12 **Abstract.**

13 Correct, timely and meaningful interpretation of polarimetric weather radar observations requires an accurate understanding
14 of hydrometeors and their associated microphysical processes along with well-developed techniques that automatize their
15 recognition in both the spatial and temporal dimensions of the data. This study presents a novel technique for identifying
16 different types of hydrometeors from Quasi-Vertical Profiles (QVP). In this new technique, the hydrometeor types are
17 identified as clusters belonging to a hierarchical structure. The number of different hydrometeor types in the data is not
18 predefined and the method obtains the optimal number of clusters through a recursive process. The optimal clustering is then
19 used to label the original data. Initial results using observations from the NCAS X-band dual-polarization Doppler weather
20 radar (NXPol) show that the technique provides stable and consistent results. Comparison with available airborne in situ
21 measurements also indicates the value of this novel method for providing a physical delineation of radar observations.
22 Although this demonstration uses NXPol data, the technique is generally applicable to similar multivariate data from other
23 radar observations.

1 **1 Introduction**

2 The task of radar-based hydrometeor classification (HC) can be broadly defined as the recognition of different hydrometeor
3 types in the atmosphere as represented by the various observed moments collected by weather radar. In general, HC is able to
4 label radar signatures observed at any one time with physical properties and, over a period of time, the evolution of these labels
5 can provide insight into the underlying atmospheric processes. As such HC has many impactful applications: HC simplifies
6 the detection of the melting layer (Baldini and Gorgucci, 2006), HC is necessary for obtaining accurate estimates of
7 precipitation quantities (Giangrande and Ryzhkov, 2008) and HC provides critical information for improving modelling of
8 physical processes in the atmosphere (Vivekanandan et al., 1999).

9 Radar-based HC requires an extensive and accurate (i.e. expert) knowledge of the physical properties of both multivariate
10 polarimetric observations and the hydrometeor particles themselves (Hall et al., 1984). Achieving an accurate and precise
11 radar-based HC is difficult due to the deficiencies (such as low spatial-temporal resolution) and inaccuracies (such as
12 attenuation) that are inevitable in all radar measurements. The process of HC is made even more difficult when this analysis
13 needs to be performed during the operational processing of the radar observations where there is a lack of time for expert
14 assessment. Therefore, automatization of spatial and temporal analysis of multivariate polarimetric data is an important task
15 for which an advanced and well-tested technique should be developed and utilized.

16 The development of radar-based HC started in the 1980s and 1990s with the works of Hall et al. (1984), Hendry and Antar
17 (1984), Aydin et al. (1986), Straka and Zrnić (1993) and Straka (1996). Further refinement and development of automatic HC
18 algorithms included the application of fuzzy-logic (Straka et al., 2000; Liu and Chandrasekar, 2000), machine-learning
19 techniques (such as the identification of clusters representing data-wise similarities) (Wen et al., 2015; Grazioli et al., 2015;
20 Besic et al., 2016; and Ribaud et al., 2019) and neural networks (Wang et al., 2017).

21 Modern radar-based HC methods (Straka et al, 1996; Liu and Chandrasekar, 2000; Al-Sakka et al., 2013; Grazioli et al., 2015;
22 Besic et al., 2016; Besic et al., 2018; Bechini and Chandrasekar, 2015; and Wang et al., 2017) are based on the multivariate
23 data of polarimetric Doppler radar observations. This includes (but is not limited to): the horizontal reflectivity factor Z_H ,
24 differential reflectivity Z_{DR} , the copolar correlation coefficient ρ_{HV} , differential phase shift on propagation Φ_{DP} , and specific
25 differential phase K_{DP} (for definitions see Bringi and Chandrasekar, 2001) as well as associated derived variables (e.g. standard
26 deviation). Additionally, temperature and other meteorological data, retrieved from radiosondes or NWP models, are often
27 utilized (Grazioli et al., 2015; Wen et al., 2015).

28 In most existing radar-based HC methods, the multivariate input data are analysed per measurement voxel and determined
29 classes are assigned to the hydrometeor types only according to their characteristics. Such an approach neglects intra-class
30 relationships and the temporal evolution of the identified classes. This valuable information can also be used in the labelling
31 of the hydrometeor types and the identification of corresponding microphysical processes. Additionally, almost all methods
32 within the existing literature are based on theoretical assumptions on the scattering properties of observed particles and/or are
33 only applicable for a defined (i.e. previously recognized) number and type of classes. Both of these aspects of existing HC

1 methods are limitations. For example, theoretical assumptions about the scattering properties of ice-phase hydrometeors are
2 very uncertain due to unknown size distributions, varying dielectric properties, fall orientation, and their diverse and often
3 complex geometry (Johnson et al., 2012). A pre-defined number of classes or hydrometeor types is subjective and creates
4 artificial boundaries for algorithms and, thus, subtle differences in undefined sub-classes are masked, which inhibits
5 identification of the underlying microphysical processes.

6 Thus, in this study we take a different approach and ask the following question: can a data-driven HC approach provide an
7 optimal number of classes from the observations? We define the optimal number as the lowest number of classes representing
8 all pronounced dissimilarities in the input data. Once the optimal set of classes is identified, the burden of analysis in this
9 approach is to relate the identified clusters of radar signatures to possible physical properties of hydrometeors. Thus, this
10 approach does not impose a predefined physical view on the observations but provides a framework for a more efficient
11 physical interpretation of the properties of the resulting clusters of observed multivariate data in which subtle differences and
12 intra-cluster relations are easier to identify. In this sense, this approach inverts the procedure of existing methods. Additionally,
13 we ask whether such an approach can be used to provide information on the temporal evolution of the identified hydrometeors
14 and reveal relationships between the identified classes. Such information is key for identifying the processes that lead to high
15 impact weather (i.e. flooding) and improving the physical parametrizations in NWP.

16 The point of this study is not to create a set of cluster characteristics that could be applied to other datasets. Rather the goal is
17 to demonstrate the viability of this type of data-driven methodology for creating a set of labelled clusters (i.e. hydrometeor
18 classes) based on QVP data. As such, the comparison to in situ data and labelling done as part of this study is only shown as
19 an example of how this tool can be used.

20 The existing data-driven unsupervised (Grazioli et al., 2015; Ribaud et al., 2019 and Tiira and Moisseev, 2019) and semi-
21 supervised approaches (Bechini and Chandrasekar (2015), Besic et al., 2016; Wang et al., 2017; Roberto et al., 2017 and Besic
22 et al., 2018) only partially provide an answer to the first question (Grazioli et al., 2015) and do not consider the temporal
23 evolution or dependencies between the identified classes. The approach described here performs an unsupervised clustering of
24 quasi-vertical profiles (QVP). QVP were first used in Kumjian et al. (2013) and Ryzhkov et al. (2016) as a way of constructing
25 a substitute for a vertical profile from a scan conducted at constant elevation, which is a typical mode of scanning for radars
26 used in operational networks. Calculation of the QVP requires horizontal homogeneity of the observed atmospheric processes.
27 The height-vs-time format of QVP represents the general structure of the storm or its evolution. Note that this is a novel
28 application of the QVP data product and the interpretation of QVP polarimetric variables differs from that of PPI or RHI scans
29 due to the averaging used to construct them.

30 The QVP input is used in this work to build a hierarchical structure based on the identified clusters and deliver an optimal
31 number of clusters based solely on internal properties of the multivariate polarimetric data. The optimal clustering is then used
32 to label the hydrometeor classes and to analyse the temporal evolution of the labelled microphysical processes.

33 The paper is organised as follows: in Section 2 we introduce the clustering methods we employ, Section 3 contains a description
34 of the polarimetric radar data and their processing, Section 4 describes the iterative clustering approach, leading to the

1 development of the hierarchical structure, Section 5 is devoted to the characterization of the clusters and their labelling, and
2 Section 6 concludes with a summary, discussion, and thoughts on further perspectives.

3 **2 Background of employed methods**

4 The proposed hierarchical clustering algorithm identifies the optimal number of groups of data points (clusters) in a recursive
5 loop and organizes the clusters in a hierarchical structure (undirected weighted graph). The two main steps of this approach
6 are the cluster identification and the optimality check. The cluster identification is achieved after performing dimensionality
7 reduction by principal component analysis followed by spectral clustering. The optimality check uses validity indexes to
8 identify the final set of clusters, which best classifies the provided set of data. The description of the dimensionality reduction
9 and clustering methods with background information about the validity indexes employed can be found in this section directly
10 after a short introduction to the hierarchical clustering.

11 **2.1 Hierarchical clustering**

12 Hierarchical clustering is a type of clustering technique that splits or combines the data through an iterative process. Unlike
13 “flat” clustering techniques, hierarchical clustering is not performed in one stage. Rather, it repeats the clustering process
14 iteratively and keeps the information about each iteration of clustering in a hierarchical structure. In general, for a given set of
15 multivariate data points, a hierarchical clustering algorithm, depending on top-down or bottom-up direction, either partitions
16 (divides) or merges (agglomerates) the data into groups (a set of clusters) where data points assigned to the same cluster show
17 similarity in multivariate values (depending on the context, it could be, for example, having a small distance to each other if
18 the points are in Euclidean space). The direction of the process (top-down or bottom-up) may be chosen and depends on the
19 number of individual points in the multivariate dataset and the needs of the underlying problem.

