Abstract. In this manuscript, we use observations from the NASA ORACLES (ObseRvations of CLouds above Aerosols and their intEractionS) aircraft campaign to develop a framework by way of two parameterizations that establishes regionally representative relationships between aerosol-cloud properties and their radiative effects. These relationships rely on new spectral aerosol property retrievals of the single scattering albedo (SSA) and asymmetry parameter (ASY). The retrievals capture the natural variability of the study region as sampled, and both were found to be fairly narrowly constrained (SSA: 0.83 ± 0.03 in the mid-visible, 532 nm; ASY: 0.54 ± 0.06 at 532 nm). The spectral retrievals are well suited to calculate the direct aerosol radiative effect (DARE) since SSA and ASY are tied directly to the irradiance measured in presence of aerosols – one of the inputs to the spectral DARE.

The framework allows for entire campaigns to be generalized into a set of parameterizations. For a range of solar zenith angles, it links the broadband DARE to the mid-visible aerosol optical thickness (AOD) and the albedo (α) of the underlying scene (either clouds or clear sky) by way of the first parameterization: $P(AOD, \alpha)$. For ORACLES, the majority of the case-to-case variability of the broadband DARE is attributable to the dependence on the two driving parameters of $P(AOD, \alpha)$. A second, extended, parameterization $PX(AOD, \alpha, SSA)$ explains even more of the case-to-case variability by introducing the mid-visible SSA ϖ as third parameter. These parameterizations establish a direct link from two or three mid-visible (narrowband) parameters to the broadband DARE, implicitly accounting for the underlying spectral dependencies of its drivers. They circumvent some of the assumptions when calculating DARE from satellite products, or in a modeling context. For

example, the DARE dependence on aerosol microphysical properties is not explicit in P or PX because the asymmetry parameter varies too little from case to case to translate into appreciable DARE variability. While these particular DARE parameterizations only represent the ORACLES data, they raise the prospect of generalizing the framework to other regions.

1 Introduction

During the African burning season of August-October, a semi-permanent stratocumulus cloud deck off the southern African west coast is overlaid by a thick layer of biomass burning aerosols. These aerosols are advected over the southeast Atlantic Ocean from the interior of the African continent and account for nearly 1/3 of the total global biomass burning aerosol (van der Werf et al., 2010). The seasonal environment of high biomass aerosol loading above clouds has large, variable radiative impacts that have yet to be fully characterized.

In addition to many other science objectives, the NASA ORACLES aircraft campaign aimed to obtain the Direct Aerosol Radiative Effect (DARE) in both cloudy and clear skies for this region (Zuidema et al., 2016; Redemann et al., 2020). The distinction between DARE in cloudy versus clear skies is crucial since the albedo below an aerosol layer strongly influences the sign and magnitude of DARE. The albedo from below an aerosol layer can determine the sign of the top of the atmosphere (TOA) DARE independently of the aerosol itself (Twomey, 1977; Hansen et al., 1997; Russell et al., 2002; Keil and Haywood, 2003; Yu et al., 2006; Chand et al., 2009; Zhang et al., 2016; Meyer et al., 2013; Meyer et al., 2015). In a region like the southeast Atlantic, this makes determining DARE challenging since the cloud fields change rapidly according to the flow of the marine boundary layer. Depending on the cloud albedo, the aerosol could be warming (positive DARE) or cooling (negative DARE) at the TOA (Yu et al., 2006; Russell et al., 2002; Twomey, 1977). The albedo value where DARE transitions from positive to negative, or warming to cooling, is known as the critical albedo (Haywood and Shine, 1995; Russell et al., 2002; Chand et al., 2009).

The spectral DARE in Wm^{-2}nm^{-1} is determined from the difference between the net irradiance (F_λ^{net}) with and without the aerosol layer:

60

$$DARE_\lambda = F_{\lambda,aer}^{net} - F_{\lambda,no\ aer}^{net}. \tag{1}$$

Aircraft measurements, such as those collected during ORACLES, provide direct observations of the components necessary to calculate DARE. However, measurements are only taken for a sub-sample in time and space and may not be representative of the region as a whole. DARE calculated from aircraft observations alone would therefore leave the larger question of whether the aerosols warm or cool the southeast Atlantic unanswered.

In the case of DARE, the translation from individual observations into a common framework was first introduced by Meywerk and Ramanathan (1999). The radiative forcing efficiency (RFE) empirically relates DARE to the aerosol optical depth (AOD):

70   DARE=RFE*AOD.   (2)

The RFE is defined as the (usually broadband) DARE normalized by the (usually mid-visible) AOD, or sometimes as the derivative of DARE with respect to the AOD. It can be regarded as an intensive property of an airmass that allows the direct conversion from AOD to DARE, complementing calculations based on aerosol microphysical and optical properties. When
75   the RFE is aggregated for an entire field mission, it can provide a representative airmass characteristic that lends aircraft observations a broader scientific impact than the contributing individual measurements. If aerosol microphysical and optical properties are insufficiently known in a region of interest, this mission-aggregated RFE constitutes a DARE parameterization that solely requires AOD (equation 2). If the RFE varies little in a region and season of interest, it can be used to derive regional DARE estimates via AOD statistics from satellites – at least in principle. More fundamentally, observations of the dependence
80   of flux changes on AOD help to develop confidence in radiative forcing calculations based on measured aerosol properties (Russell et al., 1999, Redemann et al., 2006). In this sense, the RFE in conjunction with Eq. (2) provides closure to those calculations, and thus constrains them from the radiative flux and DARE perspective.
In this paper, we generalize the concept of RFE by explicitly taking into account the dependencies of DARE not only on AOD as expressed in equation (2), but also on both the aerosol and cloud properties. ORACLES measurements are used collectively
85   to develop two parameterizations of instantaneous DARE in the form of:

$$DARE = P(AOD_{550\,nm},\ \alpha_{550\,nm}),$$ (3)

and

$$DARE = PX(AOD_{550\,nm}, \alpha_{550\,nm},\ SSA_{550\,nm}),$$ (4)

90

where AOD, α and SSA are the aerosol optical depth, albedo, and single scattering albedo at 550 nm. The 550 nm albedo is the albedo of the scene below the aerosol layer (open ocean and/or cloudy scene), and the SSA is a measure of aerosol absorption. P stands for the two-parameter representation of DARE and PX stands for an extended version with three parameters. Both parameterizations provide instantaneous *broadband* DARE that are based upon *spectral* aerosol and cloud
95   properties. The right-hand sides of equations 3 and 4 are mid-visible quantities, while the left-hand sides are broadband results. The parameterizations have the advantage of implicitly accounting for the spectral dependencies of the aerosol and cloud properties (e.g. aerosol scattering phase function, aerosol vertical distribution, spectral dependence of aerosol absorption, cloud optical depth, cloud effective radius, cloud top and base height), whereas the dependence on mid-visible AOD, SSA, scene albedo, and solar zenith angles is explicit. They are not meant to replace detailed or approximated radiative transfer calculations
100   (e.g., Coakley 1975), which would require all these inputs, but rather to arrive at a broadband DARE with a minimum set of input parameters that drive its regional variability.

From the user standpoint, applying the parameterizations is straightforward because broadband DARE can be estimated with minimal information on the cloud and aerosol properties. The parameterization coefficients encompass the many complexities of transitioning from narrowband to broadband, such that the spectral dependencies of the cloud and aerosol properties are not

105 necessary. Of course, the parameterization only represents the "mean" conditions encountered in the ORACLES region and sampling time, and it becomes invalid outside of this mission envelope. Equation (3) only requires AOD and scene albedo at mid-visible 550 nm, which can be readily obtained from satellite observations. If mid-visible SSA is also known (from satellite or aircraft retrievals, in-situ observations, or from a climatology), the second parameterization (Eq. 4) can be used, which decreases the uncertainty of DARE, as we will discuss below.

110 To arrive at the final parameterizations, we first build upon the method presented in Cochrane et al. (2019; further denoted as C19) and determine the aerosol intensive properties of SSA and asymmetry parameter (g) that best represent the ORACLES region during August and September of 2016 and 2017. We evaluate the radiative effects of those aerosols where the relationships found between DARE, AOD, and albedo form the foundation of the parameterizations that capture the collective variability sampled from the viable cases from ORACLES 2016 and 2017.

115 The paper has two parts, which can be read independently depending on the reader's main interest: In the first part (Section 2), we describe the data and the methods used to determine spectrally resolved SSA and g. We generalize earlier work (C19) by adding a methodology for a uniform processing of multiple cases. The second part (Section 3) translates AOD, albedo, and SSA into DARE, and the P and PX parameterizations are constructed by progressively capturing more of the case-to-case DARE variability. In Section 5, we provide a quick summary and interpretation of both parts of the paper.

120 **2 Data and Methods**

2.1 Data

The ORACLES project conducted research flights in the southeast Atlantic for 3 one-month periods over three consecutive years (2016-2018) during the burning season to study the biomass burning aerosols and stratocumulus cloud deck. To achieve the defined science objectives, the ORACLES project made use of the NASA P-3 aircraft for the duration of the experiment

125 and the NASA ER-2 aircraft in 2016 only. Between the 2016 and 2017 deployments, the P-3 completed 26 science flights, five of which were collocated with the ER-2. All data can be found on the NASA ESPO archive website (ORACLES Science Team, 2017a, b, 2019).

We focus on utilizing measurements taken from the P-3, primarily the irradiance measurements taken by the Solar Spectral Flux Radiometer (SSFR, Pilewski et al., 2003; Schmidt and Pilewski, 2012) in conjunction with AOD and retrievals of

130 column gas properties from the Spectrometer for Sky-Scanning Sun-tracking Atmospheric Research (4STAR, Dunagan et al., 2013; Shinozuka et al., 2013; LeBlanc et al., 2020) to achieve the specific goals of this paper. SSFR consists of two pairs of spectrometers. Each pair (one zenith viewing and one nadir viewing) covers a wavelength range of 350-2100 nm. SSFR is radiometrically and angularly calibrated pre- and post- mission. Its zenith light collector is equipped with an active leveling

platform (ALP), which keeps it horizontally aligned by counteracting the variable aircraft attitude. This allows the collection

135 of irradiance data as long as pitch and roll stay within the ALP operating range of 6°. This ensures that radiation from the lower hemisphere does not contaminate the zenith irradiance measurements, which was especially important for the bright clouds encountered during ORACLES. 4STAR provides spectral retrievals of AOD from the solar direct beam irradiance above the aircraft and is calibrated through Langley extrapolation technique before and after deployment at Mauna Loa Observatory along with in-flight high-altitude measurements (see LeBlanc et al., 2020 for details on 4STAR calibration).

140 4STAR also provides aerosol intensive properties (e.g., SSA described in Pistone et al. 2019), column water vapor and trace gas retrievals, such as ozone (e.g., Segal-Rosenheimer et al., 2014). Further details on SSFR, ALP and 4STAR instrumentations and calibrations can be found in Cochrane et al. (2019).

