13 **Abstract.** Laser induced fluorescence (LIF) is a widely used technique for both laboratory-
14 based and ambient atmospheric chemistry measurements. However, LIF instruments require
15 calibrations in order to translate instrument response into concentrations of chemical species.
16 Calibration of LIF instruments measuring OH and HO₂ (HO_x), typically involves the
17 photolysis of water vapor by 184.9 nm light thereby producing quantitative amounts of OH and
18 HO₂. For ground-based systems HO_x instruments, this method of calibration is done at one
19 pressure (typically ambient pressure) at the instrument inlet. However, airborne HO_x
20 instruments can experience varying cell pressures, internal residence times, temperatures, and
21 humidity during flight. Therefore, replication of such variances when calibrating are essential
22 to acquire the appropriate sensitivities. This requirement resulted in the development of the
23 APACHE (All Pressure Altitude-based Calibrator for HO_x Experimentation) chamber. It
24 utilizes photolysis of water vapor, but has the additional ability to alter the pressure at the inlet
25 of the HO_x instrument thus relating instrument sensitivity to the external pressure ranges
26 experienced during flight (275 to 1000 mbar). Measurements supported by COMSOL
27 multiphysics and its computational fluid dynamics calculations revealed that, for all pressures
28 explored in this study, APACHE is capable of initializing homogenous flow and maintain near
29 uniform flow speeds across the internal cross-section of the chamber. This reduces the
30 uncertainty regarding average exposure times across the mercury (Hg) UV ring lamp. Two
31 different actinometrical approaches characterized the APACHE UV ring lamp flux as $6.3 \times$
32 $10^{14} (\pm 0.9 \times 10^{14}) \text{ s}^{-1}$ depending on pressure. Data presented in this study are the first direct
33 calibrations, performed in a controlled environment using APACHE of an airborne HO_x
34 system instrument.

35

36 **1 Introduction**

37 It is well known that the hydroxyl (OH) radical is a potent oxidizing agent in daytime
38 photochemical degradation of pollutants sourced from anthropogenic and biogenic processes
39 thus accelerating their removal from our atmosphere. The hydroperoxyl radical (HO₂) also
40 plays a central role in atmospheric oxidation as it not only acts as a reservoir for OH, but is
41 involved in formation of other oxidants such as peroxides and impacts the cycling of pollutants
42 such as NO_x (= NO + NO₂) (Lelieveld et al., 2002). Therefore, measurements of OH and HO₂
43 (HO_x) within the troposphere are essential in understanding the potential global scale impacts
44 of pollutants in both the present day and in climate predictions. One common HO_x
45 measurement method is Laser Induced Fluorescence (LIF) (Stevens et al., 1994; Brune et al.,

46 1995; Hard et al., 1995; Martinez et al., 2003; Faloona et al., 2004; Hens et al., 2014; Novelli
47 et al., 2014). However, other methods have been successfully implemented to measure HO_x.
48 Chemical Ionization Mass Spectrometry (CIMS) (Sjostedt et al., 2007; Dusanter et al., 2008;
49 Kukui et al., 2008; Albrecht et al., 2019) and Differential Optical Absorption Spectroscopy
50 (DOAS) (Brauers et al., 1996; Brauers et al., 2001; Schlosser et al., 2007) have also been used
51 in the measurement of HO_x in the field and in intercomparison projects with LIF
52 instrumentation. However, low atmospheric concentrations of HO_x (Schlosser et al., 2009) and
53 potential interferences (Faloona et al., 2004; Fuchs et al., 2011; Mao et al., 2012; Hens et al.,
54 2014; Novelli et al., 2014; Fuchs et al., 2016) can make HO_x measurements especially
55 challenging. Airborne LIF-FAGE (LIF-Fluorescence Assay by Gas Expansion) instruments
56 experience large variability in pressure, humidity, instrument internal air density, and internal
57 quenching during flights, which cause a wide array of instrumental sensitivities (Faloona et al.,
58 2004; Martinez et al., 2010; Regelin et al., 2013; Winiberg et al., 2015). Therefore, it is critical
59 to utilize a calibration system that can suitably reproduce in-flight conditions to determine the
60 instrument response to known levels of OH and HO₂ to acquire robust HO_x measurements.
61 The first stage of the our Hydroxyl Radical measurement Unit based on fluorescence
62 Spectroscopy (HORUS) inlet is an inlet pre-injector (IPI), used to determine the concentration
63 of background OH interferences by removing atmospheric OH from the signal via addition of
64 an OH scavenger such as propane. IPI draws 50–230 sL min⁻¹ depending on altitude and is
65 susceptible to temperature and pressure-driven changes in internal reaction rates and residence
66 times under flight conditions. This has implications for the removal of atmospheric OH in the
67 inlet and for the characterization of background interference signals in HORUS. Therefore, a
68 device capable of providing stable high flows whilst reproducing a wide range of pressures and
69 temperatures is needed in order to calibrate the airborne HORUS instrument.

70

71 2 Experimental design and set up

72

73 2.1 APACHE design overview

74

75 Figure 1 shows the overview of the APACHE system. In front of the APACHE inlet, a series
76 of mixing blocks were installed where multiple dry synthetic air additions were injected into a
77 controlled humidified air supply ensuring thorough mixing of water vapor before being
78 measured by a LI-COR 6262 CO₂/H₂O (figure 1a). This air is then fed into a large mass flow
79 controller (MFC). The construction of the APACHE chamber itself is shown in figure 1b. The
80 first section contains the diffuser inlet with a sintered filter (bronze alloy, Amtag, filter class
81 10). This 2 mm thick sintered filter, with a pore size of 35 μm, which initializes a homogeneous
82 flow and further improves the mixing of water vapor before passing over the UV ring lamp
83 (described further in section 4). The water photolysis section contains a low-pressure, 0.8 A,
84 mercury ring lamp (uv-technik, see supplementary, figure S.1) which produces a constant radial
85 photon flux at 184.9 nm, situated 133 mm after the sintered filter and separated from the main
86 APACHE chamber by an airtight quartz window. Between the lamp and the quartz window
87 there is an anodized aluminum band with thirty 8 mm apertures, which blocks all light apart
88 from that going through the apertures, which reduces the amount of UV flux entering APACHE
89 and controls the size of the illuminated area. The HORUS inlet is clamped down 169.5 mm
90 after the photolysis section in such a way that the instrument sample flow is perpendicular to
91 the airflow passing over the inlet. The inlet protrudes 51.5 mm into the APACHE cavity much
92 like it is when installed in the aircraft shroud system (see figure 2), and is made air tight with
93 the use of O-rings. Opposite the HORUS inlet, there is an airtight block attachment containing
94 a series of monitoring systems.

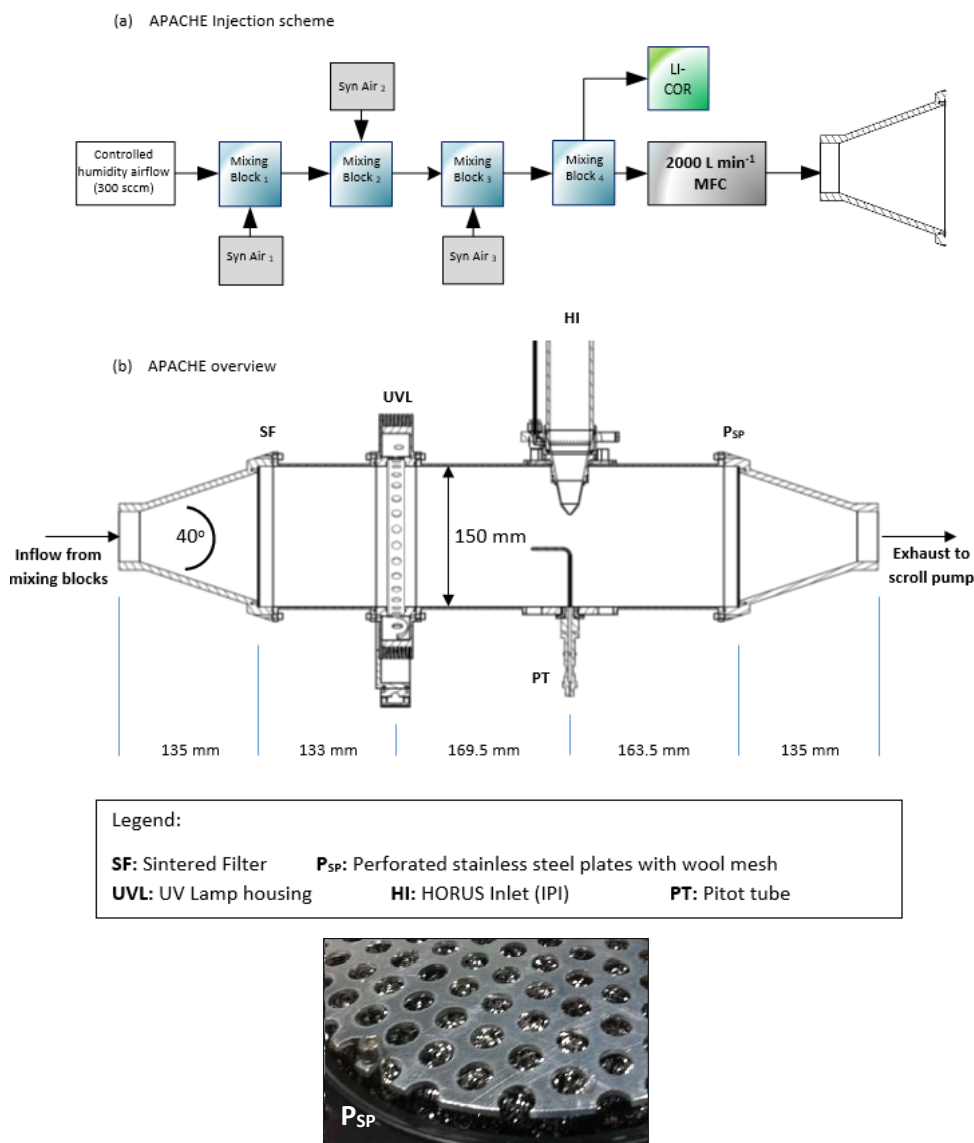

Figure 1. Overview of the APACHE system and the pre mixing set up. With a picture of perforated stainless steel plates with wool mesh.