20 The top-down method begins with all available data points organized in one cluster and splits this cluster into subclusters until
21 a certain criterion is reached or only solely singleton clusters of individual points remain in the set. The bottom-up method, on
22 the other hand, begins with all points assigned to individual clusters and at each step, merges the most similar pairs of clusters
23 into one until all the subclusters are agglomerated into a single cluster.

24 The optimal number of clusters in both approaches can be identified using a termination criterion. The hierarchical structure
25 in the bottom-up approach needs to be completely finished before the optimal number of clusters can be identified otherwise
26 the upper part of the tree will remain unknown. The top-down approach allows for the iterative process to be stopped at any
27 point whilst preserving the upper part of the hierarchical structure. Another advantage of the top-down approach is the
28 possibility to have more than two subclusters belonging to one parenting cluster. This allows an optimal number of subclusters
29 for each parenting cluster, representing the data-driven inheritances in the resulting hierarchical structure. Although this
30 advantage is often not used, and the bottom-up methods are preferred (Grazioli, 2015 and Rimbaud et al., 2019), the method
31 presented here fully exploits it for the identification of an optimal number of subclusters in each iteration.

1 **2.2 Eigenvectors and Principal Components**

2 Principal component analysis (PCA) is a statistical technique mostly utilized in exploratory analysis of multivariate data. It
3 extracts the most important information from the multivariate dataset generating a simplified view of the original data by
4 dimensionality reduction.

5 To reduce a dataset's dimensionality a set of new orthogonal, non-correlated variables called principal components is
6 calculated as linear combinations of the original variables. The first component is selected having the largest possible variance,
7 so it best represents the diversity of the given data. The second component is generated under the assumption of orthogonality
8 to the first component whilst also having the largest possible variance. This process is continued until the number of principal
9 components is equal to the number of original variables (d). These components are exactly the eigenvectors of the correlation
10 matrix and are employed as a basis for a new coordinate system (Wold, 1976; Abdi and Williams, 2010). The first q calculated
11 coordinates having satisfactory representativeness (e.g. 85 %) can be used to preserve the most important characteristics of the
12 original data. These q principal components can replace the initial d variables ($q < d$), and the original data set, consisting of
13 N measurements on d variables, is reduced to a data set consisting of N measurements on q principal components.

14 **2.3 Clustering method**

15 One of the most popular clustering methods is the k-means algorithm (Steinhouse, 1956). Through its simple interpretability,
16 it is often used either as a single method or as a part of more computationally expensive clustering methods (e.g. Gaussian
17 mixtures or spectral clustering). As a single method, it has difficulties with non-convex clusters and is known to perform poorly
18 if the input variables are correlated (von Luxburg, 2007). As a basis of a more complex method (e.g. spectral clustering) it
19 allows a solution of non-linear cluster shapes to be found (any low-dimensional manifolds of high-dimensional spaces).

20 The input data herein are multi-dimensional and were found to have non-convex cluster shapes, therefore the spectral clustering
21 method was applied (Shi & Malik, 2000; Ng et al., 2002; von Luxburg, 2007). It works by approximating the problem of
22 partitioning the nodes in a weighted graph as an eigenvalue problem of eigenvectors described above and by applying the k-
23 means algorithm to this representation in order to obtain the clusters. This work implements the Ng et al. (2002) approach and
24 analyses the eigenvectors of the normalized graph Laplacian.

25 Spectral clustering has several appealing advantages. First, embedding the data in the eigenvector space of a weighted graph
26 optimizes a natural cost function by minimizing the pairwise distances between similar data points and such an optimal
27 embedding is analytically deducible. Secondly, as it was shown in von Luxburg (2007), the spectral clustering variants arise
28 as relaxations of graph balanced-cut problems. Finally, spectral clustering was shown to be more accurate than other clustering
29 algorithms such as k-means (von Luxburg, 2007).

1 2.4 Determining optimal number of clusters

2 Clustering algorithms can be roughly divided into two groups based on whether the number of clusters to be found is
 3 predetermined or undetermined. Spectral clustering is a rather flexible technique in the sense that it can be used with a
 4 relaxation (i.e. when the number of clusters to be found is provided) or without it (when the number of clusters is determined
 5 by the multiplicity of the eigenvalue 0). As the approach chosen here is not interested in a flat partitioning of the data, rather
 6 we want to determine hierarchical structures, the determination of the optimal number of clusters is important. To identify this
 7 optimal number of clusters two evaluation scores are used in our method: the Wemmert-Gançarski (WG) index (Hämäläinen
 8 et al., 2017) and Bayesian Information Criterion (BIC) index (Pelleg and Moore, 2000; Hancock, 2017). The WG index was
 9 chosen as best performing according to comparison studies (Niemelä et al., 2018 and Hämäläinen et al., 2017). The BIC is
 10 best for the calculation of the posterior probability of a clustering. While the exact use of the indexes is described in Sect. 4,
 11 the WG and BIC indexes can be defined as follows:

12 Let the data set $X = \{x_i \in \mathbb{R}^d: i = 1, \dots, N\}$ have clustering $C_K = \{c_k: k = 1, \dots, K\}$, ($K < N$), where n_k – number of
 13 samples/points in the cluster c_k and I_{c_k} – indexes of the points in X belonging to the cluster c_k .

14 1) For the WG index: Let $R(x_i)$ represent the mean of relative distances between the points belonging to the cluster c_k
 15 and the centre of its barycentric weight g_k . The $R(x_i)$ value is calculated for each point x_i

$$16 R(x_i) = \frac{\|x_i - g_k\|}{\min_{k \neq k'} \|x_i - g_{k'}\|},$$

17 after that the WG-index

$$18 W_{G_X} = \frac{1}{N} \sum_{k=1}^K \max \left\{ 0, n_k - \sum_{i \in I_{c_k}} R(x_i) \right\}, \quad (1)$$

19 is calculated representing the WG-index for the set X of points partitioned into K clusters (Desgraupes, 2017).
 20 The WG-index is a measure of compactness based on the distances between the points and the barycenters of all
 21 clusters.

22 2) For the BIC index:

23 Let us model each cluster c_k as a multivariate Gaussian distribution $N(\mu_k, \Sigma_k)$, where μ_k can be estimated as the
 24 sample mean vector and $\Sigma_k = \frac{1}{d(N-K)} \sum_{k=1}^K \sum_{i \in I_{c_k}} \|x_i - g_k\|^2$, can be estimated as the sample covariance matrix.

25 Hancock (2017) showed that the optimal clustering is presented by maximum

$$26 BIC(C_K) = \sum_{k=1}^K \left(n_k \log \frac{n_k}{N} - \frac{d n_k}{2} \log 2\pi \Sigma_k - \frac{n_k - 1}{2} d \right) - \frac{1}{2} K(d + 1) \log N. \quad (2)$$

27 The BIC is an estimate of a function of the posterior probability of a clustering being true, under a certain Bayesian
 28 setup, so that a higher BIC in (2) means that a clustering is considered to be more likely to be the optimal clustering.
 29

1 **3 Data and processing**

2 This section presents a description of the polarimetric radar data used by the hierarchical algorithm in this study, and some
3 details of the data pre-processing that is applied before the QVP calculation-processing. Note that the method presented here
4 is generally applicable with similar multivariate data from other sources. In addition, in situ observations from the FAAM
5 Airborne Laboratory (FAAM BAe-146) are presented in this section. These data will be used for assigning the labels of the
6 hydrometeor classes to the detected clusters or cluster groups in the radar observations.

7 **3.1 X-band radar observations**

8 The polarimetric data employed to demonstrate the method developed in this study were collected by the NXPol radar whilst
9 it was located at the Chilbolton Atmospheric Observatory (CAO), part of the UK’s National Centre for Atmospheric Science’s
10 Atmospheric Measurement and Observation Facility (AMOF), in southern England (Lat. 51.145° N, Long. 1.438° W) from
11 November 2016 to May 2018 (Fig. 1). The NXPol is a mobile Meteor 50DX (Leonardo Germany GmbH) X-band, dual-
12 polarization, Doppler weather radar with a 2.4 m diameter antenna. The radar is a magnetron-based system and operates at a
13 nominal frequency of 9.375 GHz ($\lambda \sim 3.2$ cm). The detailed characteristics of the NXPol radar can be found in Neely et al.
14 (2018). From the observations made in 2017–2018 we selected eight dates with the longest precipitation events occurring
15 within 30 km range of the radar presented on Fig. 1. The exact dates and the total number of volume scans per date can be
16 found in Table 1. Radar data selected for this study can be found in the list of mobile X-band radar observations on the CEDA
17 archive (Bennett, 2020).