2.2 Methods

To construct our DARE parameterizations, aerosol intensive optical properties such as SSA and *g* must be determined for as
145 many cases as possible. Retrieving these properties from aircraft irradiance measurements is inherently challenging because the aerosol radiative effects can be relatively small compared to the horizontal variability of cloud albedo.

C19 showed for two cases that special spiral maneuvers ("square" spiral) are more successful than the heritage "stacked leg" approach because multiple measurements are taken throughout the vertical profile over a short time period (typically 20 minutes). This sampling strategy reduces the effects of cloud inhomogeneities and allows isolation of the aerosol signal, as
150 long as specific quality criteria (detailed below) are met. These criteria, preceded by two filtering steps in which data points are removed, are described in the following section and follow the order presented in the flow chart of Figure 1. The filters and criteria provide objective data conditioning prior to the subsequent aerosol retrieval and DARE parameterizations.

2.2.1 Data Conditioning

Throughout the spiral, the zenith (downwelling) and nadir (upwelling) irradiance measurements are continuously affected by
155 the aerosol layer. The aerosol-induced changes to the irradiance profiles allow us to extract information about the aerosol itself. As can be seen in Figure 2a, both upwelling ($F_\lambda^\uparrow$) and downwelling ($F_\lambda^\downarrow$) irradiance profiles have an approximately linear relationship to AOD due to the absorption and scattering of the aerosol layer. Any deviation from the linear relationship is attributed to changes in the underlying cloud; these are filtered out to isolate the radiative effect of the aerosol. This linear assumption for the global downwelling is a simplification only for initial fitting for the subsequent filtering, and deviations
160 from the linear relationship could be due to non-linearities as expected from Beer's law, or vertical dependencies of aerosol parameters. However, we expect these to be negligible compared to changes in the underlying clouds, and therefore use deviations from a linear profile to filter our data.

Following the methods described in C19, two filters are applied to the data to ensure the isolation of aerosol effects. Prior to filtering, all data are corrected to the SZA at the midpoint of the spiral according to Equation 3 in C19 to account for the minor
165 change in solar position throughout the spiral. The first is an altitude filter (see F1 in Fig. 1), where the altitude range is limited

to encompass only the vertical extent of the aerosol layer. The second is a homogeneity filter (see F2 in Fig. 1), which selects the dominant profile of measurements, whether that be cloudy or clear sky, and removes any outlying data. The filter begins with a linear fit of the irradiances with respect to the AOD for each wavelength:

$$F_\lambda^\uparrow = a_\lambda^\uparrow + b_\lambda^\uparrow * AOD_\lambda, \tag{5}$$

$$F_\lambda^\downarrow = c_\lambda^\downarrow + d_\lambda^\downarrow * AOD_\lambda, \tag{6}$$

where a_λ and b_λ (c_λ and d_λ) are the slope and intercept of the linear regression, for which the individual data points are weighted inversely by the irradiance uncertainties. In any particular spiral, the measurements could be taken from either predominantly cloudy or clear sky. The filter, which is applied to the upwelling profile, retains only those data within the 68% confidence interval (1 sigma) of the linear fit line. This ensures that the retained data contains no outlying points and is all from one mode: clear sky or cloudy sky. This filtering step is slightly modified from the method presented in C19 in two ways: 1) the irradiances were previously fit against AOD at 532 nm only rather than AOD at the corresponding wavelength and 2) the range of retained data was previously based on the confidence interval of overall mean irradiance value rather than the confidence interval of the linear fit throughout the profile. We have made these adjustments to better allow for linear variation with altitude while eliminating data that significantly deviates from the profile. There are 3 exception cases for which we maintain the original filtering from C19 using the confidence interval on the mean value. For these cases, the filtering modification overly eliminated data or retained excessive variability at small (large) AOD values (high altitude (low altitude)). Following the filters, each case must pass criteria that ensure the changes in net irradiance with altitude are caused by the aerosol radiative effects and not variability in the underlying cloud field. First, irradiance measurements must be available throughout the spiral, spanning the full AOD dynamic range between the top and bottom of the layer (C1 in Fig. 1) The most common reason for cases to fail this criterion is that the AOD never reaches background stratospheric AOD levels (near zero; 0.02-0.04 in the mid-visible), indicating measurements were not taken fully above the aerosol layer. Since the retrieval relies on the change in irradiance with altitude, incomplete profiles do not provide a sufficient change required to capture the aerosol signal.

The second requirement (C2 in Fig. 1) is to ensure that the true aerosol absorption be larger than the 3-D cloud effect known as horizontal flux divergence (see Fig 1 in C19). SSFR actually does not measure the absorption directly, but rather the decrease of the net flux F_λ^{net} from the top of the aerosol layer (TOL) to the bottom (BOL), or vertical flux divergence:

$$V_\lambda = \frac{(F_{\lambda,tol}^{net} - F_{\lambda,bol}^{net})}{F_{\lambda,tol}^\downarrow} = \frac{[(F_{\lambda,tol}^\downarrow - F_{\lambda,tol}^\uparrow) - (F_{\lambda,bol}^\downarrow - F_{\lambda,bol}^\uparrow)]}{F_{\lambda,tol}^\downarrow}, \tag{7}$$

which we normalized by the incident irradiance. V_λ is only the *vertical* part of the total flux divergence. The other part is the *horizontal* flux divergence, H_λ, which is not measured by SSFR. The true absorption, A_λ, is obtained from the *total* flux divergence:

$$A_\lambda = V_\lambda - H_\lambda. \tag{8}$$

If the condition $|H_\lambda| << |V_\lambda|$ (see section 3.1.2 in C19), then $A_\lambda \approx V_\lambda$, and the vertical flux divergence measured by SSFR can be used in lieu of the true absorption. The first step to check that this requirement is met is to calculate V_λ from the linear fit in equations (5) and (6):

$$V_\lambda = \frac{AOD_{532}^{max} * (b_\lambda^\uparrow - b_\lambda^\downarrow)}{a_\lambda^\downarrow} \quad , \tag{9}$$

where AOD_{532}^{max} is the AOD at the bottom of the spiral (just above the cloud), and a_λ, b_λ are the slope and intercept of the linear fit lines. The second step is to estimate H_λ. Neglecting its weak wavelength dependence (Song et al., 2016), we instead use H_∞, the value of H_λ at large wavelengths. As described in C19, H_∞ can be determined using measurements of AOD_λ and V_λ: the AOD decreases with increasing wavelength, and therefore the true aerosol absorption decreases as well; as AOD_λ reaches zero, so does A_λ. When this happens, any non-zero measured value of V_λ must originate from H_λ because $A_\lambda = 0 = V_\lambda + H_\lambda$. Since this occurs at long wavelengths, the vertical flux divergence $V_{\lambda \to \infty}$ yields H_∞. In practice, we obtain H_∞ from the intercept of the regression between AOD_λ and V_λ.

To determine the relative amount of absorption to horizontal flux divergence, C19 developed a unitless metric (i_λ) that determines whether the case is viable for an aerosol retrieval. i_λ is defined as:

$$i_\lambda = \frac{H_\infty}{V_\lambda - H_\infty}, \tag{10}$$

If $i_\lambda > 0.3$, then the condition $|H_\lambda| << |V_\lambda|$ is not met, and the case is not considered viable for a subsequent retrieval.

The final criteria (C3 in Fig 1.), the measured albedo at the cloud top (Bottom of Layer, BOL) and above the aerosol layer (Top of Layer, TOL) shown in 3b must be consistent in the limit of zero AOD. As the aerosol absorption decreases with increasing wavelength, the ratio between the measured albedo at the cloud top (BOL) and above the aerosol layer (TOL) must shift closer and closer to 1. Analogous to the determination of H_∞ and illustrated in Figure 2c, we determine AR_∞ as the intercept between the TOL and BOL albedo ratio and the AOD:

In the limit of: $\lambda \to \infty$:

$$lim_{AOD(\lambda) \to 0} \frac{albedo_{\lambda,TOL}}{albedo_{\lambda,BOL_\lambda}} \equiv AR_\infty. \tag{11}$$

230

AR_∞ is our final criterion, and any deviation larger than 0.1 from 1.0 (i.e., the intercept must fall between 0.9 and 1.1) indicates that other factors affect the data besides the aerosol absorption. For example, a changing cloud field could change the albedo between the beginning and end of the spiral, and the aerosol retrieval might wrongly attribute this change to aerosol absorption. To summarize, the criteria each case must pass are:

235 C1. There must be valid data from both SSFR and 4STAR throughout the entire aerosol profile. Cases cannot be used within the retrieval if there is a lack of data due to aircraft flight pattern, ALP malfunction, or AOD data flagged for bad quality.

C2. $|i_\lambda|$ must be below 0.3 to ensure that the aerosol absorption is large enough compared to the horizontal flux divergence so that an aerosol retrieval is possible.

C3. AR_∞ must fall between 0.9 and 1.1 to ensure that the spectral albedo is consistent both above and below the aerosol layer.

240 Both the filters and the criteria are designed to control for any rapidly changing, potentially inhomogeneous cloud field encountered during ORACLES. Table 1 presents the C2 and C3 criteria and retrieval status of SSA_λ and g_λ for spiral cases completed in 2016 and 2017 that passed C1. The criteria for which a case fails is indicated in red text. In 2016, five spiral profiles out of 18 met all criteria, while four out of 23 met the criteria in 2017. Table 2 provides the UTC, latitude, and longitude ranges for each successful spiral profile.

245 **2.2.2 Retrieval Algorithm**

If a spiral irradiance profile has passed every criteria metric, the aerosol property retrieval is run. The retrieval, described in detail in C19, is based on statistical probabilities between the calculated model irradiance profiles and the measured irradiance profiles. The retrieval process is similar to curve-fitting, where we vary the parameters in question (i.e. SSA and g) until the radiative transfer model (RTM) calculations best fit the measured data.

250 The SSA and g retrieval is performed with the publicly available 1-dimensional (1D) RTM DISORT 2.0 (Stamnes et al., 2000) with SBDART for atmospheric molecular absorption (Ricchiazzi et al., 1998) within the libRadtran library (Emde et al., 2016; libradtran.org). The RTM is run with 6 streams, assumes a Henyey Greenstein Phase function, and no delta-Eddington scaling is applied, all of which contribute to the inherent uncertainty within the RTM (Boucher et al., 1999). For each wavelength, we use the RTM to progress through pairs of SSA and g and calculate the upwelling, downwelling, and net irradiance profiles for

255 each pair. For each {SSA, g} pair calculation, a probability is assigned to every SSFR data point in the profile according to the difference between the calculation and the measurement based on an assumed Gaussian distribution that represents the SSFR measurement uncertainty. The overall probability of a specific {SSA, g} pair given the SSFR irradiance measurements is the product of the individual probabilities for each data point; the {SSA, g} pair with the highest overall probability between all three profiles (upwelling, downwelling, net) is the retrieval result for that wavelength. The inclusion of the net profile is an

expansion upon the method described in C19. The net irradiances provide a direct absorption constraint on the SSA retrieval, whereas the asymmetry parameter retrieval draws primarily upon the upwelling and downwelling fluxes.