 101
 102

One system being a pitot tube attached to an Airflow PTSX-K 0-10Pa differential pressure sensor (accuracy rating of 1% at full scale, 1σ), which is used to monitor the internal flow speeds within APACHE. A 3 kOhm NTC-EC95302V thermistor is used to monitor the air temperature and an Edwards ASG2-1000 pressure sensor (with an accuracy rating of ± 4 mbar, 2σ) monitors the static air pressure. Additionally, there are two one-quarter inch airtight apertures in the monitoring block that can be opened to enable other instrumentation to be installed.

103 **2.2 Pressure control**

104 For this study, the operational pressure range of APACHE used was 250 – 900 mbar, with
105 precision of $\pm 0.1\%$ (1σ) and accuracy of $\pm 2\%$ (1σ) with mass flows ranging from 200 to 990
106 sL min^{-1} . This was achieved by an Edwards GSX160 scroll pump controlling the volume flow,
107 which resulted in air speeds of 0.9 to 1.5 m s^{-1} through APACHE at 250 and 1000 mbar
108 respectively at 25 °C, used in combination with a MFC (Bronkhorst F-601A1-PAD-03-V)
109 capable of controlling a mass flow of up to 2000 sL min^{-1} dictating the mass flow of air entering
110 APACHE and thus controlling the pressure. Although not critical for this study, the operational
111 pressure range of APACHE can be extended by changing the draw speed of the Edwards scroll
112 pump. However, that may cause the flow speeds and potentially the flow speed profiles across
113 the UV ring lamp to vary in between different pressure calibrations.

114 **2.3 The airborne HORUS instrument**

115 The LIF-FAGE instrument developed by our group (HORUS), is based on the original
116 design of GTHOS (Ground Tropospheric Hydrogen Oxide Sensor) described by Faloon et al.
117 (2004) and is described in further detail by Martínez et al. (2010). The airborne instrument is a
118 revised and altered design to perform under conditions experienced during flight and conform
119 to aeronautical regulations. It was primarily developed for installation on the High Altitude and
120 Long Range Research Aircraft (HALO). The system comprises of an external inlet shroud,
121 detection axes, laser system, and a vacuum system (figure. 2). Additionally, this is the first
122 airborne LIF-FAGE instrument measuring HO_x with a dedicated inlet pre injector (IPI) system
123 installed for the purpose of removing atmospheric OH enabling real time measurements and
124 quantification of potential chemical background OH interferences. The airborne IPI system is
125 redesigned to fit within the shroud inlet system, whilst maintaining similar operational features
126 as the on-ground IPI installation (Novelli et al., 2014).

127
128 To prevent excessive collisions of OH and HO_2 with the IPI orifice and internal walls, thus
129 limiting losses of HO_x , the momentum inertia of the air passing through the external shroud
130 system had to be overcome to promote flow direction into the instrument. This was achieved
131 by installing in the shroud a choke point behind the instrument inlet, resulting in air flow to
132 decrease from ~ 200 to $< 21 \text{ m s}^{-1}$, which is sufficiently below the sample velocity of HORUS
133 ($44 - 53 \text{ m s}^{-1}$). Additionally, it limits non-parallel flows across the HORUS inlet created by
134 variable pitch, roll and yaw changes of the aircraft. As the aircraft changes pitch, roll and yaw,
135 the measured OH variability increases by $\pm 4.51 \times 10^4 \text{ cm}^{-3}$ (1σ), which is only 10 to 15 %
136 higher than the natural variability of OH on average. This increase in variability is negligible
137 as it represents, depending on internal pressure, 19 to 30 % of the detection limit of the
138 instrument. Both these effects of the external shroud improve the measurement performance
139 by reducing variable wall losses of HO_x at the HORUS inlet under flight conditions.

140
141
142

Figure 2. Overview of the airborne HORUS system as installed in the HALO aircraft. HO₂ is measured indirectly through the addition of NO that quantitatively converts HO₂ into OH. The NO injection occurs via a stainless steel 1/8 inch line, shaped into a ring perpendicular to the airflow with several unidirectional apertures of 0.25 mm diameter creating essentially a NO shower.

143

144 As with other LIF-FAGE HO_x instruments, HORUS measures an off-resonance signal to
145 discern the net OH fluorescence signal. This is achieved by successive cycling of the laser
146 tuning from on-resonance (measuring the total signal of OH fluorescence and the signal
147 originating from other fluorescence and electronic sources), to off-resonance (measuring all
148 the above except the OH fluorescence). The HORUS instrument utilizes the Q₁(2) transition
149 X²Π_{3/2}(v'' = 0) → A²Σ⁺(v' = 0) (Dorn et al., 1995; Holland et al., 1995; Mather et al., 1997).
150 The net OH signal (S_{OH}) is thus the difference between the on-resonance and off-resonance
151 signals. The OH sensitivity (C_{OH}) and average laser power within the detection axis (W_{Z₁ pwr})
152 are then used to calculate the absolute OH mixing ratio (see Eq. (1)). HO₂ is measured indirectly
153 through the quantitative conversion of atmospheric HO₂ to OH by injection of nitric oxide
154 (NO) under the low-pressure conditions within HORUS.

155

157

158 When NO is injected into the instrument, both ambient OH and HO₂ are measured in the
159 second detection axis. The net HO₂ signal (S_{HO₂}) in the second axis is therefore derived from
160 subtracting the net OH signal from the first detection axis normalized by the ratio of the OH
161 sensitivities for the two detection axes (C_{OH(2)} / C_{OH}) from the net HO_x signal (S_{HO_x}). Then
162 S_{HO₂} is corrected by the sensitivity to HO₂ (C_{HO₂}) and laser power (W_{Z₂ pwr}) to reach absolute
163 HO₂ mixing ratio (see Eq. (2)).

$$164 \quad \text{OH} = \frac{S_{\text{OH}}}{(C_{\text{OH}} \cdot W_{Z_1 \text{ pwr}})} \quad (1)$$

165

$$166 \quad \text{HO}_2 = \frac{1}{(C_{\text{HO}_2} \cdot W_{Z_2 \text{ pwr}})} \cdot \left\{ S_{\text{HO}_x} - \frac{C_{\text{OH}(2)}}{C_{\text{OH}}} S_{\text{OH}} \right\} \quad (2)$$

167

168 $W_{Z_1 \text{ pwr}}$ is the laser power in the first detection axis, $W_{Z_2 \text{ pwr}}$ is the laser power in the second
 169 detection axis and C_{OH} and C_{HO_2} are the calibrated sensitivity factors for OH and HO_2 (cts s^{-1}
 170 $\text{pptv}^{-1} \text{ mW}^{-1}$) respectively. By calibrating using a known OH mixing ratio, the instrument
 171 sensitivity C_{OH} can be determined by rearranging Eq. (1) to:

172

$$173 \quad C_{\text{OH (cal)}} = \frac{S_{\text{OH cal}}}{(\text{OH} \cdot W_{Z_1 \text{ pwr}})} \quad (3)$$

174 The sensitivity of HORUS depends on the internal pressure, water vapor mixing ratios, and
 175 temperature, which are subject to change quite significantly during flight. Therefore, further
 176 parameterization when calibrating is required to fully constrain the sensitivity response of the
 177 instrument at various flight conditions. Eq. (4) shows the terms that affect the sensitivity of
 178 the first HORUS axis that measures OH.

$$179 \quad C_{\text{OH}}(P, T) = c_0 \cdot \rho_{\text{Int}}(P, T) \cdot Q_{\text{IF}}(P) \cdot b_c(T) \cdot W_{Z_{\text{pwr}}} \cdot [\alpha_{\text{IPI}}(P, T) \cdot \alpha_{\text{HORUS}}(P, T)] \quad (4)$$

180 Where c_0 is determined by calibrations and is the lump sum coefficient of all the pressure
 181 independent factors affecting the HORUS sensitivity, for example, OH absorption cross section
 182 at 308nm, the photon collection efficiency of the optical setup and quantum yield of the
 183 detectors, as well as pressure independent wall loss effects ($\text{cts cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$). ρ_{Int} is the
 184 internal molecular density. Q_{IF} is the quenching effect of N_2 , O_2 and H_2O occurring inside the
 185 detection axis, which is normalized to 1 % water mixing ratio. Both are pressure dependent
 186 terms as denoted in Eq. (4). The Boltzmann correction (b_c) has a temperature dependency as
 187 it corrects for any OH molecules that enter the HORUS instrument in a thermally excited state
 188 and are therefore not measurable by fluorescence excitation at the wavelength used. $W_{Z_{\text{pwr}}}$
 189 is the measured laser power entering the white cell in the detection axis. α is the pressure
 190 dependent OH transmission, which is the fraction of OH that reaches the point of detection.
 191 This term is separated for the two-tier pressure conditions present in the instrument. The term
 192 α_{IPI} represents the correction for pressure and temperature dependent OH loss on the walls
 193 within IPI (post pinhole, pre-critical orifice). The term α_{HORUS} is the correction for pressure
 194 dependent OH loss to the walls within the HORUS detection axes post critical orifice. Whilst
 195 the quenching effects, internal densities and Boltzmann corrections can be quantified, and the
 196 power entering the measurement cell is measured, the two factors that need to be determined
 197 through calibration are c_0 and OH transmission. Once the c_0 coefficient and α terms are known,
 198 the final in-flight measured OH mixing ratio (pptv) is found:

$$199 \quad \text{OH} = \frac{S_{\text{OH}}}{(c_0 \cdot \rho_{\text{Int}} \cdot Q_{\text{IF}} \cdot b_c \cdot W_{Z_{\text{pwr}}} \cdot [\alpha_{\text{IPI}} \cdot \alpha_{\text{HORUS}}])} \quad (5)$$

200 As depicted in both figure 1b and figure 2, the complete system is calibrated with IPI
 201 attached and operating as it did when installed in the aircraft. Therefore, the combined losses
 202 of OH within IPI and in the low pressure regime post critical orifice contribute to the overall
 203 calibrated C_{OH} sensitivity factor in the same way during measurement and calibrations,

204 meaning that the OH transmission of HORUS can be quantified with both OH transmission
 205 terms (α_{IPI} and α_{HORUS}) combined into one term (α_{Total}).

$$206 \quad \text{OH} = \frac{S_{\text{OH}}}{(c_0 \cdot \rho_{\text{Int}} \cdot Q_{\text{IF}} \cdot b_c \cdot W_{z_{\text{pwr}}} \cdot [\alpha_{\text{Total}}])} \quad (6)$$

207 Figure 3 shows the graphical representation of the different factors described above and
 208 their impact on the overall sensitivity.