18 **3.2 Polarimetric variables and temperature data**

19 Here we chose to use the polarimetric variables Z_H [dBZ], Z_{DR} [dB], ρ_{HV} [–], and K_{DP} [$^{\circ}$ km $^{-1}$] as well as temperature T [$^{\circ}$
20 C] to demonstrate the described clustering technique. The four polarimetric variables were selected as a subset of all the
21 possible variables as they provide complementary information about the observed hydrometeor properties. Here K_{DP} is
22 calculated as the linear gradient of differential phase shift, where the phase shift has been filtered to remove non-meteorological
23 targets ($\rho_{HV} > 0.85$) and progressively smoothed using decreasing length averaging windows and Z_H and Z_{DR} are corrected
24 for attenuation using the ZPHI method (Testud et al. 2000) where $\alpha=0.27$, $b=0.78$ and specific differential attenuation is 0.14
25 times the specific horizontal attenuation. Temperature was added to the set of input variables following the reasoning of similar
26 studies in which either height relative to 0° C–isotherm (Grazioli et al., 2015) or the index representing ice- or liquid-phase of
27 observed precipitation (Besic et al., 2016) was included. The full input vector used in this study can be represented as:

$$28 \quad x = [Z_H, Z_{DR}, \rho_{HV}, K_{DP}, T], \quad (3).$$

29

1 Note that this does not preclude the use of differing sets of variables in future studies. The input data used here were pre-
2 processed before being utilized in the clustering algorithm: all range bins that were located at distances less than 400 m from
3 the radar were removed from all input variables data to reduce the influence of side lobe noise.

4 The temperature data were taken from the Met Office Unified Model (UM) and interpolated onto the polar grid of the radar's
5 observations. The original data can be found on the CEDA archive (Met Office, 2016). Past assessments of the accuracy of
6 these temperature values suggest that the gridded temperatures are within 1° C of co-incident profiles measured by radiosondes
7 except in the case of strong inversions or frontal boundaries. An example of one day's observations (2017-05-17) represented
8 in the height-vs-time format of the QVP of four polarimetric variables with the temperature presented as isotherms is found in
9 Fig. 2. Similarly, other dates from our list of cases (Table 1) are in Fig. B1.

10 **3.3 QVP and thresholding**

11 QVP of the input variables are obtained as the azimuthal average of the data from a standard plan position indicator (PPI) scan
12 at 20° antenna elevation angle (Ryzhkov et al., 2016). The 20° PPI is the highest of ten PPIs of the volume scanning strategy
13 used by NXPoI which starts the scanning from 0.5° elevation angle. The use of 20° PPI minimizes the effects of radar beam
14 broadening and horizontal inhomogeneity. The beam broadening effect becomes dominant at higher altitudes when observed
15 by low elevation scan as was shown in Ryzhkov et al. (2016). The radar beam of 1° opening at 20° elevation is about 100 m
16 at 2-km height, 240 m at 5-km height, and reaches almost 480 m at 10-km height. The resulting profiles have 197 voxels in
17 each QVP at the altitudes between 0 and 10 km above mean sea level (AMSL) and covering about 30 km range from the radar.
18 It was also shown in Ryzhkov et al. (2016) that the decrease of Z_{DR} from the oblate spheroidal hydrometeors at 20° elevation
19 is within the common measurement error of Z_{DR} (0.1–0.2 dB).

20 An advantage of QVP is that they reduce statistical errors within the input dataset while the height-vs-time format of QVP
21 naturally represents the temporal dynamics of microphysical processes observed in the radar data. To ensure the observations
22 are representative of large-scale meteorological features that may be averaged together, the QVP voxels are used in the analysis
23 only if more than 270 of the 360 azimuthal bins at the range in the PPI scan contain valid data.

24 **3.4 In situ Observations**

25 For the labelling of the clusters, in situ observations can be used to assess any of the clusters within the hierarchical structure
26 produced by the clustering algorithm. This allows for flexibility in the granularity used to examine the observations. In this
27 study, the in situ FAAM BAe-146 observations are used to demonstrate the labelling and assessment of the final set of clusters.
28 The FAAM BAe-146 is a publicly funded research facility that, as part of the National Centre for Atmospheric Science
29 (NCAS), supports atmospheric research in the United Kingdom by providing a large instrumented atmospheric research aircraft
30 (ARA) and the associated services. The ARA is a modified British Aerospace 146-301 aircraft. Further details of the FAAM
31 BAe-146 aircraft instrument systems are available at <https://www.faam.ac.uk/the-aircraft/instrumentation/>. In situ data for this
32 study comes from FAAM BAe-146 flights C013, C076, C081, and C082 (FAAM, 2017; FAAM, 2018a; FAAM, 2018b;

1 FAAM, 2018c) and observational data are available on the CEDA archive. The dates of the flights with corresponding flight
2 numbers can be found in Table 1.

3 For the cases examined, FAAM BAe-146 was equipped with two Cloud Imaging Probes (CIP), which are manufactured by
4 Droplet Measurement Technologies and described in Baumgardner et al., 2001. The CIP's are mounted underneath the aircraft
5 wings and provide 2-bit grayscale images of cloud particles as they pass through the instrument sample volumes. Each CIP
6 houses a 64 elements photodiode detector, with one CIP having an effective pixel size of $15\mu\text{m}$ (referred to as CIP15), and the
7 other having an effective pixel size of $100\mu\text{m}$ (referred to as CIP100). Therefore, the CIPs provide images of particles in size
8 ranges of $7.5\ \mu\text{m}$ to $952.5\ \mu\text{m}$ for CIP15 and $50\ \mu\text{m}$ to $6350\ \mu\text{m}$ for CIP100. All probes have 'Korolev' anti-shatter tips – the
9 width of which is 70 mm for the CIP100 and 40 mm for the CIP15.

10 Particle size distributions are calculated based on CIP data where particle size is defined as being the maximum recorded length
11 in either the axis of the detector array (X) or along the direction of motion (Y). All particles with inter-arrival times $< 10^{-6}\ \text{s}$
12 are rejected as indicative of shattering as in Field et. al. (2006). The centre-in approach (Heymsfield and Parrish, 1978) for
13 estimation of particle concentrations from the sample volume is used to calculate the size of partially imaged particles. It
14 should be noted that despite using the centre-in method with the CIP data, which increases the effective sample volume for
15 larger particles at the expense of uncertainty in particle size, the ability to measure particles with size $> 6\ \text{mm}$ is negligible
16 with this configuration. An indication of the potential presence of such large particles can be obtained through a visual
17 inspection of the particle images, but no conclusions can be drawn. Also, there are significant uncertainties associated with the
18 derived properties from the CIPs, which are of the order 20% for number-based properties (Baumgardner et al., 2017). In our
19 analysis we are not concerned with absolute concentrations from the CIPs. Instead, we are using the CIP data in a qualitative
20 manner to provide a general framework for comparison with the HC results obtained from the radar observations.

21 As we base our clustering on the QVP of radar observations, which at each range from the radar are averaged over all available
22 azimuths, a direct comparison to aircraft observations taken at an exact position and timestamp would not make a representative
23 comparison. Thus, for the comparison, we have selected the 20-second intervals from the CIP15 and CIP100 data that
24 correspond to the spatial domain and times of the individual 20° PPI scans that are used to create the QVP. Over these 20 s
25 intervals the mean number concentrations per particle size bin are calculated (Fig.10). Fig. 9 presents examples of particle
26 imagery from the CIPs, which typically represents less than 1s of the total 20s of data and shows derived properties of the
27 particles over the entire 20s sampling period when the airplane observed the atmosphere over the QVP domain.

28 In order to provide insight into the nature of the particle imagery, we have separated the particle concentrations in Figure 10
29 into three categories, two of which are based on an analysis of the particle shapes, and another category for partially imaged
30 particles. "Round" particles are those which have a circularity between 0.9 and 1.2, and particles with a larger circularity are
31 labelled as "Irregular" - this gives a rough separation into particles which are likely to be liquid water vs ice (Crosier et al.,
32 2011). "Edge" particles are those which are only partially imaged, as indicated by pixels at the extreme edge of the array being
33 triggered. For the particles which are considered round, the particle size and subsequent concentration is corrected for out-of-
34 focus effects (Korolev, 2007). This out-of-focus correction is not applied to the "irregular" or "edge" images, as there is no

1 evidence to show this is an appropriate correction to make. No attempts have been made to classify particle images, for two
2 key reasons. (1) The larger particles, which have the greatest influence on the polarimetric properties, are poorly sampled by
3 the CIPs. (2) A recent study by O'Shea et al. (2020, in review at AMTD) suggests existing procedures to classify particle
4 images using the CIP can lead to inaccurate results due to the effects of diffraction when particles are imaged more than a few
5 mm off the focal plane, which is a the most common scenario. A thorough assessment of the accuracy of these image
6 classification algorithms, with respect to particle size and probe configuration, is much needed.