In addition to the aerosol property pairs of {SSA, g}, the RTM ingests the spectral cloud top albedo from SSFR (set as the surface within the model at the measured altitude, around 2 km) and the aerosol extinction profile derived from the 4STAR AOD profile. The AOD profile has been conditioned such that the profile decreases monotonically to eliminate any unphysical extinction values (i.e., negative extinction). Any remaining AOD above the aerosol layer is allocated to a layer extending to an altitude of 15,000 m.

We modified the standard tropical atmosphere included in the libRadtran package (Andersen et al., 1986) to include the column water vapor measurements taken by the NASA P3 hygrometer from the level of the cloud top to the maximum altitude of the spiral; the values at altitudes that are not informed by aircraft measurements are set to the standard tropical atmosphere values. The full water vapor column was then scaled to the water vapor value retrieved with 4STAR. The column ozone amount in the standard tropical atmosphere is also scaled by the column ozone amount retrieved with 4STAR. As mentioned in section 2.2.1, the measured irradiances are corrected to the SZA at the midpoint of the spiral to account for the changing solar position during the spiral. For consistency, the SZA within the RTM is set to the same SZA of the spiral midpoint.

Table 2 lists, for each spiral case, the UTC, latitude, longitude albedo at 500 nm, mean SZA, AOD at 500 nm, column water vapor, and column ozone.

For 4 cases, the retrieval is possible only for SSA_λ and not for g_λ. This occurs when the irradiance profiles a) did not have enough data points and/or b) are subject to scene inhomogeneities despite the filters and criteria described in the previous section. The g retrieval is less sensitive than the SSA retrieval since the effect of g is smaller than that of SSA on the irradiance profile. For these specific cases, the retrieval is modified such that g is an input to the retrieval rather than a variable, and SSA is the only retrieved parameter. For each wavelength, the input of g is set to the mean value from the cases for which we had valid g retrievals. Table 1 lists which properties (SSA and g; SSA only) were retrieved for each case.

2.3 DARE

2.3.1 DARE Calculations

The retrieved pairs of SSA_λ and g_λ serve as the aerosol properties for the $DARE_\lambda$ calculations that the parameterizations are based upon. $DARE_\lambda$ can be calculated at any level. We focus on the TOL calculations since they will resemble those calculated at the tropopause which is used as a metric for the cooling/warming impact of aerosols (e.g. Forster et al., 2007.)

For each pair of retrieved SSA_λ and g_λ, we calculate instantaneous $DARE_\lambda$ for SZAs from 0° to 80° with a 10-degree resolution for a range of albedo and AOD values. Since the SSA_λ and g_λ retrievals are valid only for the shortwave wavelength range ($\lambda \leq 781$ nm), we extend to longer wavelengths (up to 2100 nm) as described in detail in Appendix A.

Finally, the albedo must be generalized to all SZAs for a range of albedo spectra to be used within the $DARE_\lambda$ calculations. Since we measure albedo only at a single SZA, we must use the RTM to determine the spectral shape and magnitude of the

albedo at each SZA. We make this transition via a cloud retrieval; cloud properties of effective radius and cloud optical thickness (COT) are retrieved from the original cloud top albedo spectrum measured by SSFR at the bottom of the spiral. The effective radius is then held constant and the albedo spectra are calculated for a range of COTs at each SZA. Specific details of the albedo calculations can be found in Appendix A.

At each SZA, the RTM is run twice for each set of AOD values and cloud albedo spectra: with and without the aerosol layer included. The difference between the two runs is the $DARE_\lambda$. The calculations are completed for wavelengths between 350 and 2100 nm; the integration of the $DARE_\lambda$ spectrum provides broadband DARE. This is done for each pair of SSA_λ and g_λ.

2.3.2 Parameterizations

In the past, the Radiative Forcing Efficiency served the purpose of scaling measurements to larger regions and into climate models. However, the RFE excludes both the dependence of DARE on cloud albedo and the non-linearities of the DARE-AOD relationship. Our first goal was to develop a parameterization that builds upon the RFE concept and generalizes it to explicitly include the dependencies and non-linearities that the RFE excludes while maintaining simplicity. The parameterization (P_{DARE}) provides a broadband DARE estimate with minimal inputs in the form:

$$DARE = P(AOD_{550}, \alpha_{550}) = L(\alpha_{550}) * AOD_{550} + Q(\alpha_{550}) * AOD_{550}^2 \tag{12}$$

where L and Q are the parameterization coefficients and α_{550nm} and AOD_{550nm} are required inputs of 550 nm albedo and 550 nm AOD, respectively. P_{DARE} has the significant advantage that the complexities of transitioning from narrowband to broadband for many parameters are incorporated into the parameterization coefficients, allowing for use across regional spatial scales for biomass burning aerosol since minimal information is required as input. Of course, the parameterization is only applicable for the region where the measurements were taken. It also cannot be generalized to apply for a different aerosol type.

Our second goal was to increase the level of complexity of the P_{DARE} parameterization by including the additional constraint of the aerosol SSA. While P_{DARE} requires minimal input, the more advanced parameterization, PX_{DARE}, includes the 550 nm SSA as an additional parameter; this decreases the variability between cases. PX_{DARE} is in the form:

$$DARE = PX(AOD_{550}, \alpha_{550}, \Delta SSA_{550}) = P(AOD_{550}, \alpha_{550}) + \Delta(AOD_{550}, \alpha_{550}, \Delta SSA_{550}), \tag{13}$$

where the first term on the right-hand side is P_{DARE} (Equation 12) and the second term (delta term) represents the change in DARE due to varying SSA.

The coefficients of P_{DARE} and PX_{DARE} are determined based on the DARE calculations performed for each case with the associated pair of SSA_λ and g_λ, with the end result of two parameterizations that empirically represent the relationship between

DARE and its driving parameters while capturing the variability between individual cases. Further details of the P_{DARE} and

325   PX_{DARE} development are best understood in conjunction with result figures and explained in further detail in Section 3.2.

3. From Aerosol Properties to DARE

3.1 Aerosol Properties

Figure 3a shows the retrieved asymmetry parameter values for each case with sufficient sensitivity. The red dashed line represents the average spectrum, where the error bars are calculated by propagating the uncertainty of each individual retrieval

330   (shown in Appendix E). The average spectrum is used in the SSA retrievals for cases that did not have sufficient sensitivity to retrieve g.

The asymmetry parameter decreases with increasing wavelength more rapidly than found in AERONET retrievals from sites in the SE Atlantic (São Tomé, Ascension Island and Namibia; Appendix B, Fig B2). The AERONET retrieval algorithm is fundamentally different from the one used here. The AERONET operational inversion method assumes a size-independent

335   complex refractive index (Dubovik and King, 2000), which can potentially lead to errors in the retrieved size distribution from which the optical properties are determined (Dubovik et al., 2002; Dubovik et al., 2006; Chowdhary et al., 2001). At 550 nm, the average g value is 0.52; by 660 nm, g has dropped to 0.43. Simple Mie calculations, shown in Appendix B, confirm that this spectral dependence is possible with a particular fine to coarse mode aerosol ratio. In addition, the AERONET sites are located at the perimeter of the ORACLES study region: At the very north (São Tomé), west (Ascension) and southeast

340   (Namibia) ends of where the P3 flew. As such, the aerosol measured at the AERONET sites might actually differ from that measured during our retrievals.

Figure 3b shows the retrieved SSA spectra from each successful spiral case, and the mean retrieved SSA and g for each wavelength are presented in Table 3. Our retrievals of SSA range from 0.78 to 0.88 at 550 nm, with an average value of 0.83. The red spectrum shows the mean of all cases. The SSA retrieved through our new method is spectrally flatter than reported

345   from the SAFARI 2000 campaign, which took place in the southeast region of the ORACLES measurement domain (Eck et al., 2003; Haywood et al., 2003; Russell et al., 2010). The SAFARI SSA values tend to be higher at the shorter wavelengths (i.e. < 550 nm), and they decrease more rapidly with increasing wavelength. The mean retrieved SSA values shown here are within the range of the 550 nm ORACLES 2016 SSA values from multiple instruments presented in Pistone et al. (2019), but are lower than most values from SAFARI 2000 (Haywood et al., 2003; Johnson et al., 2008; Russell et al., 2010). However,

350   the mean SSA is close to the 0.85 value reported by Leahy et al. (2007). The lowest retrieved 550nm SSA value is only slightly lower than that reported by Johnson et al., 2008 for the Dust and Biomass-burning Experiment (DABEX): 0.78 compared to 0.81.

Figure 4 compares our retrieved values of SSA to the *in situ* column average for a) 450 nm b) 530 nm and c) 660 nm for all cases where such a comparison was possible. The *in situ* measurements are taken from a three-wavelength nephelometer (TSI

355   3563) and a three-wavelength particle soot absorption photometer (PSAP) (Radiance Research). The combination of scattering

from the nephelometer and absorption from the PSAP provides SSA. SSA is calculated as the ratio of scattering from the nephelometer to the sum of scattering (again from the nephelometer) and absorption (from the PSAP). In order to best compare the retrieved values to the *in situ* values of SSA, the *in situ* measurements throughout the spiral profile are weighted by the weighting function, obtained by the transmittance, and then averaged to obtain a column value of SSA. Further details of the transmittance-weighted averaging can be found in Appendix C.

Although there are many factors that control aerosol SSA such as emission state, source location, distance from the source, and age (Haywood et al., 2003; Eck et al., 2013; Konovalov et al., 2017; Dobracki et al., 2020 in prep), the values we find here are well within the range of SSA values reported by other ORACLES instruments (Pistone et al., 2019). As seen in Figure 4, the mean SSFR/4STAR retrieved SSA value tends to be slightly lower than the in-situ mean (shown by the blue curve on x- and y- axis). However, there does not seem to be a distinct correlation or anti-correlation for these cases, especially considering the uncertainties. This is consistent with the results shown in Pistone et al. (2019), which also showed no distinct correlation between the SSA derived or measured by different instruments (top row in Figure 8).

It is important to note that the error bars shown in Figure 4 reflect different values between the instruments: the *in situ* error bars represent the standard deviation of the entire column, whereas the SSFR-retrieved error bars represent the error estimate of the retrieval. The *in situ* measurements provide a range of SSA, and the standard deviation illustrates the variability throughout the aerosol layer. Conversely, the SSFR/4STAR retrieval provides only one value of SSA with the associated retrieval uncertainty for the entire layer. We cannot, however, detect any altitude dependence of SSA that may be present, such as suggested by Wu et al. (2020) and Dobracki et al. (2020).