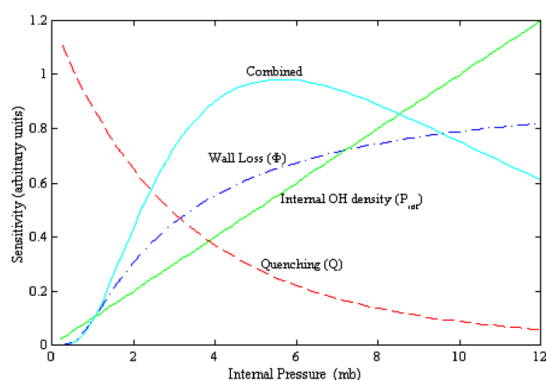

Figure 3. Pressure dependent components affecting LIF sensitivity. Internal density (solid green line), OH transmission (dotted blue line), and quenching (dotted red line). The product of these factors produce the expected pressure dependent sensitivity. (Modified after Faloona et al., 2004).

209

210 3 Calibration method and theory

211 As an overview, table 1 shows common calibration techniques for OH instruments. The
 212 APACHE system is based on the production of known quantified and equal concentrations of
 213 OH and HO₂ via photolysis of water vapor in pure synthetic air using a Hg ring lamp emitting
 214 UV radiation at 184.9 nm.

219 Stable water mixing ratios with a variability of < 2 % were achieved by heating 300 sL min⁻¹
 220 flow of synthetic air to 353 K and introducing deionized water using a peristaltic pump into
 221 this heated gas flow causing it to evaporate before entering a 15 L mixing chamber. This
 222 prevents re-condensation and humidity spikes when the pump is introducing the water. The
 223 humidified gas flow is then diluted (to around 3 mmol mol⁻¹) and mixed further with additional
 224 dry pure synthetic air via a series of mixing blocks to achieve the required and desired stable
 225 water vapor mixing ratios. The photolysis of H₂O has only one spin-allowed and energetically
 226 viable dissociation channel at 184.9 nm (Engel et al., 1992), meaning the quantum yield of OH

227 and H* are unified (Sander et al., 2003). Even though reaction R3 is possible particularly since
 228 the H* atoms can carry transitional energies of 0.7 eV at 189.4nm (Zhang et al., 2000), the fast
 229 removal of energy by reaction R4 allows for the general assumption that all H* atoms produced
 230 leads to HO₂ production. The use of water photolysis as a OH and HO₂ radical source for
 231 calibration of HO_x instruments has been adopted in a number of studies (Heard and Pilling.
 232 2003; Ren et al., 2003; Faloona et al., 2004; Dusanter et al., 2008; Novelli et al., 2014; Mallik
 233 et al., 2018). As an example, the factors required to quantify the known concentrations of OH
 234 and HO₂ during calibrations are shown below:

$$235 \quad [\text{OH}] = [\text{HO}_2] = [\text{H}_2\text{O}] \cdot \sigma_{\text{H}_2\text{O}} \cdot F_{184.9 \text{ nm}} \cdot \Phi_{\text{H}_2\text{O}} \cdot t \quad (7)$$

236 **Table 1.** Various known methods for OH instrument calibrations.

	Technique	Method	Quoted (1σ) Uncertainty	Limitations	References
(I)	Water UV- Photolysis	See section 3.1	10-30%	Dependent on lamp, photon flux measurement, and absorption	(Creasey et al., 2003; Heard and Pilling. 2003; Holland et al., 2003; Ren et al., 2003; Faloona et al., 2004; Smith et al., 2006; Martinez et al., 2010; Mallik et al., 2018)
(II)	Pulsed N ₂ - H ₂ O RF discharge	At low pressure (0.1 Torr); OH and NO produced using a low power RF discharge. Concentrations of NO and OH are closely linked	20%	Requires NO measurement using stable ambient air calibrations	(Dilecce et al., 2004; Verreycken and Bruggeman. 2014)
(III)	Low- pressure flow-tube RF discharge	OH radical production by titration of H atoms with NO ₂ . Known amount of H atoms produced using microwave discharge using low pressure flow tube	30%	Stable ambient air calibrations	(Stevens et al., 1994)
(IV)	Continuous ly Stirred Tank Reactor	In a CSTR, OH produced through UV-irradiation of specific Hydrocarbon in presence of H ₂ O and NO. concentration of OH relates to loss of the Hydrocarbon	36%	Time intensive, systematic wall loss of OH in reactor	(Hard et al., 1995; Hard et al., 2002)
(V)	Steady- State O ₃ - alkene	A steady state OH concentration produced from ozonolysis of a known concentration of an alkene	42%	Time consuming, large uncertainties compared to other methods	(Heard and Pilling. 2003; Dusanter et al., 2008)
(VI)	Laser photolysis of Ozone	Photolysis of O ₃ with 284 nm light producing O(¹ D). Which then reacts with H ₂ O producing OH	40-50%	Requires large apparatus	(Tanner and Eisele. 1995)

237

238 Where in Eq. (7), the OH and HO₂ concentrations are a product of photolysis of a known
 239 concentration of water vapor [H₂O], σ_{H₂O} is the absorption cross section of water vapor, 7.22
 240 (± 0.22) × 10⁻²⁰ cm² molecule⁻¹ at 184.9 nm (Hofzumahaus et al., 1997; Creasey et al., 2000).

241 $F_{184.9\text{ nm}}$ is the actinic flux (photons s^{-1}) of the mercury lamp used for photolysis, $\phi_{\text{H}_2\text{O}}$ is the
242 quantum yield and t is exposure time. The quantum yield of water vapor photolysis at the 184.9
243 nm band is 1 (Creasey et al., 2000).

244

245 **4 APACHE conditions and parametrizations**

246 **4.1 Flow conditions**

247 With any calibration device, the flow conditions must be characterized to inform subsequent
248 methods and calibrations. Regarding APACHE, the two main factors to be resolved are (i)
249 how uniform are the flow speed profiles and therefore exposure times in respect to the
250 APACHE cross section, and (ii) the impact of OH wall losses.

251 To this end, experimental and model tests were performed to determine whether the
252 combination of the sintered filter, and the stainless steel perforated plates and wool
253 arrangement could provide a homogeneous flow. This means that under operation the flow
254 speeds should be uniform along the cross section of APACHE to within the uncertainty of the
255 measurements. This is to ensure that the air masses passing across the lamp have the same
256 exposure times irrespective of where they are in the cross section. Additionally, model
257 simulations can provide an indication of, as a function of APACHE pressure, the development
258 and scale of boundary air conditions where air parcels experience extended contact time with
259 the interior walls of APACHE, and so have pronounced OH wall losses. This highlights
260 potential flow conditions where there is sufficient time between the photolysis zone and the
261 HORUS inlet to allow APACHE boundary air to expand into and influence the OH content of
262 the air being sampled by HORUS.

263

264 **4.1.1 Flow speed profiles**

265 During calibration, the pressures within the HORUS instrument had to be controlled and
266 monitored to replicate the inflight conditions. The APACHE chamber pressure is equivalent to
267 the inflight pressure in the shroud where the HORUS system samples. The pressure of the
268 detection axes depends on the pressure at the inlet and the efficiency of the pumps. For IPI
269 however, the airflow through it is dependent on the pressure gradient between the shroud and
270 the ambient pressure at the IPI exhaust or alternatively the APACHE pressure and pressure in
271 front of the XDS 35 scroll pump (post IPI blower). During the campaign, the exhausts of all
272 blowers and pumps of the HORUS system were attached to the passive exhaust system of the
273 aircraft and were thus exposed to ambient pressure. Therefore, in the lab and throughout the
274 calibrations, the pressure at the exhaust for every blower and pump involved in the HORUS
275 instrument was matched to the respective in-flight ambient pressures by attaching a separate
276 pressure sensor, needle valve and XDS35 scroll pump system. Figure 4 shows the lab setup
277 described above.