7 **4 Clustering of QVP**

8 Here the clustering steps are described in general. A corresponding overview of the approach is provided in Fig. 3. The
9 proposed approach uses QVP voxels and temperature data that has been interpolated to the same volume. This data forms the
10 points of a 5-dimensional space ($d = 5$). The PCA (Sect. 2.2) reduces the number of dimensions to q . The q -dimensional data
11 are partitioned into K clusters, where K iteratively increases ($K = 2, 3, \dots$) until the optimal number of clusters is reached,
12 according to the WG index Eq. (1) in Sect. 2.4. With each of the clusters achieved in this level (“Outer Loop” in Fig. 3), the
13 process is recursively repeated starting with the PCA calculation and continuing until the optimal partitioning of the sub-
14 clusters is reached (“Inner Loop” in Fig. 3). The total partitioning is confirmed with the BIC index Eq. (2) in Sect. 2.4. When
15 the BIC’s local maximum is reached the partitioning is considered to be optimal. A detailed description of each of these steps
16 can be found in the following subsections and the code can be made available on request.

17 **4.1 Start of hierarchical clustering**

18 The hierarchical clustering starts with data standardization and dimensionality reduction of the original 5-variable input data
19 X Eq. (3) into a q -dimensional dataset of principal components (Sect. 2.2). The non-parametric transformation based on the
20 quantile function maps the data to a uniform distribution. This standardization helps to deal with outliers and satisfy PCA data
21 assumptions.

22 To start the loop, all N pixels of the input data are used. In later loops, only subsets of the original 5-variable data (I_{c_k})
23 belonging to active cluster c_k are processed in the Inner Loop (Fig. 3). The first q principal components with the largest
24 variance, having in total at least 85 % representativity of the original dataset, are selected in this step.

25 The representativity threshold of 85 % was chosen arbitrarily as it reduces the initial 5-variable input space up to 3-dimensions
26 ($q \leq 3$) in most cases, which effectively simplifies the clustering problem and does not influence the overall outcome. The
27 threshold can be reduced to further reduce the dimensionality, but it was found that this negatively influences the clustering
28 accuracy. A higher threshold will retain the high dimensionality of the original dataset but will slow down the clustering
29 process without gaining further information from the dataset.

1 **4.2 Iterative process to find the optimal number of clusters (Inner Loop)**

2 At the start of the hierarchical clustering, we begin directly with the first call of the Inner Loop (Fig. 3). The iterative process
3 in the Inner Loop commences with all N QVP pixels represented by the first q principal components. The spectral clustering
4 processes these input data starting with the number of clusters $K = 2$. The number of clusters increases ($K = 2, 3, \dots$) with
5 each cycle of spectral clustering within the Inner Loop, and at the end of each iteration the WG index Eq. (1) is calculated for
6 the achieved clustering C_K . At the moment the local maximum is achieved in the WG index values, the clustering in which it
7 was reached (C'_K) is accepted as the main cluster set of the current level of the hierarchical tree and these clusters become the
8 set of active clusters (A). Set A will be used in the Outer Loop of the implemented hierarchical algorithm. The active clusters
9 detected in the first level of the hierarchical structure by spectral clustering for the data on 2017-05-17 are shown in Fig. 4.

10 **4.3 Optimal number of clusters for the total dataset (Outer Loop)**

11 In the Outer Loop of the hierarchical algorithm, the BIC index Eq. (2) is calculated for the active clusters produced by the
12 Inner Loop (Fig. 3). If the BIC index is calculated for the first time (i.e. the start of the algorithm run, $j = 1$) or the BIC index
13 values do not show any local maximum, the algorithm continues by calling the Inner Loop for each individual cluster from the
14 set of active clusters (A_j) formed by the calls of the Inner Loop described above.

15 For the first level of hierarchical clustering all C'_K are immediately accepted as active $A_1 = C'_K$. In the Outer Loop, after
16 calculating the BIC, the original 5-dimensional data belonging to each cluster $c'_k \in C'_K$ are sent to the Inner Loop and clustering
17 (C''_K) achieved by the Inner Loop is used to replace the cluster c'_k in the set of active clusters A_1 . If the BIC index calculated on
18 this ‘suggested set’ shows that the clusters introduced to the A_1 increase the value of BIC, the suggested replacement is accepted
19 and the set of active clusters is updated as $A_2 = C''_K \cap C'_K/c'_k$. The Outer Loop then continues with the next cluster from the
20 original set A_1 . When the BIC value does not increase with the ‘suggested set’ the set of active clusters does not change, and
21 the algorithm continues with the next cluster from the set A_1 .

22 **4.4 Next recursion or finalization of results**

23 The final set of active clusters is reached when the value of the BIC index does not increase with any further suggested split
24 in the current active set of clusters. At this level of detailization, the optimal clustering for the provided input data has been
25 reached. For the QVP dataset described in Sect. 3, a final set of 13 active clusters is reached (see Fig. 5 and Fig. 6). The
26 relations between these final clusters (f_cl1, ..., f_cl13) and the 3 parent clusters from the first Inner Loop run (Fig. 4, panel
27 (a)) are shown in Fig. 5.

1 5 Labelling

2 Once the optimal number of clusters is determined and the hierarchical clustering structure is built, the clusters can be
3 characterized by their centroids and labelled with appropriate hydrometeor classes using the available verification data. The
4 clusters for which direct verification data are not available may still be labelled with an appropriate hydrometeor class based
5 on the scattering characteristics described by the original polarimetric radar variables and considering their position in the
6 hierarchical tree and height-vs-time QVP representation. As QVP polarimetric characteristics differ from polarimetric
7 characteristics of hydrometeors observed by PPI and RHI scans, care must be taken when comparing these results to the
8 literature. Labelling the obtained clusters can be performed for the different levels of granularity depending on the user's needs
9 and interests. Note the purpose of the labelling shown here is to demonstrate the ability and validity of the technique rather
10 than performing a rigorous study of the underlying microphysics observed. The latter will be reserved for follow-up studies
11 utilizing this technique in a focused manner.

12 5.1 Level by level clusters check

13 From the visual verification of the first level parent clusters in Fig. 4 panel (a) and panel (b) we can deduce that there are two
14 child clusters representing the upper/elevated (ice dominated root.cl2) and the lower (water dominated root.cl1) parts. The
15 second level clusters from the second loop (panels (c) and (d)) show a well-identified “bright band”, belonging to the melting
16 layer (ML), (root.cl2.cl2) and a main solid-phase cluster (root.cl2.cl1), both belonging to the cluster representing the ice-phase
17 dominated part (root.cl2) of the QVP (panel (b)). The three child clusters of the parent root.cl1 cluster (panels (c) and (d)) are
18 the two rain-type clusters (root.cl1.cl2 and root.cl1.cl3) below the “bright band” and cluster root.cl1.cl1 with most points
19 located above the “bright band”. In further loops, the main ice-phase cluster (root.cl2.cl1) is split into nine child clusters (Fig.
20 5) and examples of their positioning in time-vs-height format of QVP can be observed in Fig. 6 or Fig. B1.

21 5.2 Characteristics of the clusters

22 The 13 final clusters can be characterized by their centroids (Fig. 7) or their relevant statistics (Fig. 8 and Table A1). The
23 centroid characteristics in Fig. 7 are plotted as spider plots where each of the five variables is represented by an azimuthal axis.
24 The filled pentagons in each subplot represent the cluster's centroid in the five-variable space based on all the data available
25 in this study. Each vertex of the pentagon shows the centroid's value in one of the five variables. The non-solid lines in the
26 subplots of Fig. 7 represent the centroids of the same cluster but based solely on the data from one of the eight cases (Table
27 1).

28 Figure 7 confirms a distinction made at the first and the second cycles of the Outer Loop (Fig. 4) between three types of
29 clusters: liquid-phase clusters (f_cl1, f_cl2 and f_cl3), having lower K_{DP} and warmer T values, ice-phase clusters (f_cl4, f_cl5,
30 f_cl6, f_cl7, f_cl8, f_cl9, f_cl10, f_cl11), and f_cl12 all with more pronounced ρ_{HV} values; and a very different looking f_cl13,
31 having warmer T and rather low ρ_{HV} values.

1 The largest differences between the centroids selected from the total dataset and the centroids corresponding to the eight
2 considered cases occur in the temperature (T) values, especially for the clusters f_cl2 , f_cl3 , f_cl7 , f_8 , f_cl10 and f_cl12 .
3 These variations can be explained by the origin of the temperature data, which are estimates from the NWP model and do not
4 always correctly represent the real situation.

5 The next variable with a rather large variation in several clusters is K_{DP} . In part this variation may be due to the fact that
6 this variable has an extremely skewed distribution. Clusters f_cl1 , f_cl7 , f_cl11 , f_cl12 and f_cl13 have the highest
7 variation in K_{DP} values between the centroids calculated on different cases (Fig. 7). As K_{DP} can be influenced by the amount
8 of ice/water particles in the atmosphere, it might be that the clusters have variations in the number of particles. This hypothesis
9 can only be verified with FAAM BAe-146 observations of the same cluster on different dates. Unfortunately, such verification
10 is not possible for all clusters and more in situ observations are required.

