Abstract. Several satellites have been launched to monitor the increasing concentrations of greenhouse gases, especially CO₂ and CH₄ in the atmosphere, through back-scattered hyperspectral radiance in the shortwave infrared (SWIR) band. The vertical profiles of greenhouse gases and aerosol could strongly affect the results from these instruments. To investigate the effects of the vertical distribution of CO₂ on uncertainty in SWIR satellite retrieval results, we conducted observations of the vertical profiles of CO₂, CH₄, and aerosol particles at 0.6–7 km above sea level using a Beechcraft King Air 350ER in Jiansanjiang (46.77°N, 131.99°E), Heilongjiang province, Northeast China, on August 7–12, 2018. The profiles from this aircraft captured a decrease in CO₂ from 2 km to the minimum altitude due to uptake from vegetation at the surface in summer. CH₄ measurements showed an average 0.5 ppm increase from 2.0 to 0.6 km, which may result from emissions from the large area of paddy fields below, and a constant mole fraction between 1.951 and 1.976 ppm was recorded at 2 km and above. Comparison of CO₂ profiles from a new version of the carbon cycle data assimilation system Tan-Tracker (v1), retrievals from OCO-2 and aircraft measurements was conducted. The results from OCO-2 and the assimilation model system Tan-Tracker captured the vertical structure of CO₂ above 3 km, whereas below 3 km, the values from OCO-2 and Tan-Tracker model were lower than those from in situ measurements. Column-averaged CO₂ volume mole fractions calculated from in situ measurements showed biases of -4.68 ± 0.44 ppm and $-1.18\% \pm 0.11\%$ compared to OCO-2 retrievals.

1 Introduction

Global warming due to greenhouse gases (GHGs) has become one of the most urgent and widely studied issues facing scientists in recent years. The Fifth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC) noted that the global average temperature has increased by 0.85°C over the period 1880–2012. GHGs, especially the increasing CO₂ levels in the atmosphere related to anthropogenic activity, are blamed for global warming, because they absorb and emit radiant energy

within the thermal infrared range. Emission of CO₂ from fossil fuel combustion and industrial processes has contributed about 78% of the total GHG emissions increase from 1970 to 2010 (IPCC, 2015). Accurate measurement of CO₂ concentrations and their spatial and temporal variations in the atmosphere is essential for estimation of sources and sinks in regional and global models. The Global Atmospheric Watch program (<http://www.wmo.int/gaw>) coordinates the systematic observation and analysis of GHGs and other trace substances, providing an important source of local and global GHG data. However, ground-based and in situ measurements near the surface can only provide information about the lower atmosphere, and are insufficient for analysis of total-column GHGs, which exhibits variations in both vertical and horizontal directions. Over the past few years, several satellites, including the Greenhouse Gases Observing Satellite (GOSAT, launched in January 2009), Second Orbiting Carbon Observatory, (OCO-2, launched in 2014), and TanSat (launched in 2016), have been launched into space to monitor CO₂ by observing back-scattered hyperspectral radiance in shortwave infrared (SWIR) wavelength, which can provide global coverage of the column-averaged dry-air mole fraction of CO₂ (X_{CO_2}). Studies have shown that, given a 1–2 ppm accuracy of X_{CO_2} , the use of space-borne instrument data can reduce the uncertainties in regional ($8^\circ \times 10^\circ$ footprint) estimation of CO₂ sources and sinks (Rayner and O'Brien, 2001). In addition, CO₂ vertical profiles in the 5–25 km altitude range can be obtained using limb viewing space-borne sounders such as the Atmospheric Chemistry Experiment Fourier Transform Spectrometer (ACE-FTS, launched in August 2003). Foucher et al. (2009) reported the feasibility and difficulties of obtaining vertical CO₂ profiles using this method.

To validate and calibrate the X_{CO_2} data from satellite measurement products, the Total Carbon Column Observing Network (TCCON), a network of ground-based solar Fourier transform spectrometers operating in the SWIR spectral region was established (Wunch et al., 2011). Several studies have been conducted to determine X_{CO_2} , the column-averaged CH₄ volume mole fraction (X_{CH_4}), and the column-averaged volume mole fractions of other trace gases (X_{gas}) from TCCON data, which have shown good accuracy (Hedelius et al., 2017; Mendonca et al., 2019). In addition, commercial mobile solar-viewing near-infrared spectrometers of lower resolution than the TCCON instruments, such as Bruker™ EM27/SUN, show potential for measurement of X_{gas} with an acceptable bias range (Hedelius et al., 2016).

