HITRAN 2008 and HITRAN 2012) change very little
- 30 the estimation of the sensitivity of the OASIS retrieval.

## 4 Conclusions and perspectives

Ground-based infrared remote-sensing is undoubtedly a promising and powerful spectroscopic technique to retrieve ammonia columns, even using FTIR instruments with moderate spectral resolution such as OASIS. Recording one spectrum over a period of approximately 10 minutes, the OASIS instrument can provide over 40 spectra per day over the Paris region and allows the observations of the diurnal cycle of ammonia. In this paper, we presented the first multi-year time series (2009-2017) of atmospheric  $\text{NH}_3$  total column measurements from ground-based infrared remote-sensing over the Paris megacity.  $\text{NH}_3$  total columns vary seasonally by 2 orders of magnitude, approximately from  $10^{15}$  molecules  $\text{cm}^{-2}$  in winter to  $10^{17}$  molecules  $\text{cm}^{-2}$  for spring peaks. Error estimations show random errors of about 10 % and systematic errors less than 25 % for individual observations, mainly due to uncertainties in spectroscopic parameters.

This study is based on the 9-year  $\text{NH}_3$ -OASIS time series to order to analyze the seasonal variability of atmospheric  $\text{NH}_3$  in the Paris region. The predominance of  $\text{NH}_3$  peaks occurring in March is particularly noticeable: all measurements are greater than  $2 \cdot 10^{16}$  molecules of  $\text{NH}_3 \text{ cm}^{-2}$ , which corresponds to the average values of the dataset plus one standard deviation over the springtime period (March/April/May), and are coincident with manure spreading time periods (Ramanantenasoa et al., 2018). Mineral fertilizers are mainly applied in the Île-de-France region because they are major arable crop (especially cereals) farming areas, which may volatilize and can generate high ammonia concentrations under sunny conditions. This study also finds high summer values greater than  $1.5 \cdot 10^{16}$  molecules  $\text{NH}_3 \text{ cm}^{-2}$ , which corresponds roughly to the average value of the dataset plus one standard deviation over the June/July/August time period. This is likely linked to an increase in the volatility of ammonia under warm meteorological conditions.

Satellite remote-sensing instruments such as Infrared Atmospheric Sounding Interferometer (IASI) on board the Metop platforms provide global distributions of atmospheric  $\text{NH}_3$  relying on valuable information (Van Damme et al., 2018). We have compared  $\text{NH}_3$ -IASI data with our measurements from OASIS over the 2009-2016 time period. We show a very good correlation of 0.79 and a mean bias of  $-0.78 \cdot 10^{15}$  molecules  $\text{cm}^{-2}$  between the two datasets. Besides the space instrument's lower sensitivity to the surface ammonia concentrations, spatial heterogeneity of ammonia within the IASI footprint can lead to lower values. Furthermore, OASIS observatory measurements of  $\text{NH}_3$  are representative of the variability at a 100-km regional scale.

This study also illustrates that ground based stations like OASIS may play a key role for validating current (e.g. IASI) and future satellite observations (e.g. Infrared Atmospheric Sounder Interferometer - New Generation - IASI-NG - and Meteosat Third Generation-InfraRed Sounder - MTG-IRS) of ammonia in the infrared for a better understanding of the space and time variability of this major source of nitrogen species in the troposphere.

Since ammonia is a major precursor of  $\text{PM}_{2.5}$  over Europe, as shown by e.g. Fortems-Cheiney et al. (2016) during a European spring haze episode, we expect a link between high ammonia concentrations and inorganic salts, such as ammonium nitrate. That period during late 2012 winter (documented by Petit et al. (2014)), was probably the most polluted

month of March of the last ten years in Paris region (Petit et al., 2017) with the highest  $\text{NH}_3$ -OASIS total columns in the period 2009-2017 over the Paris region. The link between ammonia concentrations and the formation and volatilization of fine particles such as ammonium salts is beyond the scope of this paper and will be discussed in a future study on the diurnal analysis of total and surface ammonia measurements from Paris region during a high spring pollution event. Moreover, 5 future versions of the  $\text{NH}_3$ -OASIS approach will be based on vertical profile retrieval using a Tikhonov-Philips-type regularisation. Tests of different a priori  $\text{NH}_3$  profiles will also be performed for reducing the spectral residuals between measured and simulated spectra while providing accurate retrievals of  $\text{NH}_3$  abundances.

### **Acknowledgments:**

The authors from LISA acknowledge support from University of Paris-Est Créteil and from the OSU-EFLUVE 10 (Observatoire des Sciences de l'Univers-Enveloppes Fluides de la Ville à l'Exobiologie) to make the observatory still operational. IASI is a joint mission of EUMETSAT and the Centre National d'Etudes Spatiales (CNES, France). They acknowledge the support of the Centre National des Etudes Spatiales (CNES) via the project IASI-TOSCA (Terre-Ocean-Surface-Continentale-Atmosphère). The authors also acknowledge the AERIS data infrastructure for providing access to the IASI data in this study and ULB-LATMOS for the development of the  $\text{NH}_3$ -IASI retrieval algorithms. The authors wish to 15 thank the NASA Goddard Space Flight Center for providing the temperature and pressure profiles from the National Center for Environmental Prediction (NCEP). The research was also funded by DIM Qi2 (Region Île-de-France) for internship financial support and by LEFE-CHAT. Work at IMK is funded by the ATMO program of the Helmholtz Association of Germany Research Centres.