11 From the variations of centroid values in the five input variables in Fig. 7, we can also see that the main liquid-phase cluster
12 (f_cl2) has rather different characteristics in different cases. Case to case it shows large variations in Z_H , K_{DP} , ρ_{HV} , T and the
13 highest mean temperature value (6.8°C) among all other clusters. As observed in the histogram of percentages of the cluster
14 points in Fig. 8 panel (f), f_cl2 is rather big (13.7 % of the total number of points), but does not have the highest percentages
15 of points in all eight analyzed cases, only in the 2017-05-17 case (9.3 % compared to $\leq 1.5\%$ in other cases) (Fig. 7, histogram
16 per case). Combining all these aspects together we deduce that f_cl2 includes rain of varying intensities and different drop
17 sizes.

18 The other rain cluster f_cl3 has less variability in centroid values and has ~ 20 dBZ smaller Z_H values than f_cl2 probably due
19 to the smaller drop sizes in this cluster. f_cl3 has the smallest mean Z_H (7.18 dBZ) and mean K_{DP} values ($-0.097^\circ\text{km}^{-1}$) of
20 all “water” clusters (f_cl1 , f_cl2 and f_cl3). This cluster is often observed at the beginning and at the end of the storm in height-
21 vs-time format representation of the optimal clusters (Fig. B1) and is labelled as “light rain”.

22 Almost all centroids in Fig. 7 have no or very limited variation in ρ_{HV} or Z_{DR} values except for f_cl13 . This cluster has no
23 variation in temperature (T), having all centroids at 0°C . As such, f_cl13 corresponds to the area in the data referred to as a
24 “bright band”. According to the box and whiskers plots in Fig. 8 cluster f_cl13 has the highest mean Z_H (24 dBZ), mean Z_{DR}
25 (0.99 dB), and the lowest mean ρ_{HV} (0.93) compared to the other optimal clusters and it is mostly located near 0°C . These
26 characteristics immediately indicate that f_cl13 can be labelled as the “bright band” belonging cluster having mixed-phase
27 (MP) particles.

28 The MP cluster (f_cl13 in Fig. 6) is observed to have some sagging areas: between 10:00 (UTC) and 12:20 (UTC), around
29 16:00 (UTC) and near 18:00 (UTC). Note that f_cl1 is observed above the MP cluster f_cl13 exactly at these time intervals
30 (Fig. 6). This sagging “bright band” signature is often observed where aggregation and riming processes are occurring directly
31 above the melting layer (Kumjian et al., 2016 and Ryzhkov & Zrnicek, 2019). This suggests that f_cl1 can be associated with the
32 processes of aggregation or riming and labelled accordingly.

1 Looking at the percentage of points belonging to each cluster in the optimal clustering set (Fig. 8, panel (f)), we see that clusters
2 f_cl7 and f_cl12 have less than 2 % of points and most probably represent some sporadic and/or special conditions. These
3 clusters also have been separated early from the other “low ice” (f_cl4, f_cl5, f_cl6) and “elevated ice” (f_cl8, f_cl9, f_cl10,
4 f_cl11) clusters and are located near the top of the hierarchical tree (Fig. 5). Both clusters f_cl7 and f_cl12 have smaller
5 absolute mean Z_{DR} values (-0.062 dB and 0.097 dB correspondingly) than the other “ice” clusters (Fig. 8, panel (b)). f_cl7 is
6 also characterised by the highest mean K_{DP} value ($0.44 \text{ } ^\circ \text{ km}^{-1}$) among all of the clusters (Fig. 8, panel (d)). The combination
7 of rather high Z_H (17 dBZ) and high K_{DP} at temperatures around $-15 \text{ } ^\circ \text{C}$ indicates a cluster with high particle number
8 concentration of small ice crystals mixed with a small amount of bigger aggregates. This cluster is potentially a manifestation
9 of the rapid growth of ice via vapor deposition and onset of aggregation in the dendritic growth layer (DGL) discussed in the
10 details in Griffin et al. (2018). These characteristics were also recognised as a signature of dendritic crystals in Bechini et al.
11 (2013). f_cl12 has the lowest mean Z_H value (-3 dBZ) from all optimal clusters. Combining the low mean Z_H with low mean
12 Z_{DR} (0.097 dB) and temperature about $3 \text{ } ^\circ \text{C}$ we can assume that f_cl12 can be labelled as small droplets (i.e. drizzle).
13 f_cl11 belongs to the “elevated ice” clusters and in most cases (see Appendix, Fig. B1) appears as a column in the height-vs-
14 time representation (around 07:00 UTC in Fig. 6 or in Fig. B1 panels (a) 07:00–08:00 UTC; (c) 05:00 UTC and 07:30 UTC;
15 (g) 12:00 UTC; (h) 12:00–12:30 UTC) filling all the altitudes from the top of the cloud to the ML. This cluster has low mean
16 Z_H value (3 dBZ), one of the highest mean Z_{DR} values (0.92 dB) and a close to zero mean K_{DP} value ($-0.009 \text{ } ^\circ \text{ km}^{-1}$). f_cl11
17 can be labelled as the pristine ice crystals class, as they typically have high aspect ratios ($\gg 1$) and tend to fall preferentially
18 with their major axis aligned horizontally (Keat and Westbrook, 2017).

19 Clusters f_cl8, f_cl9 and f_cl10 belong to the “elevated ice” branch of the hierarchical tree (Fig. 5). Among these clusters,
20 f_cl9 has the most different characteristics compared to f_cl8 and f_cl10 clusters. f_cl9 has higher mean Z_H (11 dBZ) and Z_{DR}
21 (0.59 dB) in combination with a lower ρ_{HV} (0.97).

22 f_cl8 and f_cl10 have rather similar characteristics to each other (Fig. 7 and Table A1). The small difference between these
23 two clusters is in a higher mean Z_H (8.6 dBZ) and K_{DP} ($0.14 \text{ } ^\circ \text{ km}^{-1}$) for f_cl8 compared to 5.8 dBZ and $0.028 \text{ } ^\circ \text{ km}^{-1}$ for
24 f_cl10. Both clusters are the main “elevated ice” clusters. f_cl10 has a warmer mean temperature ($-8.2 \text{ } ^\circ \text{C}$ compared to $-16.7 \text{ } ^\circ \text{C}$
25 for f_cl8) and most of the time is located near f_cl8 at the beginning or at the end of the observed event (Fig. B1).

26 The main “low ice” clusters are f_cl4, f_cl5 and f_cl6. Clusters f_cl5 and f_cl6 are often observed together with f_cl6 located
27 above f_cl5. The f_cl4 has several appearances in height-vs-time formats of events (see Appendix, Fig. B1, e.g. 09:00 UTC
28 panel (a); 11:00 UTC panel (b); 09:00 and 17:00-18:00 UTC panel (e)), mostly above f_cl1 reaching higher altitudes in the
29 data.

30 Measurement errors may influence the clustering results. As it was shown by Bringi et al. (1990) noise in the observations has
31 a strong impact on k-mean HCA results. Unfortunately, it is impossible to run the same type of analysis conducted by Bringi
32 et al. (1990) for an unsupervised hierarchical clustering algorithm as the added noise might deliver modified hierarchical
33 structure with another optimal number of clusters and direct comparison to the original set of final clusters would be

1 impossible. Here this issue of noise is partially addressed through our use of QVP. In particular, azimuthal averaging of a QVP
2 reduces the noisiness of the differential phase within the melting layer (Trömel et al. (2013, 2014)) and was recommended in
3 Kumjian et al. (2013) to quantify rather small enhancements of Z_{DR} and K_{DP} .

4 The mean negative values of Z_{DR} and K_{DP} in some clusters (f_cl1, f_cl3 and f_cl7) might point at potential biases due to
5 miscalibration of Z_{DR} , differential attenuation, or backscatter differential phase in the melting layer. Biases in the data
6 such as miscalibrations will not impact the clustering process but will impact the labelling as it is based on cluster
7 characteristics. A miscalibration of Z_{DR} can also be excluded as we routinely perform calibration of this variable. Z_H and
8 Z_{DR} are corrected for the attenuation in the data pre-processing. Biases caused by backscatter differential phase in the
9 melting layer (Trömel et al., 2014) have not been removed and are evident in the cluster characteristics. The influence of the
10 backscatter differential phase needs further investigation. As discussed, not all clusters can be labelled with absolute confidence
11 solely based on the cluster's characteristics and in situ observations can help to verify these initial suppositions.
12

13 5.3 Clusters versus in situ observations

14 5.3.1 In situ data

15 For the verification of the preliminary labelling made in Sect. 5.2, data from the CIP15 and CIP100 on board the FAAM BAe-
16 146 is utilised. FAAM BAe-146 aircraft flights were performed on four out of the eight days (Table 1) of radar observations:
17 2017-05-17, 2018-01-24, 2018-01-24 and 2018-02-14. The flight altitudes and the timestamps when the aircraft was inside the
18 QVP domain can be observed on the height-vs-time representations of the optimal clusters in Fig. B1.