Retrieval accuracy is affected by knowledge of the vertical distribution of aerosols and CO₂. Vertical profiles of CO₂ also affect the accuracy of estimation for regional carbon fluxes in transport modeling, and can help elucidate the global carbon cycle and climate change. Many experiments have been conducted to measure the vertical profiles of CO₂, CH₄, and other trace gases. The AirCore sampling system can be used to obtain vertical profiles of CO₂ and CH₄ from near the surface to 8–12 km with high accuracy (Karion et al., 2010; Membrive et al., 2017). Active remote sensing of atmospheric X_{CO_2} with the Raman lidar (light detection and ranging) technique has been developed and used to measure CO₂ vertically in the troposphere (Zhao et al., 2007; Gong et al., 2013; Han et al., 2017). CO₂ concentrations were measured at 8–12 km by Tohoku University (Sendai, Japan) through flask sampling on a commercial airliner operated by Japan Airlines (JAL) between Japan and Australia in 1984 and 1985 (Nakazawa et al., 1991). The Comprehensive Observation Network for TRace gases by AirLiner (CONTRAIL) project installed continuous CO₂ measurement equipment onboard aircraft operated by JAL for in situ measurement (Machida et al., 2008). The data for CONTRAIL are collected at altitudes between a few kilometers and 10 km,

taking advantage of the frequent movement of commercial aircraft around the world. The Civil Aircraft for Remote Sensing and In Situ Measurements Based on the Instrumentation Container Concept (CARIBIC) project (Brenninkmeijer et al., 1999; Brenninkmeijer et al., 2007) aimed to observe trace gases such as CO, O₃, and CO₂ by deploying measurement equipment in passenger aircraft. The HIAPER Pole-to-Pole Observation (HIPPO) project involved a sequence of five global aircraft measurement programs to sample the atmosphere from near the North Pole to the coastal waters of Antarctica (Wofsy, 2011). Direct measurements that are independently collected from aircraft provide validation information for satellite products. Several studies have shown that profile measurements of CO₂ and CH₄ obtained using aircraft and AirCore are useful for bias correction of both TCCON measurements (Deutscher et al., 2010; Hedelius et al., 2016) and satellite products (Araki et al., 2010; Inoue et al., 2013, 2014; Miyamoto et al., 2013; Frankenberg et al., 2016; Wunch et al., 2017).

Three satellites designed for CO₂ measurement, TanSAT (Yang et al., 2018; Yang et al., 2020), GMI/GF-5 (Li et al., 2016), and GAS/FY-3D (Qi et al., 2020), were launched into space in 2016, 2017, and 2018, respectively. Measurement of profiles is crucial to further validate the retrieved hyperspectral measurements from these three satellites. Because the algorithm for satellite retrieval requires a prior profiles based on the model and in situ measurements, the lack of direct and independent airborne observations may increase the bias in the satellite results over China.

In this study, in situ aircraft-based measurements of CO₂ and CH₄ were conducted in Jiansanjiang, Northeast China, in August 2018. An ultraportable greenhouse gas analyzer (UGGA; model 915-0011; Los Gatos Research, San Jose, CA, USA) was used onboard the aircraft to measure the vertical mole fractions of CO₂ and CH₄ at altitudes of 0.6–7 km. Descriptions of the aircraft and onboard instruments are provided in Section 2. Details of the experimental site and the flight trajectory are provided in Section 3. A comparison of the profiles obtained using aircraft with OCO-2 and the assimilation system Tan-Tracker (v1) is described in Section 4. Finally, the methods used to calculate X_{CO₂} and extrapolate in situ profiles, as well as error estimation, are discussed in Section 5.

2 Methods

2.1 Aircraft Instrumentation

The aircraft used for this experiment was a Beechcraft King Air 350ER, which is a twin-turboprop aircraft designed for weather modification missions and measurement of trace gases and aerosols by the China Meteorological Administration (CMA). The cruising speed and maximum speed of the aircraft are 441 and 561 km/h, respectively. Temperature, wind speed, relative humidity, and other meteorological data were detected and recorded by an Aircraft Integrated Meteorological Measurement System (AIMMS-20AG) installed on the aircraft. The geolocation information including latitude, longitude, ambient pressure and height of the aircraft is also measured by AIMMS-20AG. The relative humidity is calculated by temperature and dew point, measured by the Total Temperature Sensor (Model 102 Type Non-De-iced, Rosemount Aerospace Inc) Dew Point Hygrometer (Model 137 Vigilant™, EdgeTech), respectively.