278

279

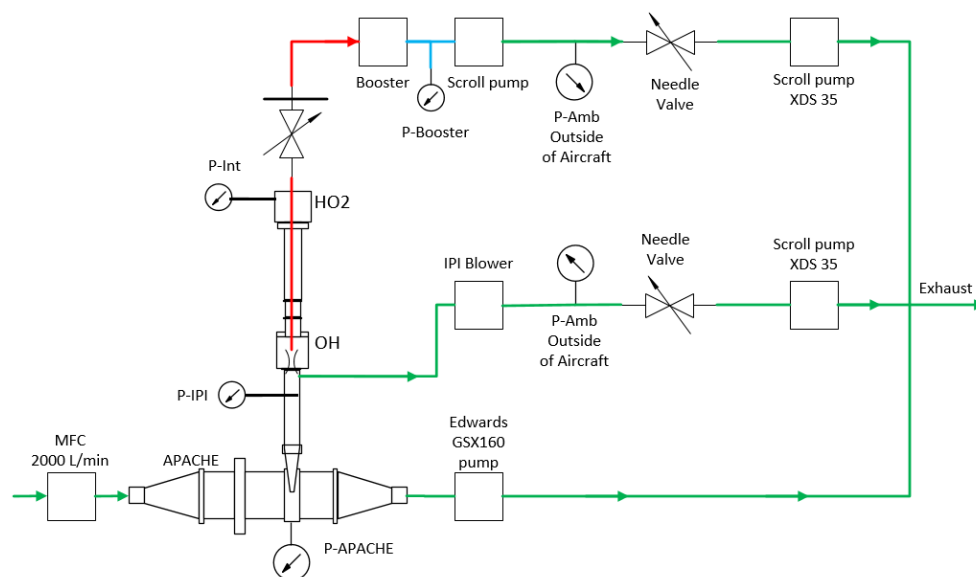

Figure 4. The experimental setup with the additional needle valves, pressure sensors and XDS35 scroll pumps attached to the exhausts of all pumps and blowers of HORUS to match in-flight pumping efficiencies when calibrating with APACHE. The red lines depict the low-pressure region within HORUS, the blue is the pressure monitoring line between the booster and scroll pump that drive the HORUS sample flow, and the green show the external gas lines.

280

281 To limit the effect of wall loss, HORUS samples air from the core of the APACHE flow system
282 and draws only a fraction of the total air flow as shown in figure 5. At 900 hPa the HORUS
283 instrument takes 20 % and at 275 hPa HORUS takes 30 % of the total volume flow entering
284 APACHE. To validate that this proportional volume flow into HORUS does not disturb the
285 flow conditions within APACHE, flow speed profiles were performed using the Prandtl pitot
286 tube installed directly opposite the HORUS inlet, which can be positioned flush against the
287 internal wall up to 60.5 mm into the APACHE cavity, which is 15 mm from the APACHE
288 center. Figure 6 shows the measured flow speed profile (blue data points) when the APACHE
289 pressure was 920 hPa. As the distance between the APACHE wall and the pitot tube inlet
290 increased, no significant change in the flow speed was observed. The largest change observed
291 was between 46.6 and 60.5 mm where the flow speed increased by 0.16 m s^{-1} , which is 22.8 %
292 smaller than the combined uncertainty of these two measurements $\pm 0.21 \text{ m s}^{-1}$ (2σ). Compared
293 to the other four measurement points performed at 920 mbar, the 1.54 m s^{-1} measured at 60.5
294 mm is not significantly different. However, when performing the speed profile tests at the low
295 pressures, the pressure difference measured was close to or below the resolution of the
296 differential pressure sensor. Consequently, the flow inside APACHE and the HORUS inlet
297 system was simulated using the computational fluid dynamics (CFD) model from COMSOL
298 multiphysics to gain a better understanding of the flow speed profiles at all pressures. The CFD
299 module in COMSOL uses Reynolds Averaged Navier-Stokes (RANS) models (COMSOL.
300 2019). The standard k-epsilon turbulence model with incompressible flows was used for this
301 study as it is applicable when investigating flow speeds below 115 m s^{-1} (COMSOL. 2019).
302 An extra fine gridded mesh of a perforated plate with a high solidity ($\sigma_s = 0.96$) was
303 implemented in the turbulence model to generate the turbulence and replicate the flows created

304 by the bronze sintered filter (Roach, 1987). The model was constrained with the pressures
305 measured within APACHE and the HORUS inlet. The volume flow was calculated from
306 measured mass flow entering APACHE and temperatures were constrained using the
307 thermistor readings. To gain confidence in the model, the flow speed output data was compared
308 to the available measured flow speed profile, see figure 6. Overall, the modelled flow speed
309 profile did not differ significantly from measured. The only point where the model
310 significantly disagreed with measurements was at the boundary (< 4 mm away from the
311 APACHE wall), where the model predicted a flow speed of 1.3 m s^{-1} , which is 6 % lower than
312 the minimum extent of the measurement uncertainty 1.38 m s^{-1} . However, as this is occurring
313 within a region that ultimately does not influence the air entering HORUS, see section 4.1.2,
314 the disagreement between modelled and measured flow speeds at distances less than 4 mm
315 from the APACHE wall is ignored.

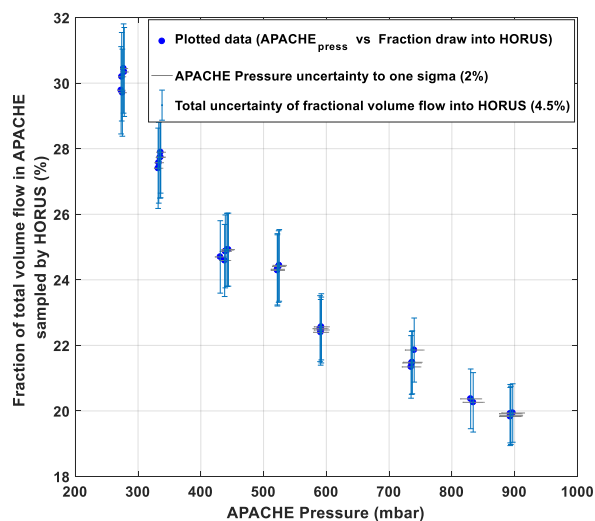

Figure 5. The percentage of the total volume flow entering APACHE, which is sampled by HORUS as a function of pressure within APACHE. All error bars are quoted to 1σ .

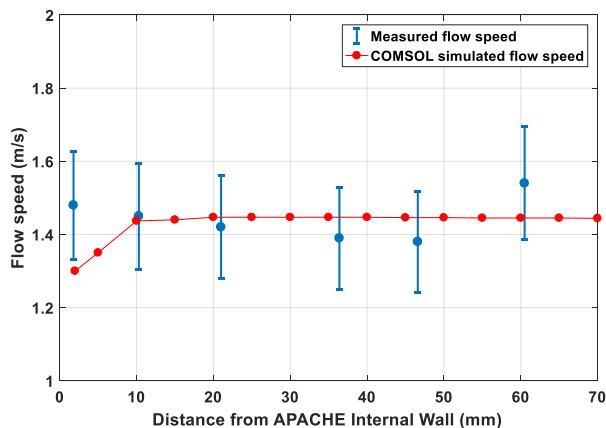

Figure 6. The measured (blue) and COMSOL simulated (red) flow speed profiles within APACHE, at 920 hPa. The x-axis is the distance from the internal wall of APACHE. The error bars are quoted to 2σ .

316 Figure 7 shows the simulated flow speeds at six discrete pressures within APACHE. The black
317 lines depict the streamlines of the HORUS sample flow and the color gradient relates to the
318 flow speed. The flow conditions in the center flow within the HORUS inlet, post pinhole, the
319 center of the streamlines and the undisturbed flow airflow not influenced by the sample flow
320 of HORUS are indicated. The figure shows the internal APACHE dimensions starting from the
321 sintered filter to the first perforated stainless steel plate 0.135 m and 0.601 m from the
322 APACHE inlet, respectively. From the simulations, the centerline flow speed differs by less
323 than 0.1 % compared to the undisturbed flow, which is also the case at 275 mbar when HORUS
324 is drawing in the highest percentage of the total volume flow entering APACHE. After the
325 sintered filter the high calculated Reynolds numbers ($Re > 2300$) support the statement that a
326 turbulent flow regime is created. Additionally, the measurements in conjunction with
327 simulations show that the small pores of the sintered filter release a uniform distribution of
328 small turbulent elements across the diameter of APACHE, which remain prevalent all the way
329 up to the HORUS inlet.
330

331 4.1.2 HO_x losses in APACHE

332 The modelled OH mixing ratios (pptv) in figure 8 show the change in OH content as the air
333 flows along the length of APACHE. Mixing ratios were used as they are independent of the
334 changing density within APACHE. In every simulation, the OH and HO₂ concentrations were
335 initialized at zero, and losses at the walls were fixed to 100 % for both OH and HO₂. The radial
336 photolytic production of OH and HO₂ as calculated using Eq. (7) and Eq. (8), occurred when
337 the air passed the UV ring lamp. For all simulations, the HO_x radical-radical recombination
338 loss reactions, (reactions R6-R8), and the measured molecular diffusion coefficient of OH_{Dm}
339 in air (Tang et al., 2014) was used:

$$340 \text{OH}_{\text{Dm}} = 179 (\pm 20) \text{ Torr cm}^2 \text{ s}^{-1} \quad (238.65 \pm 26.7 \text{ hPa cm}^2 \text{ s}^{-1})$$

341 In literature, there have been no reports of successfully performed tests that accurately
342 measure HO₂ diffusivity coefficients in air. However, calculations of HO₂ diffusion
343 coefficients using the Lennard-Jones potential model have been performed (Ivanov et al.,
344 2007). Ivanov et al. (2007) performed a series of measurements and Lennard-Jones potential
345 model calculations to quantify the polar analogue diffusion coefficients for OH, HO₂ and O₃ in
346 both air and pure helium. The calculated OH and O₃ diffusion coefficients in air from the
347 Lennard-Jones potential model were in good agreement with the recommended measurement
348 values in Tang et al., (2014) well within the given uncertainties. Therefore, to best replicate the
349 diffusivity of HO₂ within the simulations, the following diffusion coefficient of HO₂ in air from
350 the Ivanov et al., (2007) paper was used:

$$351 \text{HO}_{2 \text{Dm}} = 107.1 \text{ Torr cm}^2 \text{ s}^{-1} \quad (142.8 \text{ hPa cm}^2 \text{ s}^{-1})$$

352 It is clear from figure 8, that irrespective of pressure the air masses at the boundary (where
353 wall losses are 100 %) do not have sufficient time to expand into the HORUS sample flow
354 streamlines, and influence HO_x content entering HORUS. Lateral exchanges between air at the
355 walls of APACHE and the free air in the center are suppressed due to the preservation of the
356 small turbulence regime between the sintered filter and the HORUS inlet. Table 2 provides, for
357 six pressures, the evolution of OH along the length of APACHE, within the streamlines created
358 by the HORUS sample flow as depicted in figure 8.