19 Out of the four available flights, there are 23 periods of 20-second intervals which result in a total of 460 seconds of flight
20 time when the aircraft was inside the QVP domain and a cluster can be assigned to the corresponding height. Of these 23
21 periods there are observations corresponding to 9 unique clusters (f_cl1, f_cl2, f_cl3, f_cl4, f_cl5, f_cl6, f_cl8, f_cl10, f_cl12).
22 This samples 70 % of the final clusters. From these time series, we present examples of CIP15 and CIP100 images for each
23 cluster (Fig. 9) and mean particle size distributions of the data observed during the 20-second interval (Fig. 10).

24 5.3.2 Liquid-phase clusters

25 The liquid-phase clusters f_cl1, f_cl2 and f_cl3 correspond to in situ data which contains relatively high concentrations (>1
26 000 m^{-3}) of small particles (mostly $< 200 \mu\text{m}$ in size) which appear round (Fig. 9 and Fig.10, panels (a)–(c)). This strongly
27 supports the idea of large amounts of liquid water being present in the cloud, which supports the labelling of f_cl1-f_cl3 as
28 being influenced by liquid water hydrometeors. When looking in detail at CIP100 in situ observations, and to some extent
29 CIP15 observations at sizes $> 200 \mu\text{m}$, we can see some significant difference between f_cl1-f_cl3, which we will now discuss.
30 f_cl1, observed above the “bright band”, was previously assigned to be the result of aggregation and riming. In this region, the
31 CIP100 (Fig. 9, lower part of panel (a)) shows particle imagery and particle size distributions segregated by shape which show

1 the presence of large ice particles (Fig. 10, panel (a)), again confirming the previous cluster labelling. The CIP100 data shows
2 the presence of irregularly shaped particles, ranging in size from $\sim 1-4$ mm, with concentrations in each bin of the order 1 m^{-3} .
3 This suggests a mode of snow particles is present at the same time as the previously mentioned liquid droplet mode. Many
4 small water droplets in the CIP15 observations (Fig. 9 and Fig.10, CIP15 of panel (a)) could indicate either the presence of
5 warm cloud processes or small ice crystals melting first around the ML. The second interpretation is supported by the imagery
6 from the CIP100 which suggests melting has not started to occur on the larger particles. In this case, the larger aggregate
7 snowflakes fall to lower altitudes before they start to melt and form the clear “bright band” in the QVP.

8 f_{cl2} was characterized by the strong variation in Z_H , K_{DP} , ρ_{HV} , and T of the cluster’s centroids in different cases. Both CIP15
9 and CIP100 have small round shape particles in the corresponding images (Fig. 9, panel (b)). The mean concentrations per
10 particle size distributions (Fig. 10, panel (b)) show the prevalence of particles recognised by shape as water droplets. The
11 droplets of < 2 mm size have the occurrences of the order from 10 m^{-3} to $90\,000 \text{ m}^{-3}$ with higher orders corresponding to
12 particle sizes $< 200 \mu\text{m}$. Summing up previous analysis and in situ observations we can assign f_{cl2} to a “liquid” cluster, which
13 includes rain of varying intensities and different drop sizes.

14 f_{cl3} also has predominantly small round shape particles (mean size $\mu = 128 \mu\text{m}$) in the CIP15 panels (Fig. 9 and Fig.10,
15 upper part of panel (c)). The CIP100 data (Fig. 9, lower part of panel (c)) were not processed due to technical issues with the
16 probe so water/ice concentrations based on this data are unfortunately not available. The high concentrations ($1000-5000 \text{ m}^{-3}$)
17 of small size ($< 200 \mu\text{m}$) particles are assigned to water (Fig.10, panel (c)). Concentrations of the larger particles ($> 200 \mu\text{m}$
18 and $< 800 \mu\text{m}$) are very low ($< 100 \text{ m}^{-3}$). Considering these observations, the cluster’s characteristics and the fact that the
19 cluster appears mostly in the beginning or at the end of the events (Fig. B1) we can assume that the cluster either represents a
20 very light rain/drizzle or indicates a partially filled QVP domain in the original data.

21 5.3.3 Solid-phase clusters

22 The CIP15 images for f_{cl4} show a mix of larger irregularly shaped particles (aggregates of snowflakes) and relatively few
23 tiny ice crystals (Fig. 9, panel (d)) having very small irregular shapes. The mix of small (< 1 mm) particles recognised as water
24 and ice has low total concentrations ($500-800 \text{ m}^{-3}$; Fig.10, upper part of panel (d)). Particles of larger sizes (> 1 mm and < 3.0
25 mm) have concentrations from 100 m^{-3} to 800 m^{-3} (Fig.10, lower part of panel (d)) and were recognised as ice due to their
26 irregular shapes. The small number of “round” particles recognized as liquid are likely an artefact of the data processing due
27 to out-of-focus imaging of the numerous ice particles which are present - such artefacts appear when particles are observed at
28 the edges of the depth of field (O’Shea et al, 2019). Accordingly, this cluster can be assigned to the mix of pristine ice and
29 some formed aggregates, all having low concentrations.

30 f_{cl5} and f_{cl6} show very similar images in CIP15, but the CIP100 images illustrate the difference between these two clusters
31 (Fig. 9 panels (e) and (f)). The shape analysis of CIP100, suggests both clusters include a low concentration ($40-50 \text{ m}^{-3}$) of
32 small round shape particles (< 1 mm size; the lower part of panels (e) and (f), Fig. 10). Similar to f_{cl4} , the number of liquid

1 particles are likely an artefact of the data processing (O’Shea et al, 2019). The main difference between these clusters is shown
2 in the part of the data recognized as ice. The mean size of the particles of f_cl5 is about 1.7 mm and has occurrences of order
3 100 m^{-3} (Fig. 10, panel (e)). While the mean size of particles in f_cl6 is a bit smaller - 1.4 mm and particles around that size
4 have a higher occurrence of order 400 m^{-3} (Fig. 10, panel (f)). This difference between f_cl5 and f_cl6 resembles the
5 aggregation processes when dendritic crystals of higher concentrations formed at higher altitudes (f_cl6) start to clump together
6 during their fall and form aggregates (f_cl5) with a lower concentration of particles.

7 Clusters f_cl8 and f_cl10, belonging to the “elevated ice” branch of the hierarchical tree (Fig. 5), are also represented by the
8 very similar images of CIP15 and CIP100 observations (Fig. 9, panels (g)–(h)) with the difference in the particles’
9 concentration (Fig. 10, panels (g)–(h)). f_cl8 has a higher concentration of small size ($<1 \text{ mm}$) particles (up to 1000 m^{-3})
10 recognised as spherical than f_cl10 (up to 300 m^{-3}). The bigger particles captured in CIP100 corresponding to f_cl8 are of
11 bigger size (from 1 mm and up to 3 mm) and also have a higher concentration ($< 500 \text{ m}^{-3}$) compared to particles of f_cl10
12 having a maximum size of about 2 mm with concentrations $< 200 \text{ m}^{-3}$. The example of CIP100 images suggests that these
13 particles are dendritic in nature (Fig. 9, panel (h)). Again, similar to the artefacts discussed when looking at the CIP
14 observations for f_cl4, f_cl5 and f_cl6, there is likely an erroneous classification of small size particles (O’Shea et al, 2019).
15 Thus, according to in situ data, f_cl8 can be assigned to a mix of pristine ice and bigger aggregates and f_cl10 to a low
16 concentration mix of pristine ice and smaller aggregates.

17 The last in the list of clusters verifiable with the FAAM BAe-146 data is f_cl12 (Fig. 9, panel (i)). The lower panel (i) of Figure
18 10 shows occurrences of order $10\,000 \text{ m}^{-3}$ for very small particles up to $150 \mu\text{m}$ and occurrences of order 1000 m^{-3} for the
19 droplets of sizes between $150 \mu\text{m}$ and $250 \mu\text{m}$ with almost no occurrences of bigger particles. Unfortunately, concentrations
20 from CIP100 data are not available for this cluster due to technical issues in the CIP100 probe. f_cl12 contains the fewest
21 number of data points in QVP analysis (Fig 8. panel (f)) and there are no other in situ observations related to this cluster. Based
22 on available data, we could assume that the cluster has a high concentration of tiny water droplets (potentially drizzle). On the
23 other hand, similar to the data for other classes, the CIP analysis may have misclassified these as liquid due to their small round
24 appearance in the observations when in reality the observations could represent high concentrations of small ice particles.
25 Likewise, the mean temperature of this cluster is close to 0°C , so no definitive label may be given based on the observations.
26 Thus, the physical interpretation of this cluster is ambiguous though the cluster is separate within the multivariate space.