The ultraportable greenhouse gas analyzer, UGGA (model 915-0011; Los Gatos Research), was connected to an aircraft-based impactor inlet system which consists of CVI (Model 1204; Brechtel Manufacturing Inc.) and ISO inlet (Model 1200; Brechtel Manufacturing Inc.) in the pressurized cabin for continuous measurement of CO₂ and CH₄. The CVI and/or ISO inlet was mounted on the top of the aircraft body as shown in figure 1, and the air flow rate of the inlet is kept constant by the automatic air flow controller of the inlet (Aircraft-based Counterflow Virtual Impactor Inlet System CVI - Model 1204, Brochure; Isokinetic Inlet System ISO Inlet - Model 1200, Brochure). The UGGA uses a laser absorption technology called off-axis integrated cavity output spectroscopy to determine the trace gas concentration with a high precision of < 300 ppb (CO₂) and < 2 ppb (CH₄) and a 10-s response time (UGGA user manual, model 915-0011; Los Gatos Research) and was tested and controlled in the laboratory. As shown in the in-flight schematic diagram (figure 1), the external oil-less diaphragm vacuum pump (F-9A 08-03, GAST) was mounted between the CVI inlet and/or the ISO inlet, with the maximum pressure of 31.15 lpm (litter per minute) used to keep a stable airflow. The ISO inlet was used as the aircraft pass through clouds, and CVI inlet was used in the other times. Similar system for airborne GHG measurement have been reported by O'Shea et al. (2013) and Palmer et al. (2013).

During the flight, the pressure of the sample cavity was kept constant by an small pump inside the instrument with the airflow about 0.3 lpm. The sample cavity temperature was also kept stable and constant by the temperature controller of the instrument. The instrument automatically recorded and saved the temperature and pressure in the cavity during operation. According to the records, the standard deviation of the cell pressure during three flights is 0.029, 0.029, 0.033 on 7, 9 and 10 August and the range of the cell pressure on each flight is below 0.12 torr. For the cell temperature, the standard deviation is 0.46, 1.55 and 1.18 on each day and the range is below 3.11 °C. The UGGA was calibrated against standard GHGs (provided by the National Institute of Metrology, China) before takeoff and after landing of each flight to ensure the accuracy of the data measured with the UGGA. Before this study, the GHG standard gases have been used by the CMA, Chinese Academy of Sciences, and other scientific research institutions for calibration and validation, showing that these standard gases have good performance and reliability. The standard gas we used is based on dry and clean air with greenhouse gases known concentration value, filled in a 29.5L aluminum alloy cylinder with silanization and other special treatment on the inner wall, traceable to the world meteorological organization global atmospheric observation network (WMO-GAW) level 1 standard gas. The concentration of the CO₂ is 400.13 ppm and CH₄ is 1.867 ppm. The standard gas we use has been measured in the laboratory for the proportion of $\delta^{13}\text{C}$ in CO₂. The range of the proportion is -8.0‰ to -8.2‰ close to the natural content, so it will not cause significant isotopic effect on the measurement of CO₂ by optical method and meet the requirements of standard gas (Yao et al., 2013).

Just before taking off, UGGA was calibrated against standard gas, and the stability of instrument was checked and tested again using the same standard gas of CO₂ and CH₄ immediately after landing. As shown in Figure 2, the concentration of CO₂ and CH₄ before and after landing is stable around the value of standard has concentration, and there is almost no drift after the flight. The precision and reparability of the instruments are also checked and test multiple times in laboratory and the results show that it is stable and good for the measurements.

Based on the nonlinear least squares four-dimensional variational data assimilation algorithm (NLS-4DVar) and the Goddard Earth Observing System atmospheric chemistry transport model (GEOS-Chem), Tan-Tracker provides surface flux inversion estimates and profiles of CO₂ with 47 levels of vertical resolution from the surface to 0.03 hPa and horizontal resolution of 2.5° × 2°. The NLS-4DVar assimilation model Tan-Tracker (v1) and OCO-2 X_{CO2} (v9r) retrievals are used to optimize surface
135 terrestrial ecosystem CO₂ flux and ocean CO₂ flux, while prior Fossil Fuel emission and prior Fire emission remain unchanged (details of model setting and prior flux information can be found in Han and Tian, 2019).
The Orbiting Carbon Observatory-2 (OCO-2), successfully launched on 2 July 2014, obtained global measurement of CO₂ through hyperspectral measurement of reflected sun light from earth atmosphere in one NIR and two SWIR bands centre at 0.76, 1.61 and 2.06 μm, more details about the mission, retrieving algorithm and data characteristic can be found in Crisp et al. (2008) and O'Dell et al. (2012). The uncertainty and bias of the X_{CO2} products related to surface properties, aerosol and cloud, and the retrieving algorithm has been reported by Butz et al. (2009), Jung et al. (2016) and Connor et al. (2016). The
140 OCO-2 data (V9r) including X_{CO2}, CO₂ profile and the a priori profile was used in this study.

3 Experimental Site

Aircraft measurement were carried out from 7 to 10 August over Jiansanjiang (47.11°N, 132.66°E, 61 m above sea level),
145 located in Heilongjiang province, Northeast China. Figure 3 shows the geolocation of the Jiansanjiang aircraft and the flight path. The area is mostly covered with large tracts of farmland. Rice cultivation is carried out primarily in summer, and crop growth is vigorous during this period. Due to the influence of plant photosynthesis, a large amount of CO₂ uptake occurs near the surface.