359

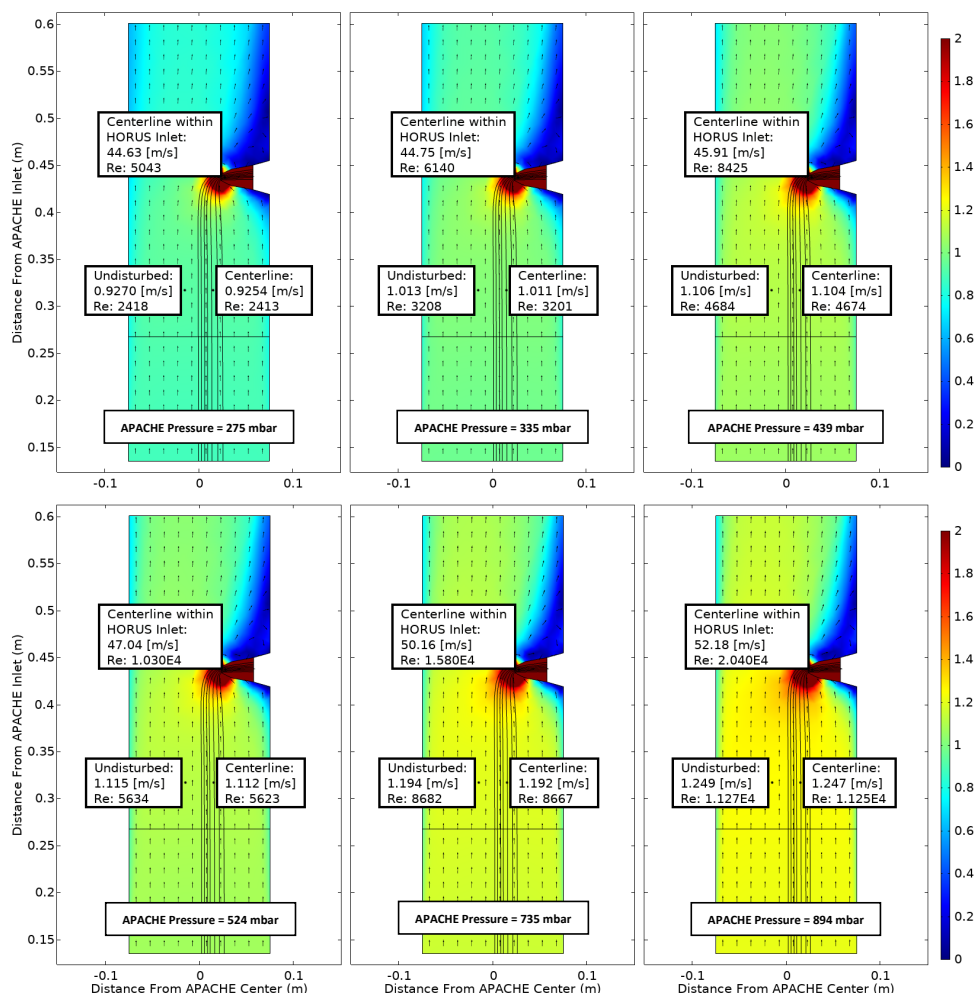

Figure 7. COMSOL Multiphysics output data, simulating the flow speed conditions at 6 discreet pressures within APACHE ranging from 275 to 894 mbar, between the sintered filter and the first perforated stainless steel plate. The color represents flow speed in m s^{-1} . The black lines are the streamlines created by the HORUS sample flow. The black arrows depict the flow direction. The x-axis is the distance from the center of APACHE in meters. The y-axis is the distance from the APACHE inlet. The centerline within HORUS inlet tags show the flow conditions in the center of the fully formed flows after the HORUS pinhole, the undisturbed tags show the flow conditions outside of the HORUS streamlines, and the centerline tags show the flow conditions in the center of the streamlines (i.e. the area of flow influenced by HORUS sampling).

360

361 The L term represents OH mixing ratios on the left most streamline, C represents OH mixing
 362 ratios in the center of the streamlines, and R represents OH mixing ratios on the right most
 363 streamline. The mean mixing ratio at each APACHE pressure does not change significantly
 364 and is thus independent of the distance from the lamp. Conversely, the standard deviations of
 365 the OH mixing ratios within the HORUS sampling streamlines decrease as the distance from
 366 the lamp increases, indicating that the air is homogenizing. However, figure 8 and table 2, with
 367 support from available measurements, indicate that the OH-depleted air masses (i.e. air masses

368 that have experienced loss of OH at the APACHE walls) do not expand into and influence the
 369 OH content of air that is being sampled by HORUS. The main loss process that influences
 370 HO_x entering HORUS is the wall loss at the HORUS inlet itself. On average, 22.2 (± 0.8) %
 371 (1σ) of OH and HO₂ is lost at the inlet, which will form part of the α_{PI} loss calculation in
 372 section 5.

373

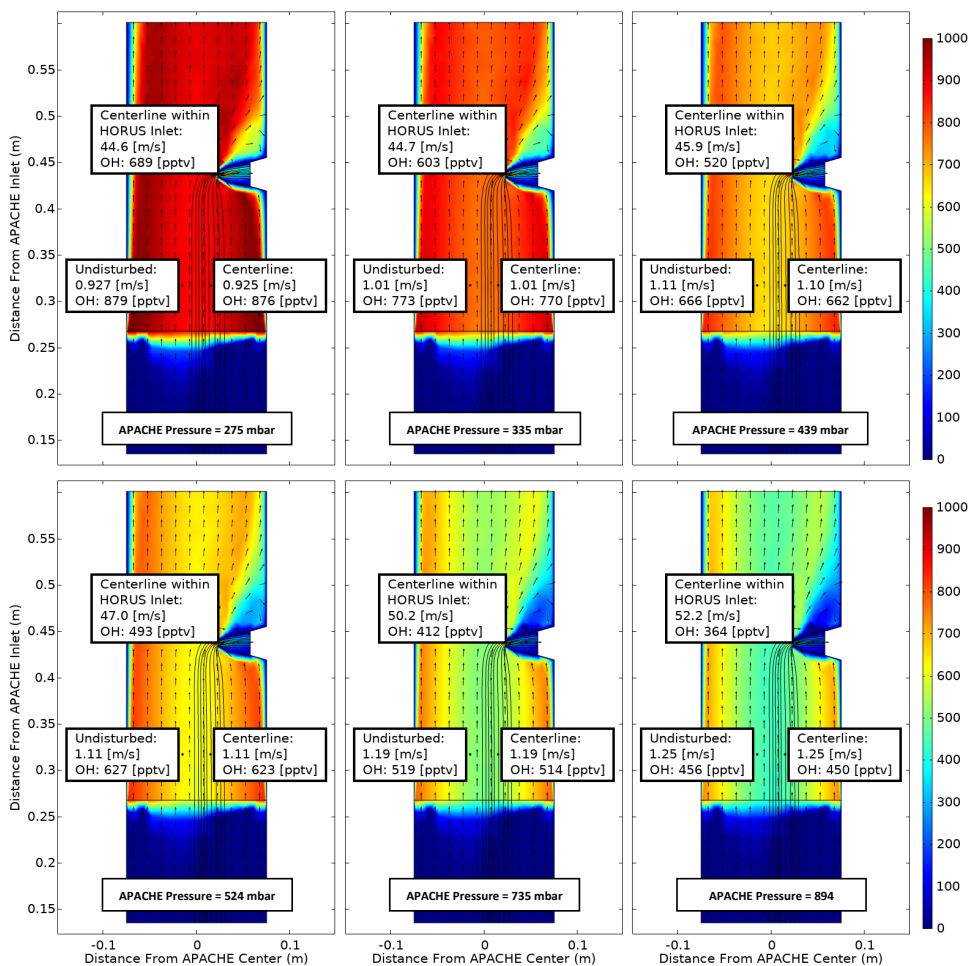

Figure 8. COMSOL Multiphysics output data, simulating OH conditions at 6 discrete pressures within APACHE ranging from 275 to 894 mbar, between the sintered filter and the first perforated stainless steel plate. The color is OH mixing ratio (pptv), with initial OH production occurring at the lamp (0.26 m from APACHE inlet), using Eq. (7) and Eq. (8). The black lines are the streamlines created by the HORUS sample flow. The black arrows depict the flow direction. The x-axis is the distance from the center of APACHE in meters. The y-axis is the distance from the APACHE inlet. The centerline within HORUS Inlet tags represent the flow and OH concentrations in the center of the fully formed flows after the HORUS pinhole. The undisturbed tags show the flow conditions outside of the HORUS streamlines, and the centerline tags show the flow conditions in the center of the streamlines (i.e. the area of flow influenced by HORUS sampling).

Table 2. The evolution of OH within the HORUS sample flow streamlines, along the length of APACHE, at all six pressures, within the streamlines created by HORUS sampling as depicted in figure 8. The L term represents OH mixing ratios on the left most streamlines, C represents OH mixing ratios in the center of the streamlines, and R represents OH mixing ratios on the right most streamline. The centerline within HORUS inlet column shows the OH mixing ratios in the center of the flow in the HORUS inlet. All standard deviations are quoted to 1σ .