In addition, new, more accurate (compared to filter-based *in situ* measurements), cavity ring down and photo acoustic spectrometry instrumentation has recently been deployed to the SE Atlantic during the CLARIFY-2017 deployment. Davies *et al*. (2019) performed an analysis of the SSA of aerosol dominated by biomass burning aerosol using such instrumentation and found mean SSA values of 0.84, 0.83 and 0.81 at interpolated wavelengths of 467, 528, and 652 nm respectively. These values are included in Figure 4 (dashed cyan line) to highlight the agreement with the results of this work. Wu *et al*. (2020a) extended this analysis by examining the BBA in the free troposphere, finding a mean and variability in BBA SSA of 0.85 ± 0.02 and 0.82±0.04 at 405 and 658 nm with evidence that the BBA at higher altitudes in the free troposphere is less absorbing. These results appear entirely consistent with those derived here.

3.2 DARE Parameterizations

The first (basic) parameterization P_{DARE} uses only two input parameters: AOD_{550} (mid-visible optical thickness) and α_{550} (scene or cloud albedo below the aerosol layer). The *L* and *Q* coefficients from Eq 12 are derived from the nine individual cases (described in section 3.3.1) where the corresponding fit coefficients for each of the cases are averaged to create the P_{DARE} parameterization coefficients:

$$L_0 = \frac{1}{9}\sum_{i=1}^{9} l_{0,i}; \; L_1 = \frac{1}{9}\sum_{i=1}^{9} l_{1,i}; \; L_2 = \frac{1}{9}\sum_{i=1}^{9} l_{2,i},$$

$$Q_0 = \frac{1}{9}\sum_{i=1}^{9} q_{0,i}; \; Q_1 = \frac{1}{9}\sum_{i=1}^{9} q_{1,i}; \; Q_2 = \frac{1}{9}\sum_{i=1}^{9} q_{2,i}.$$

390

The coefficients l_0, l_1, l_2, q_0, q_1, q_2 are the linear (l) and quadratic (q) coefficients of second-order polynomial fits to radiative transfer calculations for the DARE dependence on AOD_{550} of the *individual* cases as expressed in Eq 12 for the *average*, which simultaneously capture the dependence on α_{550} as follows:

395
$$l(\alpha_{550}) = l_0 + l_1 * \alpha_{550} + l_2 * \alpha_{550}^2, \tag{14}$$

$$q(\alpha_{550}) = q_0 + q_1 * \alpha_{550} + q_2 * \alpha_{550}^2, \tag{15}$$

 The overall P_{DARE} coefficients are tabulated for each solar zenith angle $SZA=\{0°, 5°, …, 80°\}$ (see Table 4a).

Figure 5a shows the dependence of $DARE = P(AOD_{550}, \alpha_{550})$ on the two input parameters for one specific SZA. DARE is

400 shown in percent of top-of-atmosphere irradiance[1], $S_0 * cos(SZA)$, where $S_0 = 1365$ W/m². It is clearly non-linear with respect to both input parameters, illustrating the need for a quadratic representation. However, the RFE from which P_{DARE} originates is still encapsulated in this parameterization as:

$$RFE = \frac{dP(AOD_{550}, \alpha_{550})}{dAOD_{550}}\Big|_{AOD_{550}=0} = L(\alpha_{550}), \tag{16}$$

405

which is the slope of the black line at the origin in Figure 5a. For an underlying albedo of 0, this reduces to $RFE = L_0$. In this sense, the full parameterization P_{DARE} generalizes RFE.

Whereas the black lines in Figure 5a and 5b show the average ORACLES parameterization (i.e. P_{DARE}) from Table 4a, the colored lines show the contributing 9 cases, sorted by 550 nm SSA. It is apparent that the SSA introduces considerable case-

410 to-case variability, especially for large albedos (Fig. 6), both in terms of the critical albedo (Fig. 7) and in terms of the magnitude of the DARE.

Figure 6 shows the same as Figure 5b, but here as the difference between the DARE for individual cases and P_{DARE}, (which represents the case-average DARE) expressed as a percentage difference in incident TOA solar flux. The $\pm\sigma$ range of variability (essentially the root mean square (RMS) difference, shown as dashed black lines in Figure 7) is calculated from the standard

415 deviation of this difference across all nine cases enumerated by c:

---

[1] Accompanying material (DOI:10.5281/zenodo.4311591) includes all necessary coefficients for the parameterization and the code necessary to reconstruct them, including the option to rescale for other top-of-atmosphere irradiance values.

$$\sigma = \sqrt{\frac{1}{8} \sum_{c=1}^{9} (DARE_c - \overline{DARE})^2}. \tag{17}$$

This serves as a metric for the case-to-case variability, which increases with the scene albedo and AOD. For example, the possible range in DARE for a mid-visible albedo of 0.6 and an AOD of 0.75 ($SZA=20°$) would be about $10\pm2\%$ (or 136 ± 27 Wm^{-2}). This is *without* accounting for the uncertainty in the input parameters AOD and scene albedo, which have to be propagated through the parameterization via $dP/dAOD$ and $dP/d\alpha$. The uncertainty of 27 Wm^{-2} in brackets above can be interpreted as the uncertainty in DARE due to insufficient knowledge of SSA, which drives the case-to-case variability: in Figures 5 and 6, the highest (lowest) SSA values correspond to the lowest (highest) DARE.

The extended parameterization PX$_{DARE}$ (equation 13) includes the SSA effect on DARE explicitly through an addition term not included in the P$_{DARE}$ parameterization (equation 12): $\Delta(AOD_{550}, \alpha_{550}, \Delta SSA_{550})$.

In order to quantify the effect of SSA by this term, it is convenient to start with the dependence of the critical albedo on SSA (Figure 7). To first approximation, this dependence can be represented by a linear fit. The critical albedo also weakly depends on the AOD, and rather strongly on the SZA (not shown; for example, it can attain 0.6 at low Sun elevations) (Boucher et al., 1999). In contrast with the SSA, the asymmetry parameter does not drive the critical albedo in any discernible way, nor does it explain the deviation of the case-specific critical albedo from the fit line.

In analogy to the SSA dependence of the critical albedo, the case-specific deviations of DARE from the case-average DARE (Figure 6) can be represented as linear functions $\Delta(\alpha, SSA)$ (Figure 8a). Here, this is done by defining the DARE perturbation $\Delta(SSA)$ at two specific albedos: (1) at the case-average critical albedo (i.e. the albedo where DARE changes sign in Figure 7), and (2) an albedo of 1 (maximum albedo):

$$\Delta_{crit} = \Delta\left(AOD_{550}, \alpha_{550}^{crit}, \Delta SSA_{550}\right) = C(AOD_{550}) * \Delta SSA \tag{18}$$

$$\Delta_{max} = \Delta\left(AOD_{550}, \alpha_{550}^{max}, \Delta SSA_{550}\right) = D(AOD_{550}) * \Delta SSA \tag{19}$$

where C and D are the slopes of the fit lines of $\Delta(\alpha, SSA)$ and ΔSSA is the difference between the case-specific SSA and the case-average SSA ($\overline{SSA}$, 0.83). The colored dots in Figure 8a show Δ_{crit} and Δ_{max}, while Figure 8b shows how the coefficients C and D depend on the AOD. This dependency can be represented as:

$$C(AOD) = C_1 * AOD + C_2 * AOD^2 \tag{20}$$

$$D(AOD) = D_1 * AOD + D_2 * AOD^2, \tag{21}$$

where C_1, C_2, D_1, and D_2 (and the relative uncertainties for the Δ_{crit} and Δ_{max} terms) are tabulated in Table 4b for all solar zenith angles. Inserting Eqs. 20 into 18 and 21 into 19, the perturbations Δ_{crit} and Δ_{max} become:

$$\Delta_{crit}(AOD_{550}, SSA_{550}) = (C_1 * AOD + C_2 * AOD^2) * (SSA - \overline{SSA}) \quad\quad\quad (22)$$

$$\Delta_{max}(AOD_{550}, SSA_{550}) = (D_1 * AOD + D_2 * AOD^2) * (SSA - \overline{SSA}) \quad\quad\quad (23)$$

The perturbation at *any* albedo between the critical albedo and 1 is simply calculated as:

$$\Delta(\alpha) = \frac{\alpha - \alpha_{crit}}{1 - \alpha_{crit}} * \Delta_{max} + \frac{1 - \alpha}{1 - \alpha_{crit}} * \Delta_{crit} , \quad\quad\quad (24)$$

while $\Delta(\alpha) = \Delta_{crit}$ for $\alpha < \alpha_{crit}$.

Equations 21, 22, 23, and 24 are used collectively to determine the additional term for the PX_{DARE} parameterization (Eq. 13). If SSA is known in addition to AOD and scene albedo, then PX_{DARE} captures DARE to greater fidelity than does P_{DARE}. This is shown by the case-to-case variability in Figure 9, expressed as the difference between the DARE for the individual cases $PX(AOD_{550}, \alpha_{550}, \Delta SSA_{550})$ in analogy to Figure 6. The $\pm\sigma$ range of variability in Figure 9 is much smaller than that in Figure 6, showing that the uncertainty in PX_{DARE} ($\pm$0.5% at an albedo of 0.3 of the incident irradiance at TOA) is significantly below the unresolved variability in P_{DARE} due to an unknown SSA ($\pm$1.2% at an albedo of 0.3, up to 2% at an SZA of 20°).

Beyond the case-to-case variability, Figure 10 confirms that including the SSA information in PX_{DARE} does in fact reproduce DARE well for each individual case, as illustrated by the agreement between the solid (PX_{DARE}) and the individual case RTM-calculated DARE. The residuals between the direct RTM DARE output and DARE estimated using P_{DARE} and PX_{DARE} (shown as contours in Figure 11a and Figure 11b) provide an estimate of the overall uncertainties inherent within the parameterizations.

As Figure 11a shows, the residuals of PX_{DARE} are significantly smaller than those of P_{DARE}. Both P_{DARE} and PX_{DARE} have small uncertainty contributions from a number of factors (e.g., measurement uncertainty of SSFR, RTM uncertainty, conversion and extrapolation from spectrally resolved retrievals to broadband values, the uncertainty of the quadratic fit leading to the *L* and *Q* coefficients, and the uncertainty in the fits leading to the *C* and *D* coefficients), but P_{DARE} also encompasses the variability due to SSA which leads to a much larger uncertainty in P_{DARE} than PX_{DARE}.