Three profiles were obtained between around 08:00 and 11:00 in local time (GMT+8) on 7, 9 and 10 August, 2018. The
150 aircraft is designed for weather modification by China Meteorological Administration (CMA), so the infrastructure of the aircraft and the gas flow system are also designed and completed in USA by the team of weather modification agency and an US company. CMA is in charge of the flight route, and there is a chance (several times later are planning) that it can carry the greenhouse gas analyzer to measure the profiles of CO₂ and CH₄. The greenhouse gas analyzer was loaded on the aircraft and some parts of air flow arrangements were modified to better fit the requirement for greenhouse profile measurement. Due to
155 the logistical problem and the ATC restriction, we must fly in the morning from around 7:30 to 11:00 (local time) of these days to avoid obstructing civil aviation. The details of the three flights are listed in table 1.

The flight trajectory on 7 August is shown in figure 4. The aircraft climbed up quickly and directly to the maximum height to about 7.5 km 30 min after taking off, and then descending down step by step at about every 300 m. Since the 3-D figure in these three days looks identical, the flight trajectory of the other two days (9 and 10 August) is not shown in figure 4.
160 Considering the sensitivity of the UGGA response, measurements collected during the ascent were discarded due rapid changes in air pressure, and only data collected and reserved while spiraling downward were regarded as valid and analyzed further.

Data recorded below 0.6 km were also rejected because samples were easily contaminated with exhaust emissions during the slowing and descent of the aircraft before landing. The spiral descent of the aircraft lasted for about 2.5 h on each of the three sampling days.

165 4 Data Processing

4.1 Water vapor correction

The mole fraction of CO₂ or CH₄ measured during flight is the volume in proportion to air containing water vapor, which cannot be directly compared with values from other data sources due to differing water vapor contents of the sampled air. Therefore, the effect of water vapor is corrected and mole fractions of CO₂ and CH₄ to dry air are given by:

$$f_{\text{gas_dry}} = \frac{f_{\text{gas}} \cdot p}{p - p_{\text{H}_2\text{O}}} \quad (1)$$

170 where $f_{\text{gas_dry}}$ (mol/mol) is the mole fraction of a gas in dry air, and f_{gas} (mol/mol) is the measured mole fraction of gas under real air conditions with water vapor. $p_{\text{H}_2\text{O}}$ is water vapor pressure in hPa, which can be calculated as:

$$p_{\text{H}_2\text{O}} = e_s \cdot \text{RH} \quad (2)$$

where e_s (hPa) is the saturated water vapor pressure at temperature T (K) at aircraft altitudes, which can be derived from the Clausius–Clapeyron equation:

$$\ln \frac{e_s}{6.11} = \frac{L_v M_w}{R} \left(\frac{1}{273} - \frac{1}{T} \right) \approx 5.42 \times 10^3 \left(\frac{1}{273} - \frac{1}{T} \right). \quad (3)$$

175 where L_v is the latent heat of vaporization, M_w is the molecular weight of water, and R is the gas constant. Where $L_v = 2.500 \times 10^6$ J Kg⁻¹, M_w is the molecular weight of water equals to 18.016, $R = 8.3145$ J K⁻¹mol⁻¹, and e_s (in hPa) at temperature T (in K). Pressure p (hPa) of the ambient atmosphere are measured by the aircraft meteorology system, AIMMS-20AG, and the temperature T (K) was measured by Total Temperature Sensor (Model 102 Type Non-De-iced). The relative humidity RH (%) was calculated by the dew point and temperature. The dew point data is obtained by Dew Point Hygrometer (Model 137 Vigilant™, EdgeTech).

180 4.2 Data processing

Before aircraft takeoff, the clocks of both the UGGA, AIMMS-20AG, the Total Temperature Sensor and other instruments were adjusted to match those of the CO₂, CH₄, and weather system measurements, synchronizing these data to the altitude and geolocation of the aircraft. The data from UGGA and synchronous meteorology measurements, including temperature, pressure, and humidity of ambient atmosphere, are recorded every second, then smoothed with a 10-s running average to
185 further remove errors caused by temporal mismatch considering the response time of the UGGA. Because the flights followed a spiral trajectory that descended approximately every 300 m, only data collected during level flight were retained and analyzed,

whereas data from the descent periods were removed to avoid effects from vertical variations in sampling during rapid descent. The time points at the beginning and end of level flight are determined according to the altitude and its variation of the aircraft. Considering the residual time of the GHG measurement system, the data obtained 220s from the start of the level flight is considered to be observed when the aircraft is descending rather than in level, which may cause uncertainty of the measurement. Therefore, the data were reserved after the level flight starting for 220s. If the duration time of certain level flight lasted less than 220s, the data observed during that level flight were also discarded.