APACHE Pressure (mbar)	OH (pptv) At the lamp				OH (pptv) 4.2 cm from lamp				OH (pptv) 8.4 cm from lamp				OH (pptv) 12.8 cm from lamp				OH (pptv) 2 cm before HORUS Inlet				In Centerline within HORUS Inlet

375 4.2 UV conditions

376 The photolysis lamp is housed in a mount with the side facing into the chamber having an
377 anodized aluminum band with thirty 8 mm apertures installed between it and a quartz wall. The
378 housing was flushed with pure nitrogen to purge any O₂ present before the lamp was turned on.
379 The nitrogen flushing was kept on continuously thereafter. After approximately one hour, the
380 lamp reached stable operation conditions, i.e the relative flux emitted by the lamp as measured
381 by a photometer (seen in Figure 1b at the UVL on the underside of the APACHE chamber)
382 was constant. The flux (F_{β}) entering APACHE is not the same as the flux experienced by the
383 molecules sampled by HORUS (F). Factors influencing the ratio between F_{β} and F are as
384 follows. (i) Absorption of light by O₂, which is particularly important as O₂ has a strong
385 absorption band at 184.9 nm and the O₂ density changes in APACHE when calibrating at the
386 different pressures. (ii) The variable radial flux, which is dependent on the geometric setup of
387 the ring lamp and on the location within the irradiation cross section where the molecule is
388 passing. These factors were resolved through the combination of two actinometrical crosscheck
389 methods. The advantage of actinometrical methods is that the flux calculated is derived directly
390 from the actual flux that is experienced by the molecules themselves as they pass through the
391 APACHE chamber. Therefore, allowing direct calibration of the flux inside APACHE itself.

392 The first actinometrical method (A) used the ground based calibration device (Martinez et
393 al., 2010) to calibrate the HORUS instrument to be used as a transfer standard. Only for the
394 purpose of this experiment, the critical orifice diameter was changed from the airborne
395 configuration of 1.4 mm to a 0.8 mm on-ground* configuration to adapt HORUS to the mass
396 flow that the ground based calibration device is able to provide. The asterisk discerns terms
397 that were quantified when the smaller 0.8 mm critical was used. The calculated instrument on-
398 ground* sensitivity was then used to translate OH and HO₂ concentrations produced by the uv-
399 technik Hg ring lamp into a value for F_{β} . Take note that for the calibrations discussed in section
400 5, the initial 1.4 mm diameter critical orifice used during the airborne campaign was re-
401 installed.

402 The HORUS on-ground* sensitivity at 1010 mbar for OH and HO₂ are 12.79 (\pm 1.8) and
403 16.59 (\pm 2.3) cts pptv⁻¹ mW⁻¹ respectively, with the uncertainties quoted to 1 σ . This sensitivity
404 was then used to calculate the OH and HO₂ concentrations at the instrument inlet with the
405 APACHE system installed and operating at 1010 mbar. To ensure sufficient flow stability
406 during calibration at this high pressure, the Edwards GSX160 scroll pump was disengaged.
407 Additionally, the water mixing ratios were kept constant (\sim 3.1 mmol mol⁻¹) and oxygen levels
408 were varied by adding different pure N₂ and synthetic air mixtures, via MFCs. The OH and
409 HO₂ concentrations at the HORUS inlet were 1.51 (\pm 0.01) and 1.43 (\pm 0.01) \times 10¹⁰ molecules
410 cm⁻³ respectively when only pure synthetic air and water vapor were injected into APACHE,
411 the uncertainties here are quoted as measurement variability at 1 σ . Using these values, the OH
412 and HO₂ concentrations at the lamp were back calculated accounting for radical-radical loss
413 reactions (R6-R8) using rate constants taken from Burkholder et al. (2015) with temperature
414 (T) in Kelvin.

418 The chemical losses of OH and HO₂ were found to be 32 % and 30%, respectively, yielding
 419 OH concentrations of $2.2 (\pm 0.02) \times 10^{10}$ molecules cm⁻³ and HO₂ concentrations of $2.0 (\pm$
 420 $0.02) \times 10^{10}$ molecules cm⁻³ at the lamp, at 1010 mbar, using a water vapor mixing ratio of 3.1
 421 mmol mol⁻¹ in pure synthetic air. The uncertainties are quoted as measurement variability at
 422 1σ. The photon flux (*F*) experienced by the air sampled by HORUS, quantified using the OH
 423 and HO₂ concentrations stated above, ranged from 3.75×10^{14} photons cm⁻² s⁻¹ to 6.1×10^{14}
 424 photons cm⁻² s⁻¹ depending on oxygen concentrations and considering the chemical losses. As
 425 described before, Eq.(7) shows how the production of OH at the lamp is calculated:

426 $[\text{OH}] = [\text{H}_2\text{O}] \cdot \sigma_{\text{H}_2\text{O}} \cdot F_{184.9 \text{ nm}} \cdot \Phi_{\text{H}_2\text{O}} \cdot t$ (7)

427 $F_{184.9 \text{ nm}}$ is the absolute flux that is encountered by the water molecules as they pass across
 428 the photolysis region, which is dependent on the attenuation of the flux (F_β) entering APACHE
 429 due to water vapor and O₂ molecules. Whereas the absorption coefficient of water vapor is
 430 constant across the linewidth of the 184.9 nm Hg emission line, the effective absorption cross
 431 section of molecular oxygen (σ_{O_2}) changes significantly at 184.9 nm within the linewidth of
 432 the Hg lamp (Creasey et al., 2000). Therefore, σ_{O_2} affecting the APACHE calibrations is
 433 dependent on O₂ concentration, and the ring lamp temperature and current. Since the operating
 434 temperature of the uv-technik Hg lamp and the current applied (0.8 A) was kept constant during
 435 the actinometrical experiments and during the APACHE calibrations, any effect on σ_{O_2}
 436 regarding the ring lamp linewidth does not need to be investigated further in this study. The
 437 relationship of $F_{184.9 \text{ nm}}$ to F_β can be derived using Beer-Lambert principles:

438 $F_{184.9 \text{ nm}} = F_\beta \cdot e^{-(\gamma_{\text{H}_2\text{O}}[\text{H}_2\text{O}] + \gamma_{\text{O}_2}[\text{O}_2])}$ (8)

439 Where F_β is the flux intensity entering APACHE from ring lamp, with:

440 $\gamma_{\text{O}_2} = R_\beta \cdot \omega \cdot \sigma_{\text{O}_2}$ (9)

441 Where R_β is the radial distance of the sampled air parcel to the ring lamp of APACHE, ω a
 442 correction factor replicating the integrated product of the absorption cross section and the
 443 ring lamp's emission line as modified by the effect of the absorption of O₂ present in between
 444 the lamp and the flight path of the sampled air, normalized by σ_{O_2} is the effective cross section
 445 of O₂. When combining Eq. (7) and Eq. (8) the OH concentration produced at the lamp is
 446 quantified as:

447 $[\text{OH}] = [\text{H}_2\text{O}] \cdot \sigma_{\text{H}_2\text{O}} \cdot \Phi_{\text{H}_2\text{O}} \cdot t \cdot F_\beta \cdot e^{-(\gamma_{\text{H}_2\text{O}}[\text{H}_2\text{O}] + \gamma_{\text{O}_2}[\text{O}_2])}$ (10)

448 Eq. (10) can be rearranged to:

449 $\ln\left[\frac{[\text{OH}]}{[\text{H}_2\text{O}] \cdot \sigma_{\text{H}_2\text{O}}}\right] = \ln(F_\beta \cdot t \cdot \Phi_{\text{H}_2\text{O}}) + (-\gamma_{\text{H}_2\text{O}} \cdot [\text{H}_2\text{O}] - \gamma_{\text{O}_2} \cdot [\text{O}_2])$ (11)

450 Figure 9, shows the measured production of OH, (left side of Eq. (11)) plotted against
 451 oxygen concentration. Given that the other terms within Eq. (11) are constant with regards to
 452 changing oxygen levels, the plotted gradient of the linear regression in figure 9 yields γ_{O_2} as a
 453 function of oxygen concentration being $1.3 \times 10^{-19} (\pm 0.05 \times 10^{-19})$ cm³ molecule⁻¹.

454

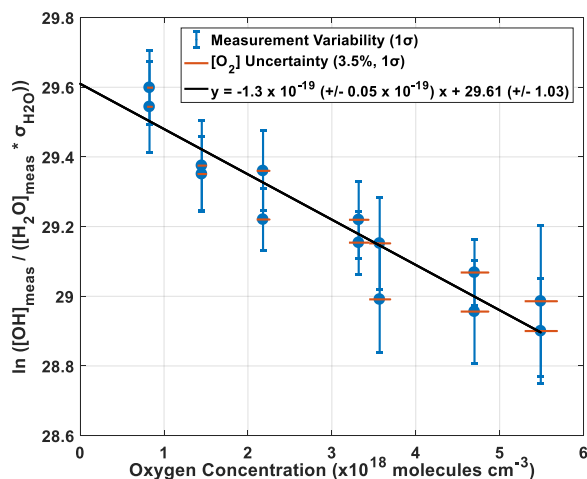

Figure 9. Plot showing the result of Eq. (11) as a function of oxygen concentration.

455 Given that, the y intercept of the linear regression, 29.61, is equal to the natural logarithm
 456 of ($F_{\beta} t \phi_{\text{H}_2\text{O}}$), the flux entering APACHE F_{β} can be characterized:

457
$$F_{\beta} = \frac{e^{29.61}}{t \cdot \phi_{\text{H}_2\text{O}}} = 6.9 \times 10^{14} (\pm 1.1 \times 10^{14}) \text{ s}^{-1} \quad (12)$$

458 The accuracy in F_{β} from this method, which we call method A, is 15.9 % (1σ).

459 **Table 3.** Parameters and uncertainties involved in method A, using HORUS as a transfer standard. The total
 460 uncertainty is the sum of the quadrature of the individual uncertainties.