27 **5.3.4 Assignment conclusions**

28 The rest of the clusters need to be assigned by means of human interpretation according to the cluster characteristics or
29 deduction from the interactions and temporal evolution of already assigned clusters. The summary of the assigned clusters can
30 be found in Table A1 of the Appendix A. Application of in situ observations for the assessment of QVP-based clusters has its
31 limits as not all optimal clusters were captured by the FAAM BAe-146 flights and this process requires a comparison of data
32 from essentially one-point measurement to the cluster based on the mean QVP domain values. An appropriate validation

1 process would utilise columnar vertical profiles (CVP) as described in Murphy et al. (2020) with the thorough collocation of
2 the aircraft observations. Utilising CVPs within the presented technique is a part of the planned work for the future.

3 **6 Summary and Conclusions**

4 This paper presents a new technique of hydrometeor classification from QVP. Note that both the data-driven approach and the
5 use of QVP is novel. In this technique, the hydrometeor types are identified from an optimal number of hierarchical clusters,
6 obtained through a recursive process. This recursive process includes an initial dimensionality reduction by principal
7 component analysis followed by spectral clustering. Spectral clustering performed in the PCA space allows us to identify
8 clusters that would have a non-convex form in the original multivariate input space. This property of the algorithm makes it
9 unique and advantageous in comparison to other classification methods, which separate classes by hyperplanes.

10 The final set of clusters is identified with an optimality check using validity indexes. This represents the first attempt, in top-
11 down hierarchical clustering of weather radar data, to identify the number of clusters based solely on the embedded data
12 characteristics. This data-driven technique produces an optimal number of clusters and keeps the hierarchical structure built in
13 the clustering process. The final set of clusters may be labelled based on their positioning in the hierarchical structure, the
14 characteristics of their centroids and co-incident in situ observations. Depending on the user's needs and interests, the labelling
15 can also be performed for different levels of granularity. In the example shown in this study, we utilise observations collected
16 during several FAAM BAe-146 flights to demonstrate the advantages this technique has in the labelling process. In this case,
17 based on the data available, 70 % of the clusters were labelled using the coincident CIP observations. The other 30 % of the
18 clusters, which were not sampled during the FAAM BAe-146 flights of this study, were labelled based on the cluster
19 characteristics, their positioning in the hierarchical structure and considering interactions with clusters in a height-vs-time
20 format of original QVP data.

21 Thus, in this study, we find that a data-driven HC approach is capable of providing an optimal number of classes from the
22 observations. Moreover, the embedded flexibility in the extent of granularity is the main advantage of the technique. Each
23 branch of the hierarchical structure can be cut out at any level and the parenting cluster characteristics can be used for labelling
24 and identifying more general processes in the atmosphere, while the lower level clusters can provide information about more
25 specific properties and features of the observations.

26 The centroids of the clusters represent characteristics of the points belonging to a cluster in the multivariate input space (in
27 this case, the polarimetric radar variables and temperature). The identification of these centroids allows the clusters to be
28 tracked in time and altitude as the centroids are calculated based on QVP from single scans. An analysis of the time series of
29 the radar volume scans is possible and would allow the clusters to be tracked in time and 3D space. Though unexplored in this

1 study, the application of the presented approach in this way could be used to provide information on the temporal evolution of
2 the identified hydrometeors and reveal relationships between the identified classes.

3 Note that the final set of clusters is optimal only for the provided input dataset (Table 1), which gives the user an opportunity
4 to select the input dataset depending on their needs. Thus, for the clustering to reflect ice properties and processes, the
5 appropriate input data climatology should be used. For identification of specific features in the data (e.g. birds or insects) a
6 subset of cases potentially including these features should be selected for the analysis. Further analysis of long-term dataset
7 could be used to create a set of climatologically representative clusters that could be used to study general processes and inform
8 the development of an operational HC scheme.

9 In this paper, the technique was used for classification of QVP of long-lasting precipitation events, but the same algorithm can
10 be applied to various needs (e.g. identification of birds, insects' or clustering of volume scans of radar data). In parallel with
11 the application of hierarchical clustering technique to other radar observations a thorough validation of the clusters using CVPs
12 following the FAAM BAe-146 is planned.

13 **Acknowledgments**

14 The authors would like to thank NCAS for support of all scientific activities and, in particular, the FAAM BAe-146 team for
15 collecting the in situ observations. Airborne data was obtained using the BAe-146-301 Atmospheric Research Aircraft [ARA]
16 flown by Airtask Ltd and managed by FAAM Airborne Laboratory, jointly operated by UKRI and the University of Leeds.
17 The authors are grateful to Hannah Price, Chris Reed and Graeme Nott for their help with CIP data processing. This work was
18 supported by the Natural Environment Research Council [grant numbers NE/P012426/1, NE/S001298/1] and used JASMIN,
19 the UK collaborative data analysis facility.

Figure 6: The time-vs-height format of the final optimal set of active clusters found by the top-down hierarchical clustering for the QVP input data described in Table 1 (The hierarchical structure behind the optimal clustering is found in Fig. 4). Example of clusters in the time-vs-height format of the 17 of May 2017 QVP presented in Fig. 2.

1

2 **Figure 7:** Characteristics of the optimal clustering centroids in four polarimetric variables and temperature. The scales of the variables: from
 3 -20 dBZ to 40 dBZ for Z_H , from -1.5 dB to 2.0 dB for Z_{DR} , from 0.9 to 1.0 in ρ_{HV} , from -0.3 km^{-1} to 0.6 km^{-1} for K_{DP} , and from -20°
 4 C to 10°C in temperature (T).