4. Summary and Interpretation

In this paper, we systematically linked aircraft observations of spectral fluxes to aerosol optical thickness and other parameters, using 9 cases from the 2016 and 2017 ORACLES campaigns. This observationally-driven link is expressed by two parameterizations of the shortwave broadband DARE, (1) in terms of the mid-visible AOD and scene albedo (P_{DARE}), and (2) in terms of the mid-visible AOD, scene albedo, and aerosol SSA (PX_{DARE}). These parameterizations can be used to translate from AOD and scene albedo (optionally also from SSA) to DARE directly, bypassing radiative transfer calculations that are usually required to arrive at DARE from observations. This is advantageous when satellite retrievals provide only limited information such as AOD and scene albedo (by way of cloud fraction and optical thickness), but not aerosol microphysics,

hygroscopic growth, or optical properties. However, this parameterization only captures the natural variability of the study region as sampled. It therefore does not necessarily represent the entire southeast Atlantic, let alone during times beyond the ORACLES campaigns. Despite this caveat, one could interpret the parameterization as the start of a DARE climatology built on two (or three) driver variables. Additional observations extending the statistics to other regions and time periods could easily be added to this framework. For example, the 2018 ORACLES data will be incorporated in a separate paper.

We find that the two parameterizations reproduce the case-specific DARE to different degrees. The majority of the case-to-case variability within the ORACLES DARE dataset is attributable to the dependence on AOD and scene albedo. Using just these two variables to span the first parameterization, P_{DARE}, the RMS bias of the case-specific DARE with respect to the parameterized baseline is 1-2% of the incident radiation for an SZA of 20° and an AOD of 0.75 (Figure 6), with a DARE value of 10% of the incident radiation for a scene albedo of 0.6 (Figure 5b). Translated into flux units, the DARE for this constellation of scene parameters is 136 ± 27 W m^{-2}, where the range of uncertainty stems from the unexplained case-to-case variability as obtained from the RMS bias. In other words, this parameterization leads to 20% DARE uncertainty due to the variability of the system caused by factors *other* than AOD and scene albedo. If satellites only provided AOD and scene albedo, this would be the uncertainty of the derived DARE (leaving the retrieval uncertainties of AOD and albedo aside for the moment). In reality, the variability is likely even larger than captured with our limited samples, so this estimate is a lower bound on the DARE variability.

Fortunately, our research showed that we can actually explain more of the case-to-case variability by introducing the mid-visible SSA as third parameter in an extended parameterization PX_{DARE}. This reduces the variability by a factor of 4 by explicitly resolving the case-to-case variability via SSA: a DARE value of 136 ± 6.8 Wm^{-2} corresponds to an SSA of 0.83 (campaign average at 550 nm), whereas 0.81 (typical low SSA value encountered during ORACLES) yields DARE of 177 ± 10.6 Wm^{-2}. The remaining uncertainty (about 5%) is due to variability drivers beyond AOD, scene albedo and SSA, such as variable aerosol microphysics or hygroscopicity. It also encompasses the measurement uncertainty of SSFR and 4STAR.

Interestingly, the mid-visible asymmetry parameter (also retrieved for most cases) is not a significant driver of the case-to-case variability. However, the retrieved spectra of SSA and asymmetry parameter can be useful for future satellite retrievals of cloud and aerosol optical thickness in the study region. Since these retrievals are directly tied to the radiative fluxes, they work without assumptions about the scattering phase function, size distribution, or aerosol type, nor do they require smoothness constraints. However, an optical closure study that involves in-situ measurements of aerosol microphysics and optical properties in conjunction with Mie calculations is required before our results can be of practical use, especially at wavelengths beyond the visible range where our retrieval uncertainties grow large. Our asymmetry parameter spectra fall off faster with wavelength than usually assumed based on land-based observations, which may be an indication that there is less coarse mode in the ORACLES measurements, which are almost exclusively over ocean.

We cannot judge whether our approach will be useful for predictive models, which usually follow the "bottom-up" paradigm, i.e., they arrive at DARE starting from detailed aerosol and cloud properties via radiative transfer calculations. At the very least, the agreement between the absolute values and spectral dependence of the SSA and asymmetry parameter retrievals

515 coming out of our and other ORACLES/LASIC/CLARIFY-2017/AEROCLO-Sa studies (Zuidema et al., 2016) such as Davies et al. (2019) and Wu et al. (2020) will provide robust constraints of the aerosol optical properties in a range of models. However, we also anticipate that our parameterized, observationally-based DARE could serve as a simple, built-in closure for the calculated DARE, adding a "top-down" model constraint, or even prove useful for model tuning.

Our paper is focused on instantaneous DARE and stops short of providing an "all-ORACLES" (diurnally-integrated) DARE
520 estimate. A promising approach in this regard is to use geostationary satellite retrievals of cloud and aerosol properties (Peers et al., 2020) in conjunction with in-situ aircraft data and radiative transfer calculations. Alternatively, one can use the satellite radiances to extrapolate from the spatially and temporally limited aircraft observations to obtain regional estimates of the diurnally-integrated DARE, circumventing the satellite retrievals. This approach, already underway within our group, builds on the *P* or PX parameterization, specifically by using albedo data from the geostationary Spinning Enhanced Visible and
525 Infrared Imager (SEVIRI) in combination with ORACLES AOD data from HSRL-2 and 4STAR (Chen et al., 2020 in preparation). A grid-box specific model-to-observation inter-comparison is also underway in the wider ORACLES team. While we limited this paper to the above-layer (TOA) DARE, the radiative effect of aerosols on the layer itself (i.e., the heating rate) is also an important deliverable from ORACLES, which will be presented in a separate follow-up paper.

Figure 1: Data conditioning flow chart. First, the data is filtered vertically (i.e. data is removed) to F1) isolate the aerosol layer only and F2) isolate either cloudy or clear sky data such that the profile represents a homogeneous sky type. Once filtered, the data must
740   **pass 3 distinct criteria to ensure that C1) the full aerosol layer is captured C2) the effect of aerosol absorption on radiative fluxes is much greater than that due to horizontal variability present and C3) the top-of-layer (TOL) and bottom of layer (BOL) albedos are mutually consistent.**
745 Figure 2: a) Above cloudy sky upwelling, downwelling, and net irradiance profiles shown versus the measured 532 nm AOD by 4STAR with associated measurement error bars for one example case. The AOD refers to the air above the aircraft and generally decreases with increasing aircraft altitude, hence the inverted y-axis. b) SSFR measured albedo spectrum at the bottom of the spiral (cloud top) and at the top of the spiral (above the aerosol layer. c) The ratio between the BOL and TOL albedo spectra (taken from Fig 2b) shown against the BOL AOD spectrum at the 4STAR wavelengths. The intercept of the fit line is criteria 3 (AR_∞); if the

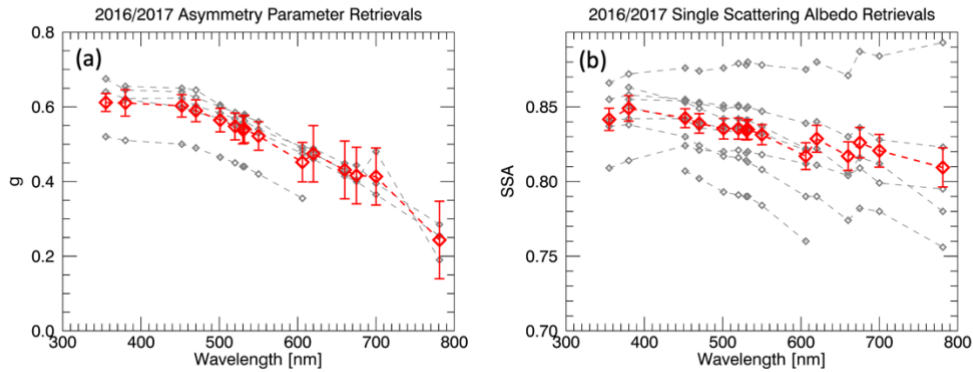
750 intercept deviates largely from 1.0, the case cannot be used for an aerosol retrieval. Select wavelengths are labelled to highlight the spectral importance of this method.


Figure 3: Retrieved a) asymmetry parameter and b) SSA spectra for 2016 and 2017 successful retrievals. The red spectrum indicates

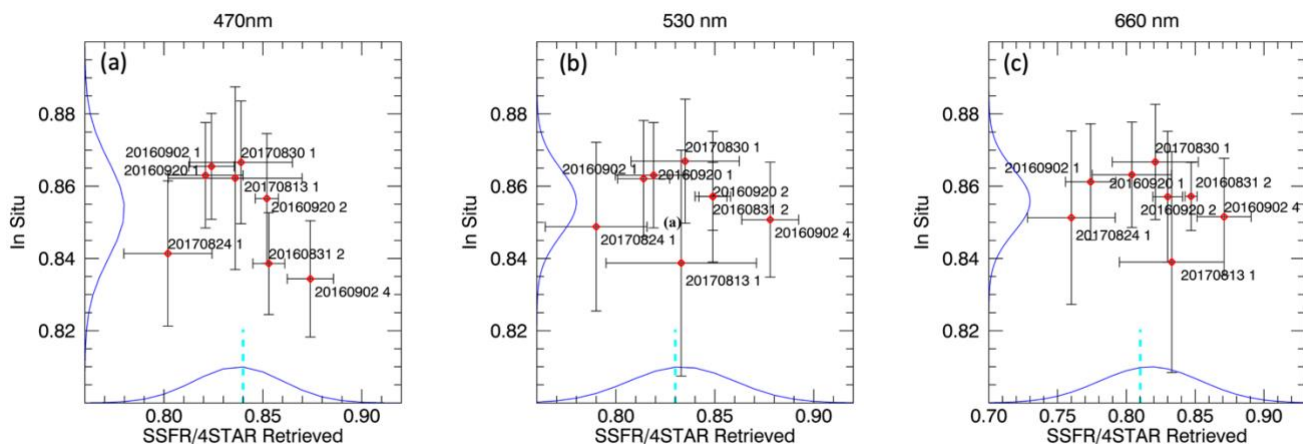
755 the mean retrieved values with associated error bars; the grey spectra are the individual retrievals.