Parameter	Comments	Total Uncertainty 1σ (%)
NO Monitor (TEI)	Calibration uncertainty	5.2
NO standard (NPL)	Purity and concentration of the gas	1
N ₂ O cross section	JPL recommendation	2
H ₂ O cross section	JPL recommendation	2
γ_{O_2}	From method A	3.5
O(¹ D) yield	Martinez et al. (2010)	1
Kinetic rate coefficients	JPL recommendation	12
F_{β} Variability	From method A	3.5
Photolysis chamber dimensions	Specifications of in-house workshop	3
[H ₂ O]	From calibration with NIST standard Dew point generator	2
[O ₂]	From method A	3.4
Mass flow controllers	Calibration with NIST DryCal	2
Pressure and Temperature sensors	Validated against NIST standard	2
Overall Experimental Stability	Variability of measured terms	4
Overall uncertainty		15.9

461

462 The second actinometrical method (B) involved using an ANSYCO O3 41 M ozone monitor
 463 to measure the ozone mixing ratio profile between the HORUS inlet and the wall surface of
 464 APACHE, at ground pressure (1021 mbar). This method utilizes O₂ photolysis at 184.9 nm,

465 which produces two O(³P) atoms capable of reacting with a further two O₂ molecules to
 466 produce O₃.

469 The value of $1.3 \times 10^{-19} \text{ cm}^3 \text{ molecule}^{-1}$ for γ_{O_2} found in the previous method was used to
 470 calculate the actinic flux entering APACHE:

471
$$F_\beta = \frac{[O_3]}{[O_2] \cdot \gamma_{O_2} \cdot \Phi_{O_2} \cdot t \cdot e^{-(\gamma_{O_2}[O_2])}}$$
 (13)

472 Φ_{O_2} is the quantum yield of O₂ at 184.9 nm, which has been determined to be 1 between
 473 242 and 175 nm (Atkinson et al., 2004). As in method A, the ozone produced at the lamp is
 474 quantified by back calculating from the ozone measured at the ANSYCO O3 41 M inlet
 475 position. Typical ozone mixing ratios ranged from 45 – 72 ppb depending on the oxygen
 476 concentration. From this approach, the calculated F_β is $5.7 \times 10^{14} (\pm 0.74 \times 10^{14}) \text{ s}^{-1}$ with a total
 477 uncertainty of 12.9 % (1 σ). From the combination of the two experiments, the final values
 478 taken for the UV environment within APACHE are:

479 Actinic flux (F_β) = $6.3 \times 10^{14} (\pm 0.9 \times 10^{14}) \text{ s}^{-1}$

480 Accuracy in F_β = 14.4 % (1 σ)

481 **Table 4.** Parameters and uncertainties involved in Method B, using ANSYCO O3 41 M monitor. The total
 482 uncertainty is the sum of the quadrature of the individual uncertainties.

Parameter	Comments	Total Uncertainty 1 σ (%)

Pressure and Temperature sensors	Validated against NIST standard	2
Experimental Stability	Variability of values	10.1
Overall uncertainty		12.9

483

484 5 Results and discussion

485 5.1 Evaluation of instrumental sensitivity

486 Figure 10 shows the sensitivity curve of HORUS, the quenching effect, the linear fits used
 487 to quantify the pressure independent sensitivity coefficients, and relative HO_x transmission
 488 values for OH, OH in the second axis, and HO₂ plotted as a function of the HORUS internal
 489 density. Table 6 shows the pressure independent sensitivity coefficients for OH in the 1st axis,
 490 OH in the 2nd axis, and HO₂ in the 2nd axis found from the slopes in figure 10 row C. As

491 described in section 3.2, the pressure driven wall losses in IPI and post critical orifice both
 492 contribute to the overall sensitivity curve. The OH transmission terms (α_{IPI} and α_{HORUS}) can
 493 be considered together as the total OH transmission (α_{Total}). According to the COMSOL
 494 simulations, the losses of HO_x occur mainly at the inlet itself resulting in for both OH and HO₂
 495 to be 78 (± 0.8 , full range) %. To calculate the loss of HO_x within IPI, the following was used:

$$496 \quad \alpha_{\text{IPI OH}} = 1 - \left[\frac{\text{OH}_{\text{DM}}(P) \cdot t_{\text{r IPI}}(P,T) \cdot \pi}{\text{IPI}_A \cdot P_{\text{IPI}}} \right] \quad (14)$$

$$497 \quad \alpha_{\text{IPI HO}_2} = 1 - \left[\frac{\text{HO}_{2 \text{ DM}}(P) \cdot t_{\text{r IPI}}(P,T) \cdot \pi}{\text{IPI}_A \cdot P_{\text{IPI}}} \right] \quad (15)$$

498 Where $t_{\text{r IPI}}$ is the transit time within IPI, i.e. the time it takes air to flow from the IPI inlet to
 499 the critical orifice of HORUS. IPI_A is the internal cross sectional area of IPI and P_{IPI} is the
 500 measured pressure within IPI. The OH_{DM} and $\text{HO}_{2 \text{ DM}}$ terms are the OH and HO₂ diffusion
 501 coefficients as described in section 4.1.2. By applying Eq. (14) and Eq. (15), $\alpha_{\text{IPI OH}}$ and $\alpha_{\text{IPI HO}_2}$
 502 ranged from 0.98 to 0.995 and 0.99 to 0.997 respectively across the pressure range within IPI
 503 of 210 – 1010 mbar and IPI transit times of 90 – 120 milliseconds. Summing the inlet wall
 504 loss found from the COMSOL simulations (78 ± 0.8 %) and $\alpha_{\text{IPI OH}}$ and $\alpha_{\text{IPI HO}_2}$ calculated from
 505 Eq. (14) and Eq. (15) results in a combined α_{IPI} term for OH of $76.7 (\pm 2.2, \text{ full range})$ and for
 506 HO₂ of $77.3 (\pm 1.6, \text{ full range})$. However, to calculate α_{Total} , the OH transmission post critical
 507 orifice, α_{HORUS} , must be resolved. α_{HORUS} regarding OH and HO₂ can be calculated by adapting
 508 Eq. (14) and Eq. (15) to the internal HORUS conditions producing:

$$509 \quad \alpha_{\text{HORUS OH}} = 1 - \left[\frac{\text{OH}_{\text{DM}}(P) \cdot t_{\text{r1}}(P,T) \cdot \pi}{\text{HORUS}_A \cdot P_{\text{int}}} \right] \quad (16)$$

$$510 \quad \alpha_{\text{HORUS OH}_2} = 1 - \left[\frac{\text{OH}_{\text{DM}}(P) \cdot t_{\text{r2}}(P,T) \cdot \pi}{\text{HORUS}_A \cdot P_{\text{int}}} \right] \quad (17)$$

$$511 \quad \alpha_{\text{HORUS HO}_2} = 1 - \left[\frac{\text{HO}_{2 \text{ DM}}(P) \cdot t_{\text{r2}}(P,T) \cdot \pi}{\text{HORUS}_A \cdot P_{\text{int}}} \right] \quad (18)$$

512 Where t_{r1} and t_{r2} are the transit times within HORUS from the critical orifice to the 1st and
 513 2nd detection axis respectively. HORUS_A is the internal cross sectional area of HORUS and P_{int}
 514 is the measured internal pressure within HORUS. The OH transmission from the critical orifice
 515 to the 1st detection cell ($\alpha_{\text{HORUS OH}}$) ranged from 0.84 to 0.96, the OH transmission from the
 516 critical orifice to the 2nd detection cell ($\alpha_{\text{HORUS OH}_2}$) ranged from 0.59 to 0.88, and the HO₂
 517 transmission from the critical orifice to the 2nd detection cell ($\alpha_{\text{HORUS HO}_2}$) ranged from 0.82 to
 518 0.96. These ranges are quoted under the HORUS internal pressure range of 3.7 to 18.4 mbar
 519 and internal transit times to the 1st detection axis (3.8 to 4.3 milliseconds) and 2nd detection
 520 axis (23.5 to 27.8 milliseconds). The combined α_{Total} values for OH, OH at the second detection
 521 axis, and HO₂ are plotted in figure 10 row D as a function of the internal density of HORUS.

522 The two actinometric methods used to calibrate the flux entering APACHE from the uv-
 523 technik ring lamp, yielded encouraging and comparative results. The F_{β} found from ozone
 524 actinometric method ($5.7 \pm 0.74 \times 10^{14} \text{ s}^{-1}$) and from the HORUS transfer standard actinometric
 525 method ($6.9 \pm 1.1 \times 10^{14} \text{ s}^{-1}$) agree with the difference of $1.2 \times 10^{14} \text{ s}^{-1}$ representing only 60
 526 % of the combined 1σ uncertainty in F_{β} , $\pm 2 \times 10^{14} \text{ s}^{-1}$ from the two methods.

527

528

529 **5.2 Absolute Calibration Uncertainty**

530 The contribution of parameter uncertainties to the respective sensitivities are summarized in
 531 tables 5 to 8.

532 **Table 5.** Parameters within APACHE, their ranges and uncertainties, contributing to the uncertainty in the three
 533 measurement sensitivities within HORUS.