The instrument was calibrated against the standard gas before and after each flight. All of the measurements during the calibration process, including the standard gas used for calibration can trace back to WMO scale. The maximum and the average value of the difference between the standard gas and the measurement of the instrument of each day was considered as the accuracy of the aircraft data. For the precision, noted that the instrument was not continuously calibrated against the standard gas during the flight, we calculated the one standard deviation of the data in each level flight, and the maximum of the average value of 1- σ on each day is considered as the precision of the aircraft measurement. The accuracy of CO₂ and CH₄ is below 0.66 ppm and 0.002 ppm, 0.16% and 0.10% of the CO₂ and CH₄ concentration in standard gas, respectively. For precision, the 1- σ value is below 0.71 ppm and 0.0062 ppm for CO₂ and CH₄, respectively.

5 Results and Discussion

5.1 CO₂ and CH₄ profiles

Figure 5 shows vertical profiles of the CO₂ and CH₄ mole fractions measured with the UGGA during the flight campaign over Jiansanjiang, which is an agricultural area that produces a large amount of rice. The CO₂ concentration increased with height in the troposphere (Figure 5a), which may have resulted from CO₂ uptake by rice plants near the surface during the summer growth season. The greater increase rate of CO₂ in the lower troposphere on 7 August compared to the other two days was probably attributed to differing weather conditions on the three sampling days. 7 August was a sunny day, but it was overcast on 9 and 10, August, which may have weakened photosynthesis in rice and reduced CO₂ uptake. During all three flights, the mole fraction of CO₂ reached a maximum of about 418 ppm in the free troposphere at the top of the profile.

The mole fraction of CH₄ showed a consistent decrease in concentration with height, ranging from 1.95 to 2.10 ppm from about 2 km to near the surface, which may have been the result of CH₄ emissions from agricultural activity at the surface. CH₄ showed low variability of less than 0.5 ppm at higher altitudes, from above 2 to 7 km, indicating a well-mixed vertical structure of CH₄ in the free troposphere.

Comparing the CO₂ and CH₄ observation data, the mole fraction of CH₄ varied less than that of CO₂ from 1.5–2 km up to the free troposphere, with a stable value of about 1.925 ppm. This stability indicated that CH₄ was evenly mixed at these heights and that there were no obvious sources or sinks of CH₄. Conversely, CO₂ rose with increasing altitude in the free troposphere from about 400 to 418 ppm. This increase may have been due to photosynthesis by vegetation and the large number of crops planted locally, creating a CO₂ sink at the surface, and causing the CO₂ concentration to rise with height in the free troposphere.

Our findings indicate that the vertical profile of CO₂ in summer increases with height in the upper troposphere, whereas that of CH₄ changes little with height and is relatively stable.

5.2 Comparison of profiles from the model and satellite product

Aircraft measurements were compared with CO₂ data obtained from OCO-2 (v9r) retrievals and the recently developed data assimilation system for the global carbon cycle, Tan-Tracker (v1) (Han and Tian, 2019). The assimilation data are collected and linearly interpolated spatially and temporally based on the geolocation of the observation site and time. Because no data were obtained from OCO-2 (v9r) over Jiansanjiang during the flight, the results of OCO-2 within $1^\circ \times 1^\circ$ spatially at the closest time to the flight, which were collected on 5 August were used for comparison. The height of the profile is available on the satellite product.

The structure of CO₂ varied with height could be roughly divided into three segments: surface to 2 km, 2 to 3 km, and 3 to 8 km (Figure 6). Below 2 km, CO₂ of Tan-tracker model is assumed to be well mixed and uniformly distributed with height, with values ranging from 385 to 395 ppm; therefore, the model could not reproduce the strong decrease in CO₂ from 2 km to the surface due to uptake by vegetation. From 2 to 3 km, CO₂ increased to about 400 ppm with altitude. The averaged satellite retrieval profiles correctly reproduced the decrease in CO₂ from 2 km to the surface, but the decrease rate was lower than those of in situ profiles, decreasing from 393 ppm at 2 km to 390 ppm near the surface. Flight data showed a significant CO₂ sink in this region, most notably on 7 August when it decreased from 400 ppm at 2 km to 380 ppm at 0.6 km. The impact of ground sinks was more pronounced and apparent than in results from satellite inversion and model simulations, indicating that the strong variations in the lower atmosphere and planetary boundary layer (PBL) should be more carefully considered in model and retrieval algorithms. Between 2 and 4 km, aircraft profiles showed a relatively uniform mixing level of CO₂, with roughly stable concentrations around 400 ppm.