Figure 4: *In situ* **vs. retrieved SSA values for a) 470 b) 530 and c) 660 nm.** *In situ* **values show transmittance-weighted SSA representative of the whole column, with error bars representing the standard deviation of all measured values throughout the spiral profile.** *In situ* **data is not available for the 20170812 case and is therefore not shown. The uncertainties for retrieved SSA for all wavelengths are provided in Appendix E. The blue dashed line indicates the values found by Davies et al. (2019).**
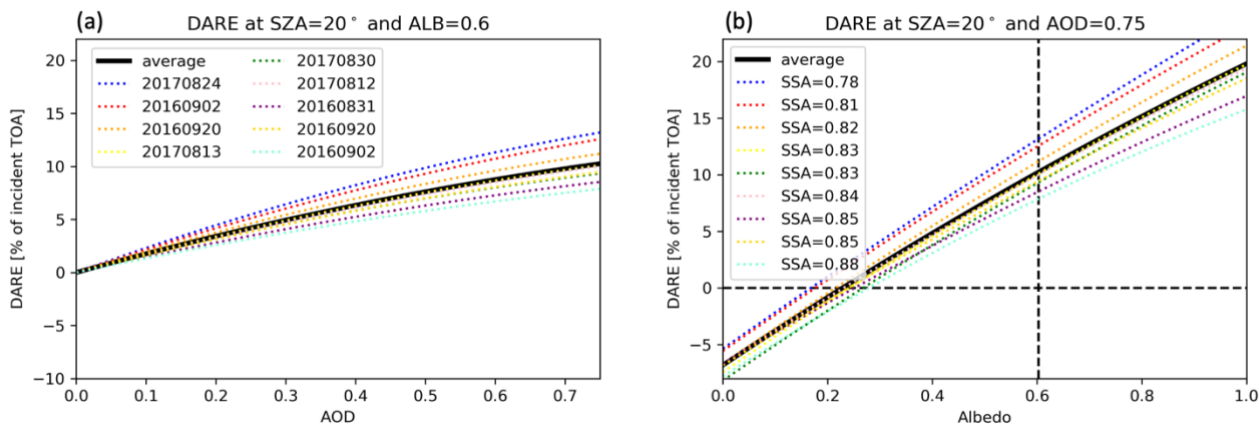

Figure 5: (a) DARE as a function of AOD for fixed underlying albedo (0.6) and SZA (20°), shown for the individual 9 cases from this study (colors) and the average (black). The average is the basic parameterization result, P_{DARE}. (b) DARE as a function of underlying albedo for a fixed AOD (0.75). The individual cases are labelled by their SSA at 550 nm (from more to less absorbing). The albedo at which the DARE changes is the critical albedo (horizontal dashed line). The vertical line marks an albedo of 0.6 for much of the ensuing discussion, which uses an AOD of 0.75, an albedo of 0.6, and a SZA of 20°. It should be noted that a 20° SZA is not representative of the mean in the region.
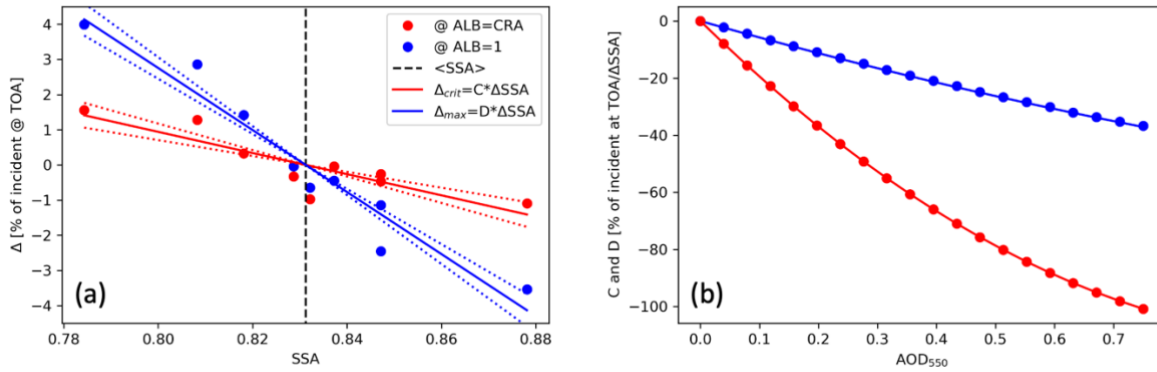
770 **Figure 6: The difference between P$_{DARE}$ and DARE for the individual cases at a fixed AOD (0.75) and SZA (20°). The range of variability is represented by the standard deviation (black dashed curves).**
Figure 7. Critical albedo as a function of mid-visible SSA. The red dashed cross shows the case-average α_{crit}.


775 **Figure 8: (a) DARE perturbations as a function of SSA at the case-average critical albedo (red) and at albedo=1 (blue) for SZA=20°. The vertical black dashed line indicates the case-average SSA. The dotted lines show the uncertainty in the C and D coefficients, which is propagated into the delta correction terms (Eq. 22 and Eq. 23). (b) the dependence of the parameters C (red curve; determined at the critical albedo (Eq. 19) and D (blue curve; determined at albedo=1 (Eq. 20) coefficients on mid-visible AOD.**
780

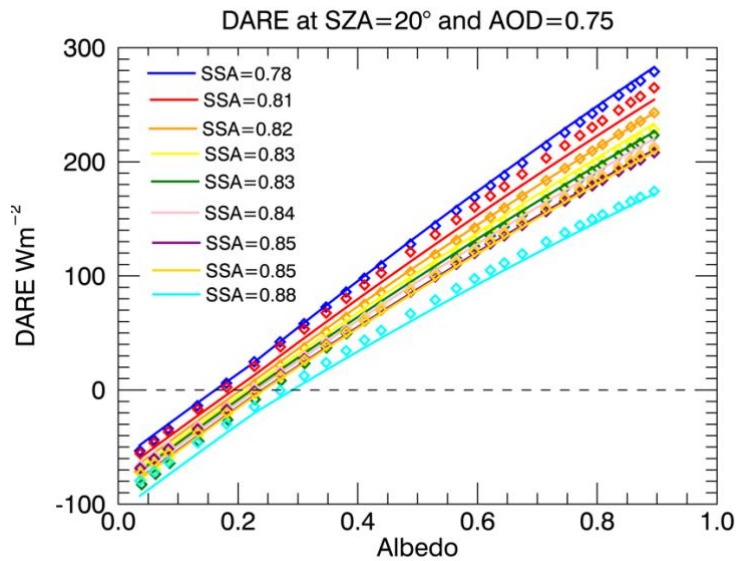
Figure 9: The difference between PX$_{DARE}$ and P$_{DARE}$ for 9 case SSAs at fixed AOD (0.75) and SZA (20°).


Figure 10: DARE as predicted by PX$_{DARE}$ for the nine cases (solid lines) and DARE as calculated by the RTM (dotted colored lines).
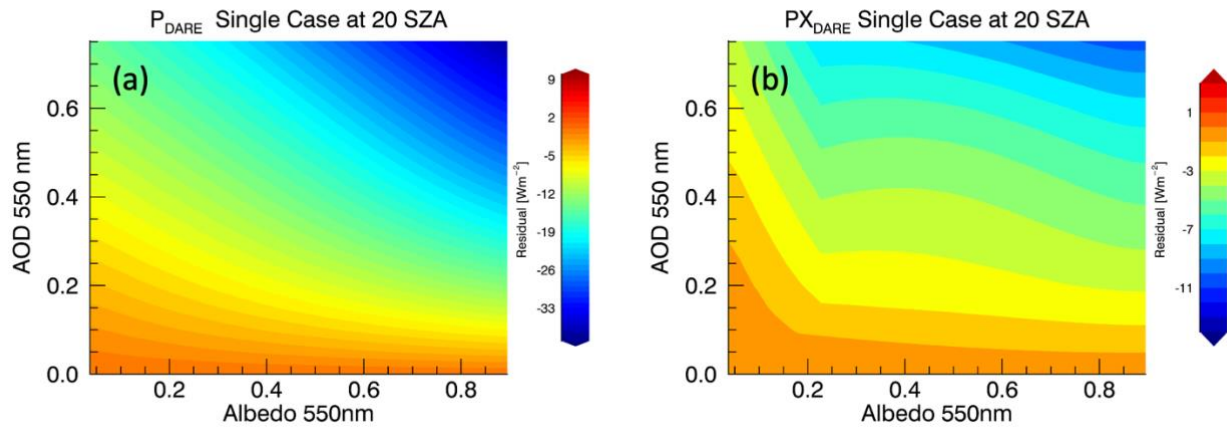

785 **Figure 11: Residual plot of directly calculated DARE (RTM output) and predicted BB DARE values using (a)P$_{DARE}$and (b)PX$_{DARE}$for a single case at a fixed SZA (20°). Residual plots for each case can be found in Appendix D. For both figures, the residuals encompass the difference between the RTM and the P$_{DARE}$ and PX$_{DARE}$ parameterizations.**

Table 1: Retrieval Quality Metrics. Spirals are listed by date and the number in which they were performed on a particular flight. Spiral cases that did not have data spanning the entire aerosol layer are excluded from the chart (i.e. did not pass criteria #1.) The second column lists the longest wavelength for which i_λ remains below 0.3; the aerosol retrieval is only valid up to this wavelength. If i_λ at all wavelengths is greater than 0.3, the case fails completely. The third column lists the AR_∞ value. The intercept must fall between 0.9 and 1.1 to pass this metric. The right-most column provides the status for the retrieval of SSA_λ and g_λ. Cases that are analysed using the mean fit rather than the updated linear fit (update 2 from C19) are indicated by *. Cases that pass a metric but have a bad spectral shape in the albedo ratio (indicating failure) are indicated by **.

Table 3. Mean retrieved SSA (row 3) and _g_ (row 5) spectra along with their associated standard deviations (σ) (row 4, row 6, respectively). The second row provides the number of valid retrievals for that wavelength. As described in C19, individual wavelengths can fail within the retrieval resulting in fewer valid retrievals than valid cases (e.g. 355 nm SSA has 5 valid retrievals despite having 9 valid cases).

830 **Table 4b. PX$_{DARE}$ additional coefficients for differing SZAs and their associated standard deviation, derived from the covariance matrix of the polynomial fits of figures 8a and 8b. These coefficients are used in Equations 22 and 23 (inserted into Equation 24) and act as extension to P in order to resolve the case-to-case variability resolvable through SSA. The units on the *C1* and *D1* coefficients are W/m^2/unit optical depth; the units on the *C2* and *D2* coefficients are W/m^2/(unit optical depth)^2. The uncertainty columns represent the relative uncertainty of the delta correction terms. These uncertainties are applicable to Equations 22 and 23, and can**
835 **be further propagated into Equation 24.**

Appendix A. Extension from spectral to broadband

Making the transition from the spectral to broadband is one of the main hurdles for both the parameterizations presented in this paper and for broadband DARE studies in general. Broadband DARE calculations require accurate aerosol and cloud information for all wavelengths, and it can be difficult to accurately determine the correct spectral dependence of these
840 properties. The cloud albedo is particularly challenging since the spectral dependence depends on the SZA.

In our work, the aerosol optical properties of SSA and *g* can be retrieved for wavelengths up to 781 nm, and AOD values from 4STAR can be retrieved for up to 1650 nm. Cloud albedo is measured for the entire SSFR wavelength range, but only for a single SZA value (the mean SZA throughout the spiral time period). We therefore must a) interpolate between wavelengths and b) extend each optical property to longer wavelengths to the best of our knowledge and compute the cloud albedo for a
845 range of SZAs.

A.1 SSA

To extend the retrieved SSA values to the remaining reported 4STAR wavelengths, we rely on the AAOD, defined as:

$$AAOD_\lambda = AOD_\lambda * (1 - SSA_\lambda). \tag{1A}$$

First, we calculate a fit line in log-log space of the AAOD for wavelengths where we have valid SSFR SSA retrievals. We
850   extend that fit to obtain the AAOD for the remaining 4STAR wavelengths. We then re-arrange Equation 1A to determine SSA
for those wavelengths where we do not have SSFR SSA retrievals. Finally, we set the SSA at wavelengths longer than 1650
nm to the mean of the longest 4STAR wavelengths, 1600 and 1650 nm. A1a illustrates the extension of SSA.