Parameter (unit)	Range or typical value	Precision (1σ)	Total Uncertainty (1σ)
F_{β} at 184.9 nm (s^{-1})	6.3×10^{14}	3.5 %	14.4 %
σ_{H_2O} (cm^2 molecule $^{-1}$)	7.22×10^{-20}	-	2 %
γ_{O_2} (cm^3 molecule $^{-1}$)	1.30×10^{-19}	1.8 %	3.5 %
[O ₂] ($\times 10^{18}$ molecules cm^{-3})	1.1 - 4.8	1.4 %	3.4 %
[H ₂ O] ($\times 10^{16}$ molecules cm^{-3})	2.00 - 7.41	1.2 %	2 %
Mass flow controller (sL min $^{-1}$)	203 - 988	< 2 %	2 %
Pressure sensors (mbar)	275 - 894	< 1 %	2 %
Temperature sensors (K)	282 - 302	< 1 %	2 %
Overall		5 %	16.2 %

534

535 **Table 6.** Pressure independent sensitivities and their overall uncertainty from calibrations with APACHE.

Parameter (cts cm^3 molecule $^{-1}$ s $^{-1}$)	Value	Precision ($\pm 1\sigma$)	Total Uncertainty (1σ)
c0 for OH in OH axis	1.44	4 %	6.9 %
c1 for OH in HO ₂ axis	0.68	4 %	6.9 %
c2 for HO ₂ in HO ₂ axis	1.3	2 %	5.6 %

536

537 **Table 7.** Pressure dependent OH and HO₂ transmission and their overall uncertainty from calibrations with
 538 APACHE.

Parameter (%)	Value	Precision ($\pm 1\sigma$)	Total Uncertainty (1σ)
α_{Total} (for OH to OH axis)	61 - 72	2.8 %	14.3 - 11.4 %
α_{Total} (for OH to HO ₂ axis)	35 - 65	4.3 %	14.1 - 11.5 %
α_{Total} (for HO ₂ to HO ₂ axis)	54 - 70	2.9 %	7.9 - 4.7 %

539

540 **Table 8.** Pressure dependent sensitivities for the three measurement within HORUS, their overall uncertainty from
 541 calibrations with APACHE. The range in the precision relates to the numbers quoted in the value column.

Parameter (unit)	Value	Precision ($\pm 1\sigma$)	Total Uncertainty (1σ)
C _{OH} (cts s $^{-1}$ pptv $^{-1}$ mW $^{-1}$)	7.9 - 26.4	1.1 - 0.5 %	17.6 %
C _{OH(2)} (cts s $^{-1}$ pptv $^{-1}$ mW $^{-1}$)	3.9 - 10.5	2.0 - 0.3 %	17.6 %
C _{HO2} (cts s $^{-1}$ pptv $^{-1}$ mW $^{-1}$)	7.5 - 22.3	0.4 - 0.7 %	17.1 %

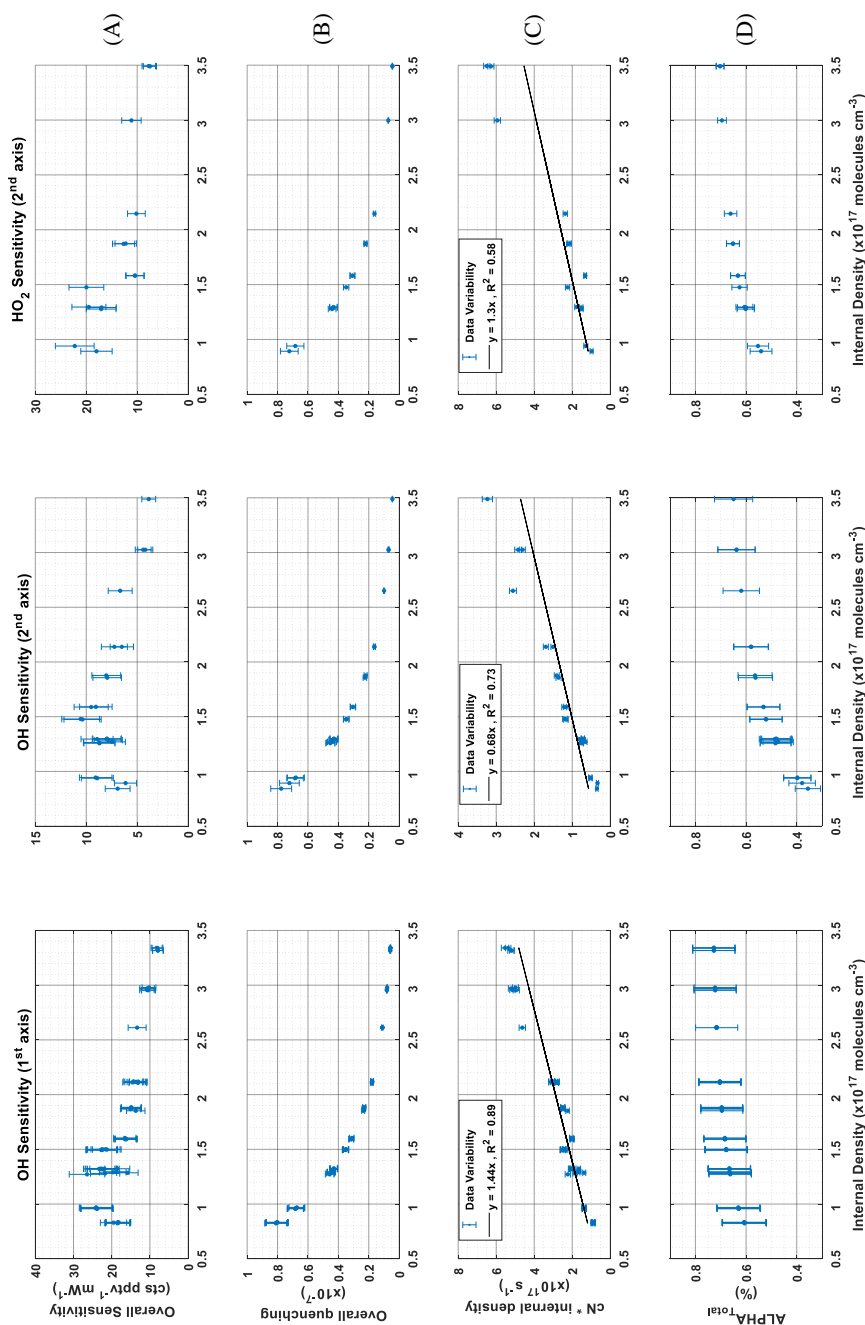

Figure 10. The determination of the pressure based sensitivity of OH in both axes and HO₂. The data shown are one-hour averages for the tested pressures, all plotted with the internal density on the x-axis. The top row (A) is the overall sensitivity curve, the second row (B) is internal quenching by N₂, O₂, and water vapor, and row (C) is internal density and cN (c0 for OH 1st axis, c1 for OH 2nd axis and c2 for HO₂), (D) is the total OH and HO₂ transmissions, all plotted against internal density. The error bars represent measurement variability (1 σ), for rows B and C. In rows A and D, the error bars represent the total uncertainty (1 σ).

543 **6 Conclusions**

544 The overall goal of this study was to develop and test a new calibration system capable of
545 providing the high flows required by the airborne HORUS system whilst maintaining stable
546 pressures across the pressure ranges experienced during flight. Such systems are critical to
547 suitably characterize airborne systems, (such as a LIF-FAGE measuring HO_x), that have a
548 strong pressure dependent sensitivity. In addition, this system is purely based on the use of
549 water-vapor photolysis, which is a frequently adopted technique for HO_x instrument
550 calibration (Martinez et al., 2003; Faloon et al., 2004; Dusanter et al., 2008). The COMSOL
551 multiphysics simulations constrained by temperature, pressure and mass flow measurements
552 demonstrated that air masses at the boundary of the APACHE system do not have sufficient
553 time to expand into the streamlines created by the HORUS sample flow and influence the HO_x
554 content entering HORUS. The main HO_x wall losses occurred at the HORUS inlet where on
555 average 23.3 % (± 1.6, full range) of OH and 22.7 % (± 0.9, full range) of HO₂ are lost. While
556 the application of these factors contribute to the uncertainty in the overall calibration factor,
557 they proved to be critical in understanding and constraining the UV conditions within
558 APACHE. The largest uncertainties result from constraining the flux (F_{β}) entering APACHE
559 ($6.3 \pm 0.9 \times 10^{14} \text{ s}^{-1}$, 1σ) and the total uncertainty in the pressure independent sensitivity
560 coefficients (ranging from 5.6 to 6.9 %, 1σ). The two actinometrical methods used to derive F_{β}
561 proved to be in good agreement with one another, with the HORUS transfer standard method
562 yielding $6.9 \pm 1.1 \times 10^{14} \text{ s}^{-1}$ (1σ) and the ozone monitor method yielding $5.7 \pm 0.74 \times 10^{14} \text{ s}^{-1}$
563 (1σ). Furthermore, the APACHE system enabled the total OH and HO₂ pressure dependent
564 transmission factors to be characterized as a function of internal pressure using both COMSOL
565 simulations and calculations of HO_x diffusivity to the walls within IPI and the low-pressure
566 regime within HORUS. Overall, the APACHE calibration system sufficiently able to calibrate
567 the airborne HORUS system across the pressure range experienced during flight. The relatively
568 low overall uncertainty of 17 - 18 % (1σ) demonstrates the suitability of this calibration
569 approach, particularly when compared to other calibration methods described earlier.

570

571 *Author contributions.* K.H, C.E, M.M, H.H, U.J, and M.R formulated the original concept and designed the
572 APACHE system. D.M, H.H, and U.J prototyped, developed, and characterized the APACHE system. T.K, D.M,
573 and H.H developed and performed the CFD simulations. D.M prepared the manuscript with contributions from
574 all coauthors.

575

576 *Acknowledgments.* We would like to take this opportunity to give a thank you to the in-house workshop at the
577 Max Planck Institute for Chemistry for construction and guidance in the development of APACHE. Additionally,
578 a special thank you to Dieter Scharffe for his assistance and advice during the development stage of this project.