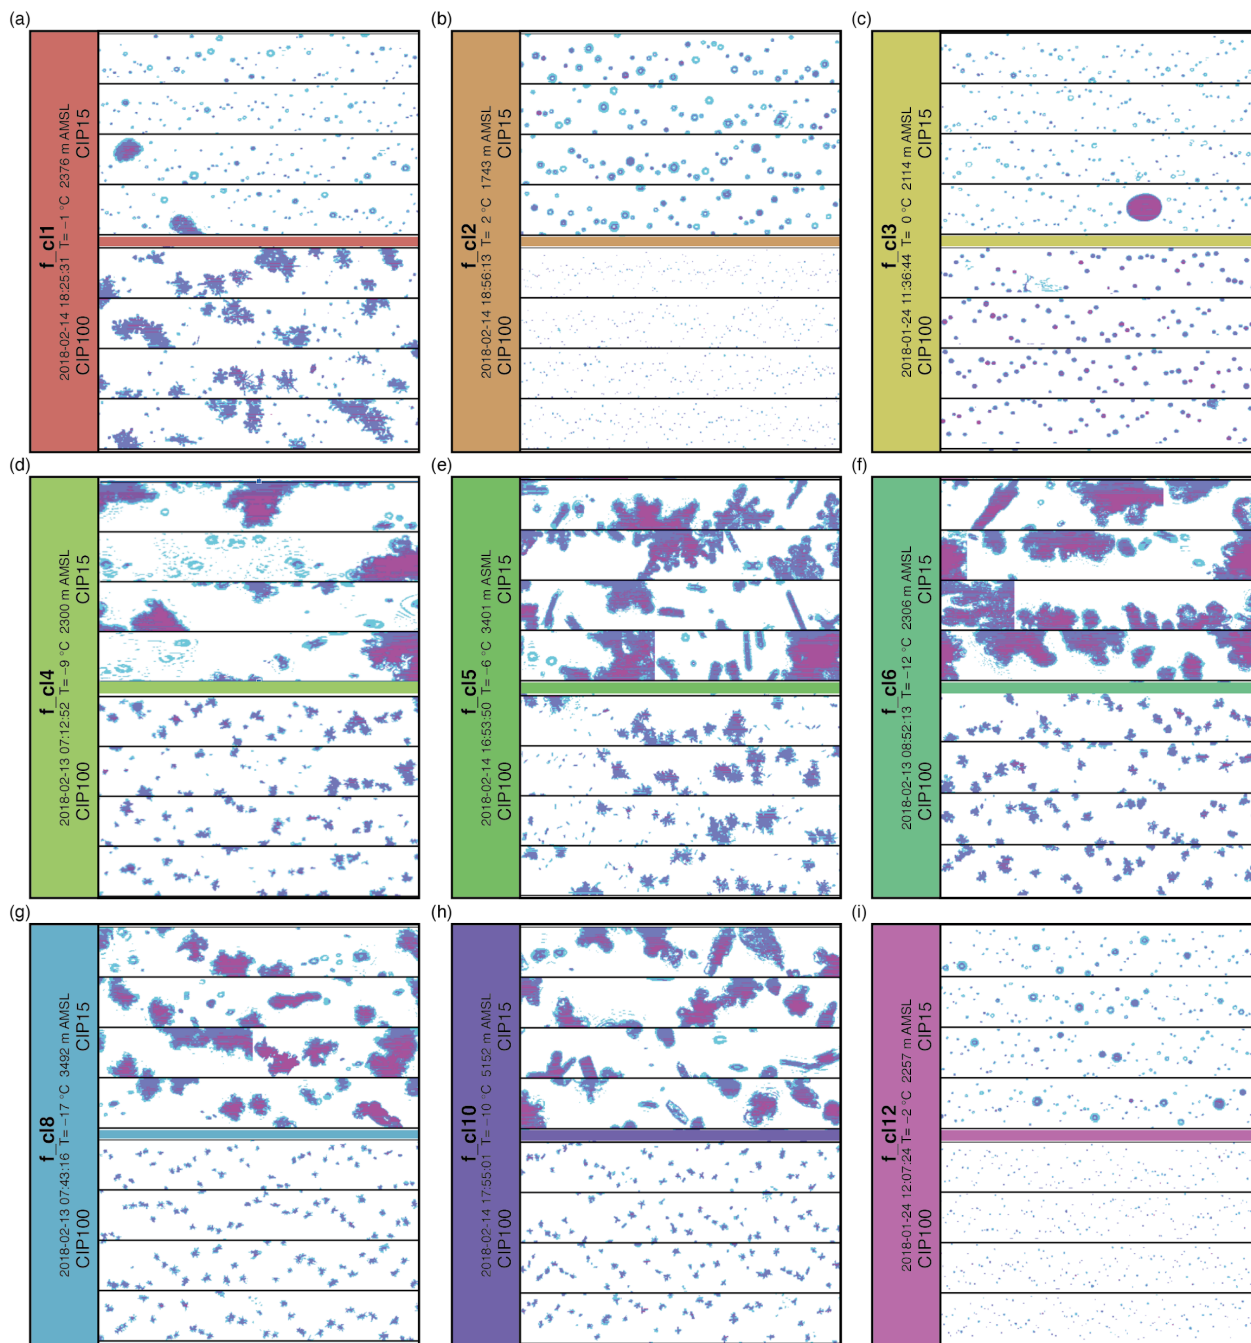

1

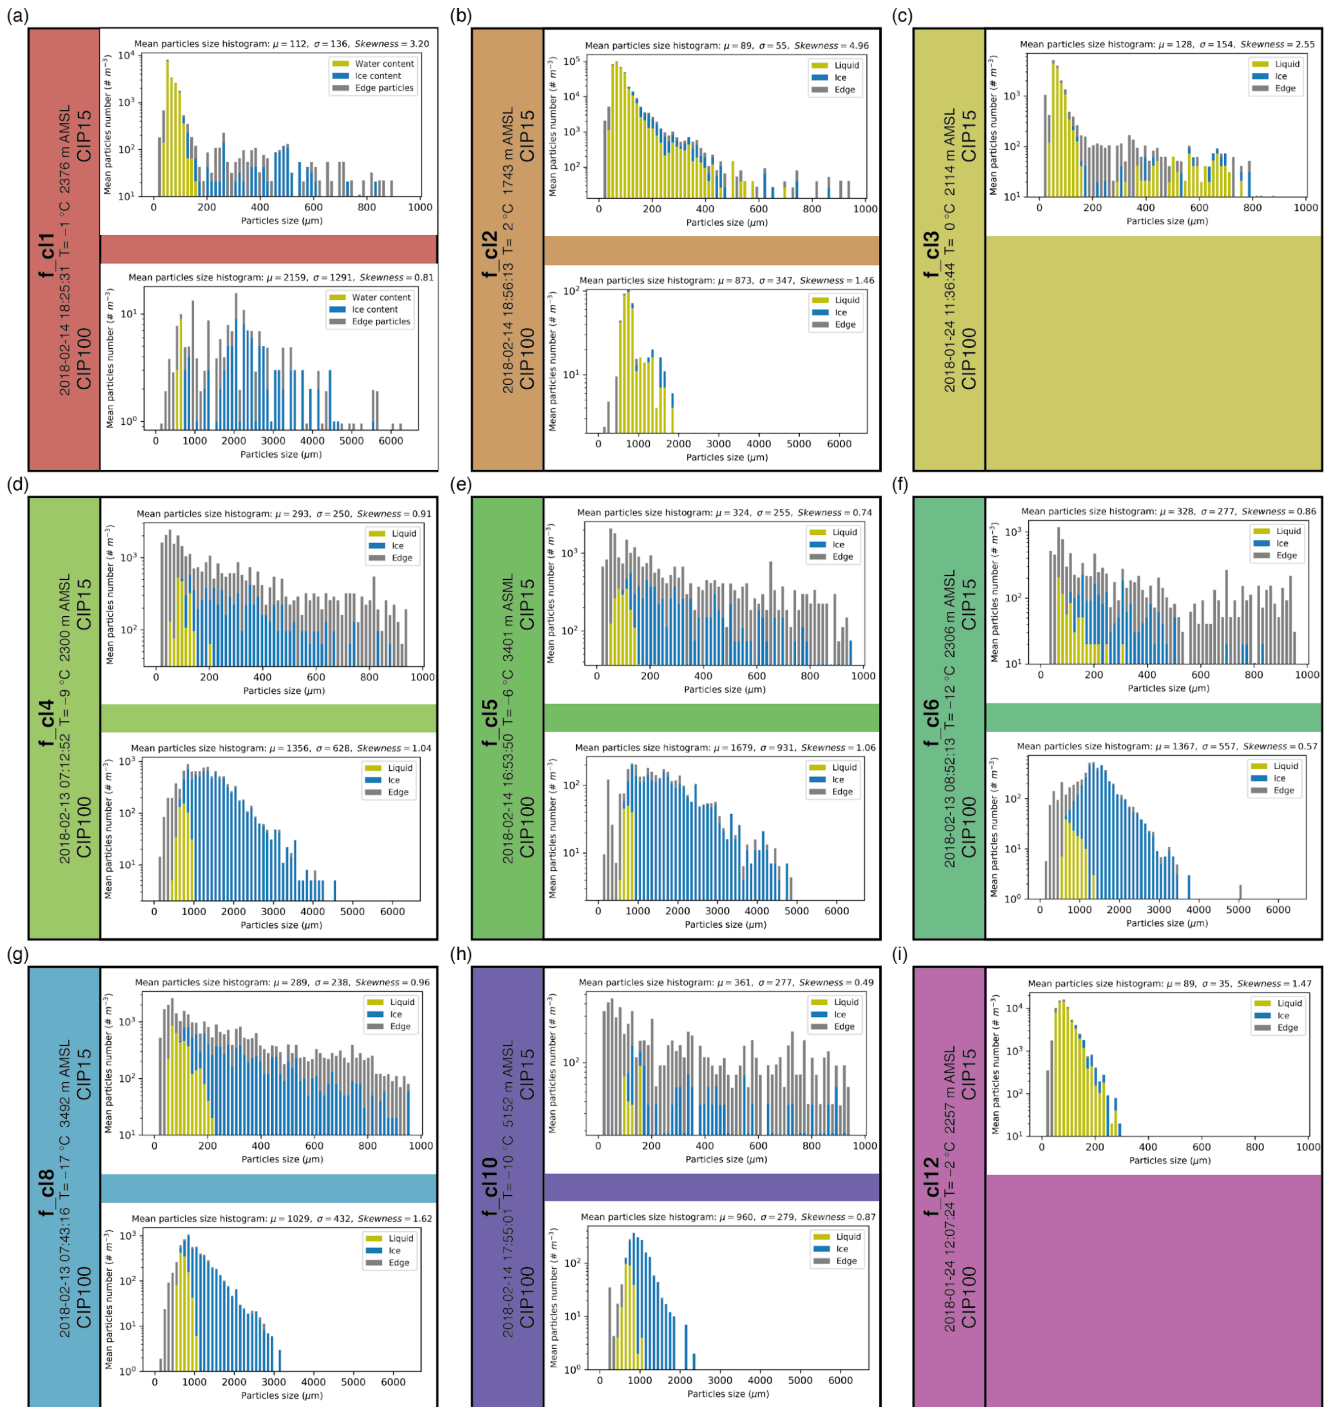

2

Figure 8: Characteristics of the optimal clustering centroids in four polarimetric variables ((a) – Z_H , (b) – Z_{DR} , (c) – ρ_{HV} , (d) – K_{DP}) and temperature (e). The percentage of points in each cluster is in the panel (f).

6 **Appendix A: Polarimetric characteristics of the optimal clusters**

7 Table A1 provides the relevant statistics of each of the thirteen optimal clusters identified in this work from a database of X-
 8 band radar data.

9 **Table A1.** Statistics describing the content of the thirteen optimal clusters identified in Sects. 4. For each polarimetric variable and for
 10 each cluster, we provide the mean value, standard deviation σ , and [minimum, maximum] values.

Variable	Cluster	Unit	MeanValue	σ	MinValue	25 %	50 %	75 %	MaxValue	Label
Z_H	f_cl1	dBZ	20	5	3	17	20	23	38	aggregation/ riming of ice crystals