A.2 Asymmetry Parameter

Using the SSFR retrieved g values, we calculate a polynomial fit for the available wavelengths. We then extend the fit to longer
855   wavelengths. Once the fit reaches 0, the remaining wavelengths are set to 0. While it would have been possible to instead use
the fine mode Mie calculations (Figure B1), we chose to utilize the retrievals and approximate the fine mode, jumping to zero
lacking other information. An optical closure study, though beyond the scope of this paper, is necessary. Figure A1b illustrates
the extension of g.

A.3 Developing the Parameterization Grid

860   In order to calculate the parameterization, we grid the AOD and albedo spectra, preserving the specific spectral shapes.

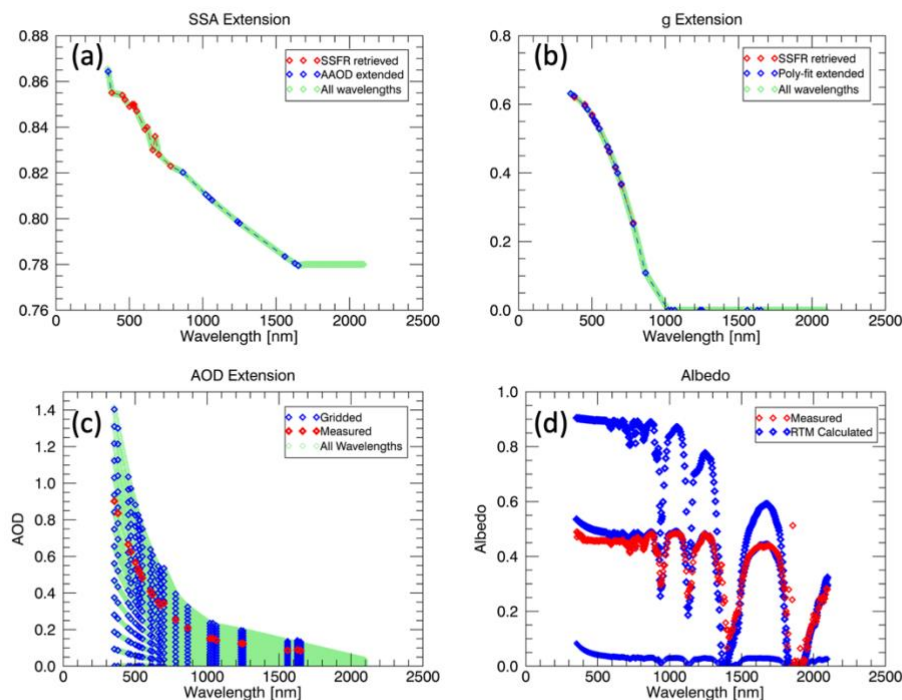
A.3.1 AOD

We take the measured AOD spectrum at the BOL and multiply that spectrum by a factor to create a grid such that the values
at 550 nm range from 0 to 0.75. In this way, each case has a normalized AOD grid at 550 nm while maintaining the specific
spectral shape of the measured spectrum. We then extrapolate the AOD spectra to the remaining wavelengths. Figure A1c
865   illustrates the extension and gridding of AOD.

A.3.2 Albedo

Obtaining the cloud albedo requires using the RTM to maintain accurate representation of the spectral shape. First, we retrieve
the cloud properties of effective radius (Reff), and cloud optical thickness (COT) from the measured albedo using the RTM,
with retrieval wavelengths of 1200 nm and 1630 nm. We then grid COT from 0 to 100 while keeping Reff constant at the
870   retrieved value. We run the RTM to calculate a spectral albedo grid for all new pairs of Reff and COT for the range of SZAs.
In these calculations, the surface for the cloud retrievals is standard Lambertian with an albedo value of 0.03. The COT range
begins at 0, and this translates to a 0 "surface" albedo for the parameterization. It is acknowledged that clouds do not exhibit
a Lambertian albedo. However, for irradiance calculations, the cloud albedo (non-Lambertian) can be substituted with a
Lambertian albedo. Also, it is acknowledged that a sea surface is even less of a Lambertian reflector than a cloud. However,

875 this is precisely the simplification that we made to fit both cloudy and cloud-free skies into a common framework. Since we are interested in DARE (the difference of fluxes) rather than the fluxes themselves, these simplifications should lead to only negligible effects relative to the contributing measurement uncertainties. Figure A1d illustrates the albedo grid for a single SZA.

While we extend the aerosol and cloud properties as accurately as possible, it is most crucial that the shortest wavelengths are
880 accurate. At the longer wavelengths, the AOD becomes increasingly small, and the optical property accuracy is therefore less critical. This works in our favor since the SSFR retrieval is valid for this wavelength range where the AOD and absorption are large.


885 **Figure A1. One example case of the extension of aerosol properties to longer wavelengths for a) SSA b) *g* and c) AOD. d) Shows the SSFR measured vs. RT-calculated albedo spectra along with the RT-calculated spectra for 0 COT and 100 COT.**

Appendix B. Irradiance Retrieval

The SSFR spectral irradiance aerosol retrieval is fundamentally different than most other aerosol retrievals, which are rooted
in knowledge of the aerosol size distribution along with both the imaginary and real parts of the index of refraction. These
methods must utilize Mie calculations to get to the aerosol optical properties of SSA and g. As described in Pistone et al.,
(2019), ORACLES instrumentation such as 4STAR, the Research Scanning Polarimeter (RSP), and the Airborne Multi-angle
SpectroPolarimeter Imager (AirMSPI) utilize this technique to obtain aerosol properties. The SSFR retrieval, on the other
hand, circumvents the need for Mie calculations and knowledge of the size distribution or index of refraction by relying on the
measured aerosol absorption itself.

However, simple Mie calculations (Figure B1) verify that a quickly decreasing asymmetry parameter is possible, and it will
even decrease to 0 if no coarse mode is present. However, that is unlikely. It is more likely that the asymmetry parameter
eventually goes back up again for long wavelengths - a result of even small coarse mode concentrations.

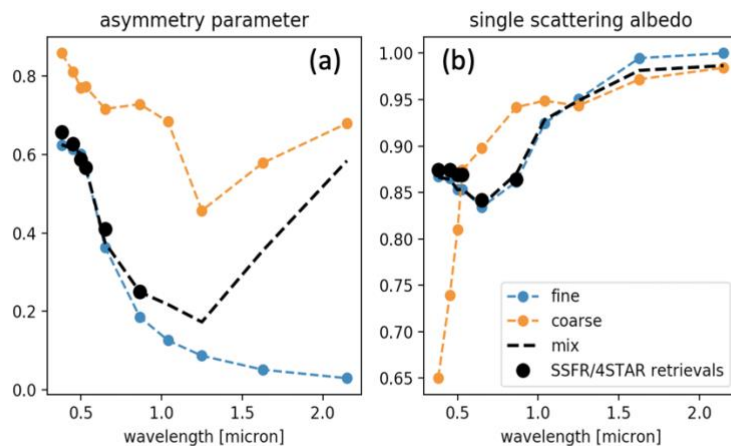
Beyond the ORACLES-specific instrumentation, AERONET stations across the globe utilize sunphotometers with the same
underlying retrieval algorithms as used with 4STAR sky radiances to provide aerosol optical properties. In figure B2a and
B2b, we show the mean SSFR SSA and g retrieval spectra compared to the nearest AERONET sites for 2016 and 2017: São
Tomé, Ascension and Namibia.


**Figure B1. Mie calculations of (a) g and b) SSA compared to SSFR/4STAR retrieved values. The black dots show the asymmetry
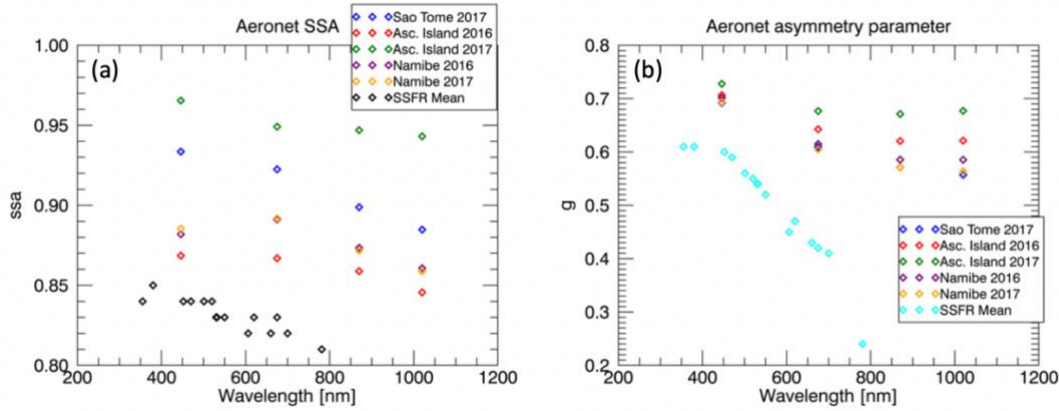
parameter spectrum (left) and SSA spectrum (right) as retrieved from SSFR/4STAR; the blue dot-dash line shows a fine-mode
aerosol (r=0.13 micron) with real index of refraction of 1.6, and imaginary index of refraction ranging from 0.05 (380nm) to 0
(2micron); the orange dot-dash line shows a coarse-mode aerosol (r=1.3 micron) with real index of refraction of 1.6, and imaginary
index of refraction ranging from 0.015 (380nm) to 0.003 (600nm) (Wagner et al., 2012); The black line shows a mix of coarse/fine
aerosol (0.02:2 optical thickness ratio).**


910

Figure B2. Retrieved values of a) SSA and b) *g* compared AERONET measured values at nearby land sites.

Appendix C. *In Situ* Transmittance Weighting

In situ SSA measurements and SSFR SSA retrievals cannot be compared directly since *in situ* SSA measurements are made continuously throughout the column (spiral), across variations in aerosol concentrations, whereas the SSFR SSA values

915 represent a single value representative of the entire column. In order to best compare the *in situ* and retrieved SSA values, we calculate a weighted *in situ* SSA average, using a weighting function based on the transmittance through the aerosol layer.