In general, all profiles from aircraft, satellite retrieval, and model showed a similar vertical distribution trend in the troposphere above 2 km, but with large differences in values. The volume mole fraction of CO₂ from both satellite and aircraft measurements indicated a CO₂ sink. GHGs profiles have been rarely observed before near the experiment site, or over Northeast of China as far as we know. The model simulations are based on data of regional emission inventory. The accuracy of simulated profiles and concentration near surface over the experiment site still remains unknown. So continuous and regular observation of the GHGs profiles are necessary to better understand the regional emission amounts and the variation of the GHGs.

5.3 Comparison of X_{CO2} products

The total column amount of CO₂, can be derived by integrating the CO₂ concentration from the surface to the top of the atmosphere under the assumption of hydrostatic conditions:

$$VC_{CO_2} = \int_0^{p_s} \frac{f_{CO_2}^{dry} \cdot (1 - f_{H_2O})}{g(p) \cdot m(p)} dp \quad (4)$$

$$m = [m_{H_2O} \cdot f_{H_2O} + m_{air}^{dry} \cdot (1 - f_{H_2O})]$$

where VC_{CO_2} is the total column amount of CO_2 , $f_{CO_2}^{dry}$ is the dry-air mole fraction (DMF) of CO_2 (mol mol^{-1}), $f_{H_2O}(p)$ is the aircraft profile of H_2O (mol mol^{-1}), which is measured using the onboard AIMMS system, $m(p)$ is the mean molecular mass of wet air, and $g(p)$ is gravitational acceleration, $m_{H_2O} = 18.02 \times 10^{-3}/N_A$ kg/molecule, $m_{air}^{dry} = 28.964 \times 10^{-3}/N_A$ kg/molecule, and N_A is Avogadro's constant. Data beyond the flight limit are taken from National Centers for Environmental Prediction (NCEP) reanalysis data interpolated to the time of flight.

The column-averaged DMF of CO_2 (X_{CO_2}) from aircraft measurements was calculated based on the method of Wunch et al. (2010), which considers the average kernel in OCO-2 satellite retrievals:

$$X_{CO_2}^{in\ situ} = X_{CO_2}^a + \sum_j h_j a_j (t_{in\ situ} - t_a)_j \quad (5)$$

where a is the average kernel (Rodgers and Connor, 2003), $X_{CO_2}^a$ is the column-averaged DMF for the a priori profile t_a , h_j is the pressure weighting function of OCO-2, and $t_{in\ situ}$ is the in situ profile from aircraft measurement. Because in situ measurements available from aircraft are limited, values outside of the aircraft's vertical observation range must be estimated to calculate X_{CO_2} . Two extrapolation methods were used to extend the profile of the aircraft measurements and then estimates the X_{CO_2} value of the in-situ measurement respectively. 1) The unknown part of the aircraft profile was directly from the OCO-2 a priori profile. 2) A well-mixed and constant mixing ratio of CO_2 is assumed from the surface to the lower limit of flight, and from the upper limit of flight to the tropopause. The CO_2 concentrations above the tropopause were calculated with an empirical model (Toon and Wunch, 2014) which considers tropopause height as well as realistic latitude and time dependencies through curve fitting of data from high-altitude balloons, AirCore, Observations of the Middle Stratosphere balloon, and aircraft. In general, the mole fraction of CO_2 decreased exponentially with height from the tropopause to upper stratosphere, and the tropopause height was obtained from NCEP reanalysis data with a $2.5^\circ \times 2.5^\circ$ resolution, which was linearly interpolated to the geographic coordinates of Jiansanjiang. Figure 7 shows the extrapolated CO_2 profiles using method (2).

X_{CO_2} calculated from aircraft measurements and differences with that from OCO-2 are listed in Table 1 and 2. The results showed that X_{CO_2} values from OCO-2 were lower, with an average difference of -4.68 ± 0.44 ppm ($-1.18\% \pm 0.11\%$) and -5.09 ± 1.28 ppm ($-1.28\% \pm 0.32\%$) by method (1) and by method (2).

Uncertainties induced by extrapolation of profiles outside the height limits of aircraft flight and by errors in tropopause estimation were analyzed. Errors in extrapolation of the profile below the lower limit and above the upper limit of flight were estimated by recalculating X_{CO_2} after a 1-ppm positive shift in the CO_2 concentrations at these altitudes. For method (1), since the value of CO_2 mole fraction of unknown part is the same as that of the OCO-2 a priori profile, as eq. (5) shows, no extra