Figure 1: Location of the FTIR OASIS observatory providing  $\text{NH}_3$  total columns in Paris region (France). One can see that Paris megacity is very urbanized close to the Paris city, and surrounded by a large rural belt with 49% agriculture surfaces (source Agreste Île-de-France <http://agreste.agriculture.gouv.fr/IMG/pdf/R1118C01.pdf>).

5 **Figure 2: Measured spectrum for both spectral windows obtained with the BRUKER Vertex 80 at Creteil on 21 March 2012, with individual contributions of the main absorbing species represented from the atlas of Meier et al. (Meier et al., 2004) in the first (on the left) and second (on the right) spectral windows.**

5 **Figure 3: Observed (black line) and calculated spectrum (red line) in radiance unit ( $\text{nW}/(\text{cm}^2 \cdot \text{sr} \cdot \text{cm}^{-1})$ ) for both spectral windows measured with the BRUKER Vertex 80 in Creteil on the 21 March 2012 with the fitting residuals (blue line).**

Figure 4: First multi-year time series of NH<sub>3</sub> total columns derived from OASIS measurements over Paris, retrieved from 4920 infrared atmospheric transmission spectra measured during 234 days between 2009 and 2017.

### OASIS mean NH<sub>3</sub> total columns per calendar month (2009-2017)

5

Figure 5: Average annual cycle of monthly NH<sub>3</sub> total columns (molecules cm<sup>-2</sup>) observed by OASIS over Paris, averaged over the 2009-2017 period. The red crosses represent the number of OASIS data per calendar month on a log scale (right axis).

10

Figure 6: Correlations between the FTIR/OASIS and IASI NH<sub>3</sub> total columns fulfilling the temporal and spatial coincidence criteria: a time difference smaller than 30 min, and a 15 km radius centered on the ground-based FTIR station. The dashed line is the straight equation with slope 1.

$$d_{\max} - d_{\min} = 15 \text{ km}$$

IASI pixels used to calculate correlation  $r$  with FTIR versus  $d_{\min}$

5 **Figure 7: Description of the 15-km rings centred on OASIS observatory that were used to select different IASI pixels for the correlation with FTIR data.**

5

**Figure 8: Correlation coefficients  $R$  (blue lines, left axis) between IASI and ground-based FTIR observations with temporal sampling difference smaller than 30 min, as a function of  $d_{min}$  to OASIS observatory, considered for the calculation of the 15 km wide rings. The data (orange lines, right axis) show the total number of IASI/OASIS coincident observations.**

10

5

**Figure 9: Regression slope (blue lines, left axis) between IASI and ground-based FTIR observations with temporal sampling difference smaller than 30 min, as a function of  $d_{min}$  to OASIS observatory, considered for the calculation of the 15 km wide rings. The data (orange lines, right axis) show the total number of IASI/OASIS coincident observations.**

10

5 **Figure 10: Typical  $\text{NH}_3$ -OASIS averaging kernel diagonal elements, illustrated on the 13 March 2014 at different times of the day and Solar Zenith Angles (SZA in degree) and using spectroscopic data from the HITRAN 2008 (HIT08) database (except for  $\text{CO}_2$  lines).**

NH <sub>3</sub> error	NH <sub>3</sub> column (molecules.cm <sup>-2</sup> )		
	average winter NH <sub>3</sub> ( $0.12 \times 10^{16}$ )	average NH <sub>3</sub> ( $0.84 \times 10^{16}$ )	max NH <sub>3</sub> ( $9.1 \times 10^{16}$ )
Random error (%)	23.3	6.7	1.8
Systematic error (%)	22.6	20.8	20.0
Total error (%)	32.4	21.8	20.1

10 **Table 1: Random and systematic errors according to NH<sub>3</sub> total columns. The total errors, combining the systematic and random errors vary from 20% up to 35%. Note that  $9.1 \times 10^{16}$  molecules cm<sup>2</sup> is the maximum ammonia column measured over Paris during the 2009-2017 period (exactly in March 2012).**

Season	No.	Mean ( $\times 10^{16}$ molecules.cm <sup>-2</sup> )	Median ( $\times 10^{16}$ molecules.cm <sup>-2</sup> )	Standard deviation ( $\times 10^{16}$ molecules.cm <sup>-2</sup> )
MAM	2486	1.17	0.83	1.03
JJA	1070	0.84	0.73	0.44
SON	691	0.38	0.31	0.28
DJF	673	0.12	0.09	0.12
all year	4920	0.84	0.62	0.86

5

10 **Table 2: Statistics of the retrieved NH<sub>3</sub>-OASIS measurements depending on the season (MAM for March/April/May, JJA for June/July/August, SON for September/October/November, DJF for December/January/February), and for all the calendar year. (No.: Number of spectra, Mean, Median and Standard deviation). Total columns are given in  $1 \times 10^{16}$  molecules cm<sup>-2</sup>.**