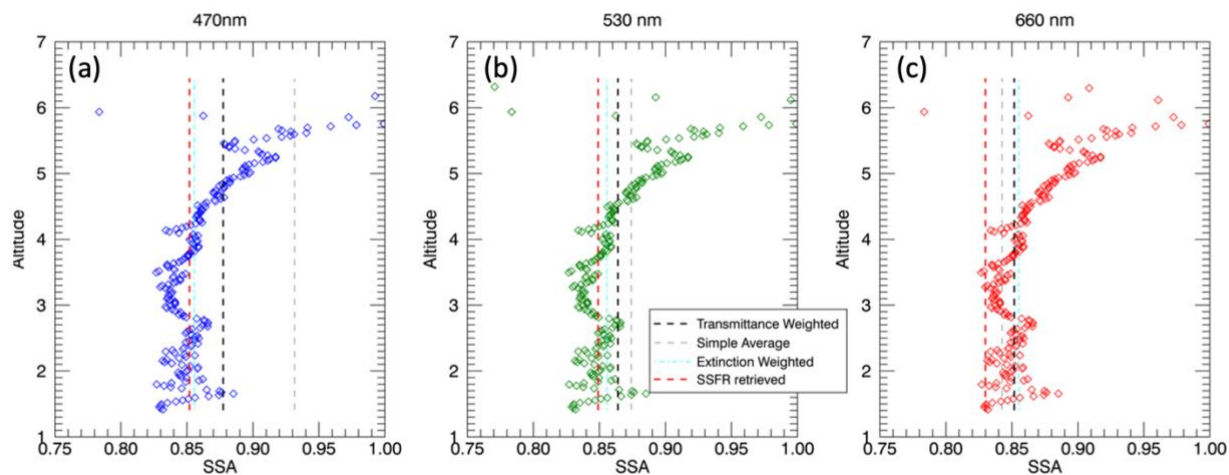
In past studies, (e.g. C19; Pistone et al., 2019) the *in situ* SSA measurements were averaged with each SSA value weighted by its corresponding measured extinction which better represents the column SSA than a simple average. However, it is the transmittance rather than the extinction which describes the aerosols' impact on the radiation throughout the layer. Since the

920 SSFR SSA retrieval is based on the change in radiation through the aerosol layer, it is most consistent to weigh the *in situ* measurements on transmittance rather than extinction.

For each spiral profile, we take the extinction profile as measured by the *in situ* instruments to calculate the weighting function as follows:

$$W(z) = \frac{\beta_e(z)}{\mu} e^{-\frac{\tau(z)}{\mu}} = \frac{\beta_e(z)}{\mu} t(z).$$

925 where $\beta_e(z)$ is the extinction, $t(z)$ is the transmittance, and $\mu = \frac{1}{cos(SZA)}$.

Figure C1 shows the *in situ* measured SSA profile for one profile case at a) 470 nm b) 530 nm and c) 660 nm. The red dashed line shows the SSFR/4STAR retrieved value; the black dashed line shows the transmittance-weighted *in situ* SSA value; the gray dashed line shows the extinction weighted *in situ* SSA value.


930   **Figure C1. An example of one spiral case with the different *in situ* averages along with the SSFR retrieved SSA for a) 450 nm b) 530 nm and c) 660 nm. The colored points show the *in situ* data as measured throughout the profile.**

Appendix D: Residual Figures.

Figures D1 and D2 show the residual values between directly calculated DARE (by the RTM) and DARE calculated using

D1) P_{DARE} and D2) PX_{DARE} for each case. The residuals are significantly higher when using P_{DARE} vs. PX_{DARE}, illustrating that

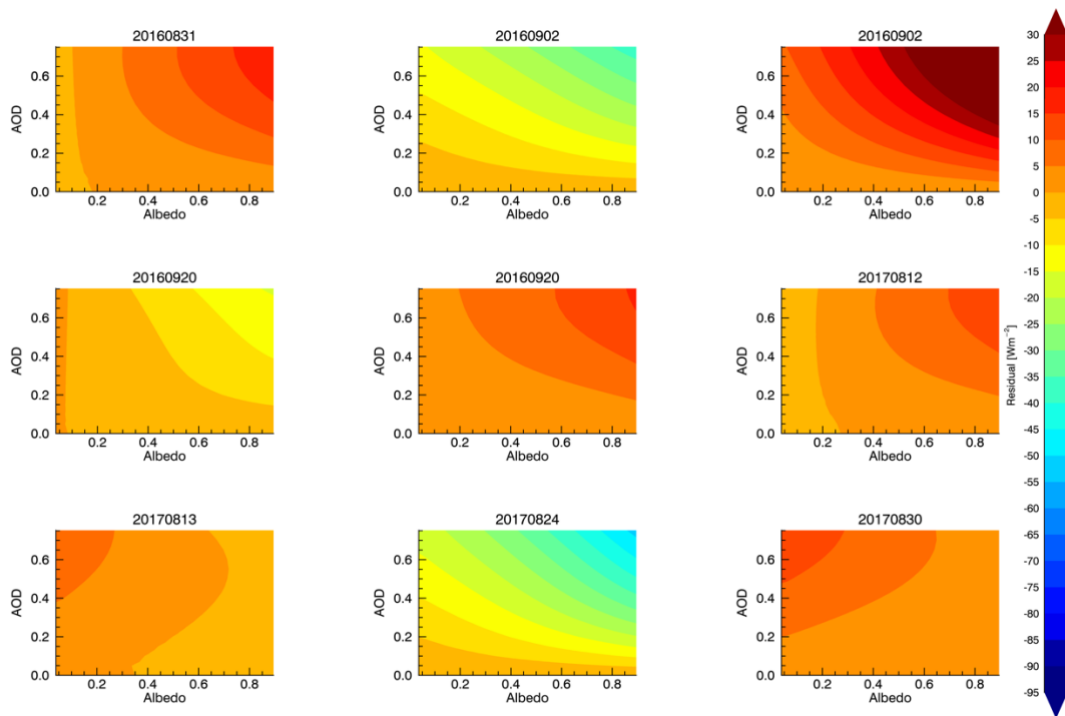
935   including the additional constraint of SSA (i.e. PX_{DARE}) greatly improves the parameterization performance.


Figure D1. Residual plot of directly calculated DARE (RTM output) and predicted BB DARE values using P_{DARE} at a fixed SZA (20°).
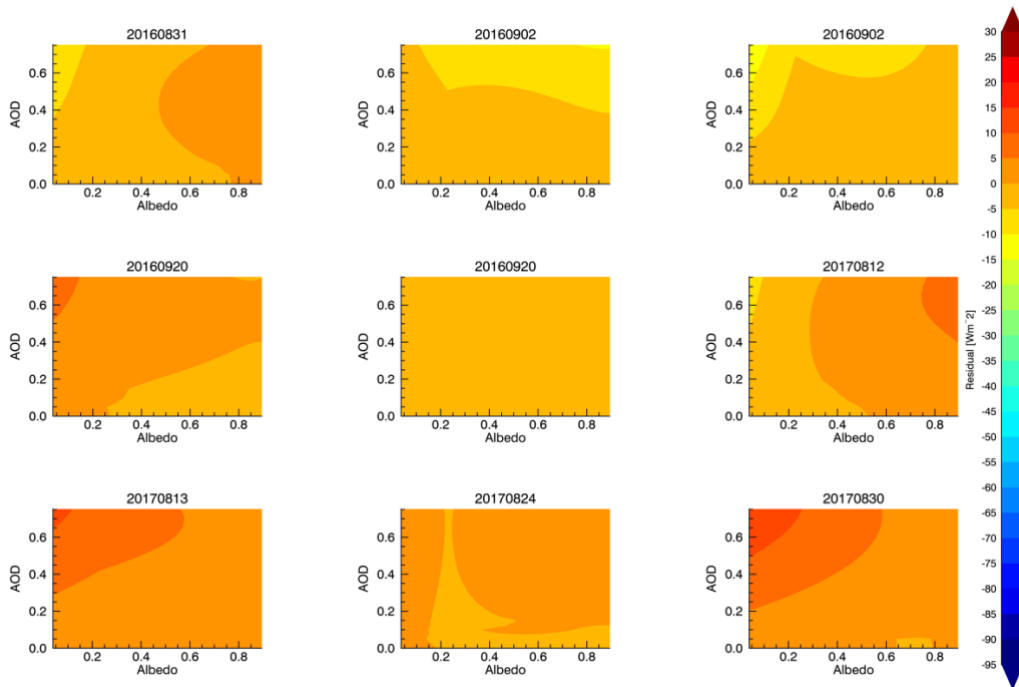


940

Figure D2. Residual plots of directly calculated DARE (RTM output) and predicted broadband DARE values using PX$_{DARE}$ at a fixed SZA (20°).

Appendix E.

945   Retrievals of SSA and *g* for each individual case with the associated retrieval uncertainty shown as error bars. Figure E1 shows

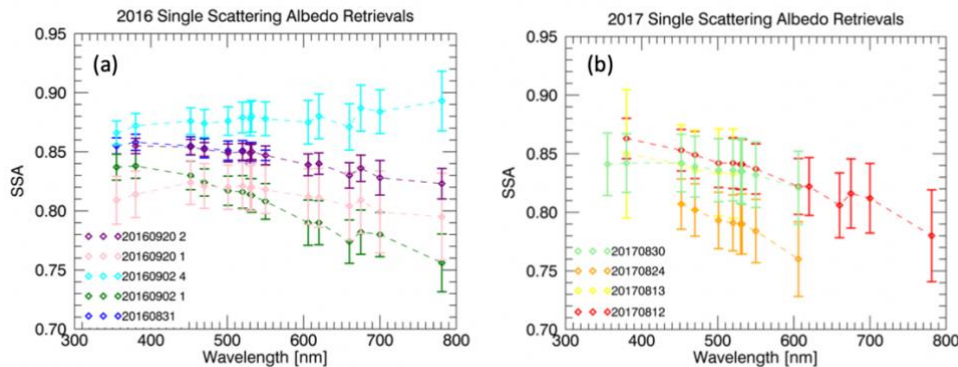
the SSA retrievals for a) 2016 and b) 2017; E2 shows both the 2016 and 2017 *g* retrievals in one figure.


Figure E1. SSA retrievals from a) 2016 and b) 2017 with associated retrieval uncertainty.

Author contributions:

SC collected SSFR data, performed the bulk of the analysis and wrote the majority paper with input from the other authors. KS collected SSFR data, helped with the methodology development and data analysis, and helped with developing, writing, and editing the paper. HC, PP, and SK helped with the data collection of SSFR. JR was one of the PI's for the ORACLES campaign and provided 4STAR data. SL was the PI of the 4STAR instrument and helped with the retrieval methodology. KP, MK, MR, YS, and CF provided 4STAR data. SH, SF, and AD provided in situ data. PZ and SD were on the leadership team for the ORACLES project and helped advise data use. All co-authors helped in the reviewing and editing of the paper.

Special issue statement: This article is part of the special issue "New observations and related modelling studies of the aerosol–cloud–climate system in the Southeast Atlantic and southern Africa regions (ACP/AMT inter-journal SI)". It is not associated with a conference.

Acknowledgments: This work was supported by the NASA grant NNX15AF62G. We thank the ORACLES deployment support teams and the science team for a successful and productive mission. We thank Warren Gore of NASA AMES for his support during the ORACLES mission. Thank you to each of the instrument teams who provided data and expertise on using them.

Competing Interests: The authors declare that they have no conflict of interest.