uncertainty would be introduced by extrapolation. But for method (2), As the profile is assumed to decrease exponentially with height above the tropopause, the height of the tropopause also introduces uncertainties for X_{CO_2} . Table 2 lists the errors resulting from three sources: 1) uncertainties from in situ measurement, 2) extrapolation of the profile in the PBL where no in situ measurements were collected, and 3) profile assumptions above the upper limit of flight observations. Errors due to uncertainty in tropopause height were analyzed by shifting the tropopause height upward by 1 km, and the results are also listed in Table 2. These results indicated that the extrapolation method and assumptions used to construct profiles where no measurements were made were the primary source of errors, among which the greatest error was from the profile above the upper limit of the flight (0.323 ppm). Errors due to uncertainty in the tropopause height were also non-negligible. Because of the lack of observation data near the surface, the missing measurement data was directly replaced by the data at the lowest altitude measured by the aircraft. The error caused by this practice is shown in table 3, with an average of 0.79 ppm for X_{CO_2} . This is also the impact of the lack of near-surface observations on the overall X_{CO_2} estimates. Therefore, observations from near the surface to about 1 km from other method, such as in-situ GHG measurement by tethered balloon and high tower, is necessary for accurate estimation of X_{CO_2} .

6 Conclusion

The vertical distributions of CO_2 and CH_4 were measured using a Beechcraft King Air 350ER over Jiansanjiang, an extensive paddy area in Northeast China, and three vertical profiles from 0.6 to 7.5 km were obtained on 7, 9 and 10 August. Measurements of the mole fraction of CO_2 showed an increase with height, whereas CH_4 decreased with height. These results are reasonable, because paddies are a sink for CO_2 and source of CH_4 during the summer growing season. Comparing the observed profiles from aircraft with those from the carbon cycle data assimilation system Tan-Tracker (v1) and OCO-2 retrievals showed that the general vertical structure was consistent, but the values of mole fraction of CO_2 from Tan-Tracker and OCO-2 had negative bias estimates. The average bias between aircraft and OCO-2 is -4.68 ± 0.44 ppm ($-1.18\% \pm 0.11\%$). The uncertainty arose mainly from extrapolation of the profile beyond the flight limit, where no in situ measurements were available.

Data availability

Data used in this study are available from the corresponding author upon request (dmz@mail.iap.ac.cn).

Author contributions

M. Duan and X. Sun determined the main goal of this study. X. Sun carried it out, analyzed the data, and prepared the paper with contributions from all co-authors. Y. Gao and N. Chen provided technical guidance for related instrument.

Competing interests

305 The authors declare that they have no conflict of interest.

Acknowledgements

This work is supported by the National Nature Science Foundation of China (No. 41527806 and No.41705014). We also acknowledge numerous staff of the Weather Modification Center, China Meteorological Administration, for supporting the experiment and the instrumentation onboard the aircraft. We also thank Jiansanjiang Airport for providing the experimental
310 site and arranging time for conducting the campaign.

Figure 1. (a) The outside view of the Beechcraft King Air 350ER instrumentation. (b) The schematic diagram of the greenhouse gases sample airflow.

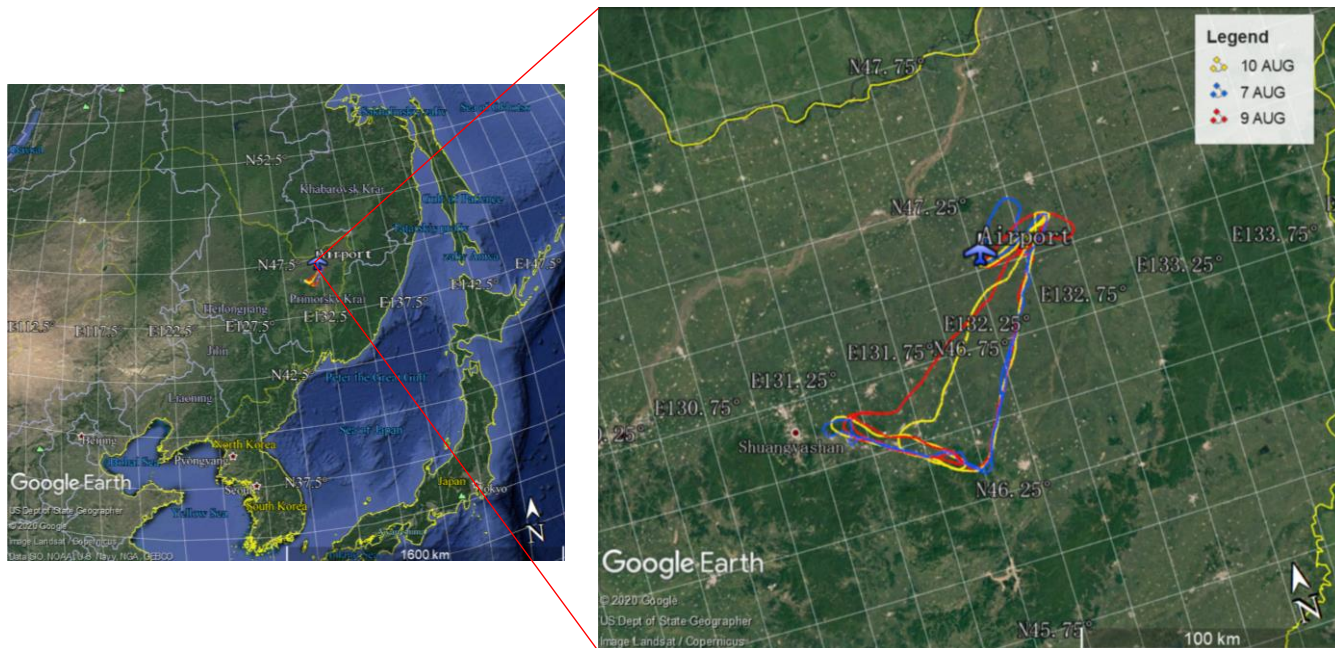

Figure 3. Observation area for aircraft-based measurement of CO₂ and CH₄ over Jiansanjiang, Northeast China, and the flight paths on 7, 9, 10 August.

Figure 4. Trajectory on the 7 August, 2018 in Jiansanjiang. The color scale shows the progression of time in local time, where blue represents the start time of the data profile, and red represents the end time.

Figure 5 Vertical profiles of (a) CO₂ and (b) CH₄ observed on August 7 (blue), 9 (red), and 10 (yellow), 2018, over Jiansanjiang measured in situ with aircraft. The aircraft-based in situ measurement data are indicated with dots, and averaged data for each flat flight stage are shown as lines.

480 **Figure 6.** Comparison of aircraft measurements (in situ measurement data are shown by the yellow line) with 1 standard deviation (yellow bars) collected on August (a) 7, (b) 9, and (c) 10, Tan-Tracker (v1) data (blue line) and the a priori profile of it (red line) at the location of Jiansanjiang linearly interpolated to the observation times on August (a) 7, (b) 9, and (c) 10, and the OCO-2 averaged profile (gray line) for the aircraft flight area from August 5 with 1 standard deviation (grey bars).

Figure 7. Extrapolated CO₂ profiles observed on 7, 9 and 10 August, 2018, over Jiansanjiang by method (2). Red, blue, and yellow solid lines show the aircraft-based (in situ) data collected on 7, 9 and 10 August, respectively, averaged for each flat stage of the flight. Dotted lines show the extrapolated parts of the profiles, with colors corresponding to sampling dates in accordance with the solid lines. Black horizontal lines show the tropopause height from NCEP reanalysis data.

Table 1 Details of the flight on each day.

Date	Flight Time (LTC)	Fight Altitude (m)
7 August, 2018	07:49:08-10:53:32	59-7205
August 9, 2018	07:50:19-10:45:57	61-7190
August 10, 2018	07:56:02-10:54:11	65-7104

Table 2. X_{CO2} derived from aircraft on each observation day (7, 9 and 10 August) supplemented the aircraft profile by method (1). OCO-2 (V9r) X_{CO2} were from August 5, which was the closest time point of X_{CO2} data from OCO-2 over Jiansanjiang to the observation period. Differences between aircraft X_{CO2} and OCO-2 are shown in the fourth (ppm) and fifth (%) columns. The average difference and standard deviation are shown in the fifth row.

Date	Aircraft* (ppm)	OCO-2 (ppm)	Difference (ppm)	$\frac{\text{OCO-2-Aircraft}}{\text{Aircraft}} \cdot 100\%$ (%)
7 August, 2018	401.95	396.91	-5.04	-1.27
August 9, 2018	401.72		-4.81	-1.21

August 10, 2018	401.10		-4.19	-1.06
		Average (1 σ)	-4.68(0.44)	-1.18(0.11)

*The effect of the average kernel was taken into consideration for OCO-2.

Table 2 The same as Table 2, but for method (2).

Date	Aircraft* (ppm)	OCO-2 (ppm)	Difference (ppm)	$\frac{\text{OCO-2-Aircraft}}{\text{Aircraft}} \cdot 100\%$ (%)
7 August, 2018	401.54		-4.63	-1.16
August 9, 2018	403.45	396.91	-6.54	-1.64
August 10, 2018	401.02		-4.11	-1.03
		Average (1 σ)	-5.09 (1.28)	-1.28 (0.32)

495 **Table 3. Aircraft integration error budget of X_{CO2} estimation for method (2). Errors in the three profiles from multiple error sources contributed to the calculation results of the integrated total column. The error is spilt into four sources, similar to previously described error budgets (Wunch et al., 2017): the contribution from the aircraft profile itself, the contribution from the unknown surface to the bottom of the profile, the contribution from the upper troposphere and stratosphere, and error from the tropopause height.**

Date	PBL error (ppm)	Upper troposphere and stratosphere error (ppm)	Tropopause height error (ppm)
7 August, 2018	0.086	0.323	0.054
August 9, 2018	0.076	0.303	0.017
