**Abstract.** Nitrogen oxides (NO<sub>x</sub> = NO + NO<sub>2</sub>) are critical intermediates in atmospheric chemistry and air pollution. NO<sub>x</sub> levels control the cycling and hence abundance of the primary atmospheric oxidants OH and NO<sub>3</sub>, and regulate the ozone production which results from the degradation of volatile organic compounds (VOCs) in the presence of sunlight. They are also atmospheric pollutants, and NO<sub>2</sub> is commonly included in air quality objectives and regulations. NO<sub>x</sub> levels also affect the production of the nitrate component of secondary aerosol particles and other pollutants such as the lachrymator peroxyacetyl nitrate (PAN). The accurate measurement of NO and NO<sub>2</sub> is therefore crucial to air quality monitoring and understanding atmospheric composition. The most commonly used approach for measurement of NO is chemiluminescent detection of electronically excited NO<sub>2</sub> (NO<sub>2</sub><sup>\*</sup>), formed from the NO + O<sub>3</sub> reaction within the NO<sub>x</sub> analyser. Alkenes, ubiquitous in the atmosphere from biogenic and anthropogenic sources, also react with ozone to produce chemiluminescence and thus may contribute to the measured NO<sub>x</sub> signal. Their ozonolysis reaction may also be sufficiently rapid that their abundance in conventional instrument background cycles, which also utilises reaction with ozone, differs from that in the measurement cycle – such that the background subtraction is incomplete, and an interference effect results. This interference has been noted previously, and indeed the effect has been used to measure both alkenes and ozone in the atmosphere. Here we report the results of a systematic investigation of the response of a selection of commercial NO<sub>x</sub> monitors, ranging from systems used for routine air quality monitoring to atmospheric research instrumentation, to a series of alkenes. The species investigated range from short chain alkenes, such as ethene, to the biogenic monoterpenes. Experiments were performed in the European Photoreactor (EUPHORE) to ensure common calibration and samples for the monitors, and to unequivocally confirm the alkene levels present (via FTIR). The instrument interference responses ranged from negligible levels up to 11 % depending upon the alkene present and conditions used (*e.g.* presence of co-reactants and differing humidity). Such interferences may be of substantial importance for the interpretation of ambient NO<sub>x</sub> data, particularly for high-VOC, low-NO<sub>x</sub> environments such as forests, or indoor environments where alkene abundance from personal care and cleaning products may be significant.

## Introduction

Measurement of atmospheric trace constituents is central to atmospheric chemistry research and air pollution monitoring. Key challenges to trace measurements are sensitivity, reactivity and selectivity – as many components of interest are only present at ppb (parts per billion,  $10^{-9}$ ) or ppt (parts per trillion,  $10^{-12}$ ) mixing ratios; in many cases their inherent reactivity necessitates *in situ* detection, and because atmospheric trace composition comprises many thousands of different chemical components (Goldstein and Galbally, 2007). Consequently, specific measurement approaches have been developed to measure key atmospheric species, within the specific conditions (analyte abundance, presence of other constituents) anticipated (Heard, 2008). This paper reports a systematic study of the interference arising in measurements of the nitrogen oxides from the presence of alkenes in sampled air, when using their most widespread air quality monitoring technique of chemiluminescence detection.

$\text{NO}_x$  (=  $\text{NO} + \text{NO}_2$ ) abundance controls the cycling and hence concentration of the primary atmospheric oxidants, hydroxyl (OH) and nitrate ( $\text{NO}_3$ ) radicals, and regulates the ozone production which results from the degradation of volatile organic compounds (VOCs) in sunlight.  $\text{NO}_x$  are also atmospheric pollutants in their own right, and  $\text{NO}_2$  is commonly included in air quality objectives and regulations (as the more harmful component of  $\text{NO}_x$ ) (European Environment Agency, 2018; Chaloulakou et al. (2008). In addition to their role in controlling ozone formation,  $\text{NO}_x$  levels affect the production of other pollutants such as the lachrymator peroxyacetyl nitrate (PAN), and the nitrate component of secondary aerosol particles. Consequently, accurate measurement of nitrogen oxides in the atmosphere is of major importance for monitoring pollution levels and assessing consequent health impacts, and understanding atmospheric chemical processing. Atmospheric NO and  $\text{NO}_2$  are formed from natural processes (lightning, soil emissions of NO, biomass burning and even snowpack emissions) and anthropogenic activities (high temperature combustion in air leading to the breakdown of  $\text{N}_2$  and  $\text{O}_2$ , and  $\text{NO}_x$  production via the Zeldovitch mechanism), where road traffic is the predominant source in many urban areas (Keuken *et al.*, 2009; Grice *et al.*, 2009; Carslaw and Rhys-Tyler, 2013). Consequently, boundary layer  $\text{NO}_x$  abundance varies over many orders of magnitude – from sub 5-ppt levels in the remote marine boundary layer, to ppm levels in some urban environments (Crawford *et al.*, 1997).

Techniques used for the measurement of atmospheric  $\text{NO}_x$  include laser-induced fluorescence spectroscopy (LIF), for both NO and  $\text{NO}_2$ ; absorption spectroscopy (long-path and cavity-enhanced differential optical absorption spectroscopy, LP- and CE-DOAS, cavity attenuated phase shift spectroscopy (CAPS), cavity ring-down spectroscopy (CRDS), and passive diffusion tubes, primarily for  $\text{NO}_2$ ), chemical ionisation mass spectrometry (CIMS) and both on- and offline wet chemical methods *e.g.* long path absorption photometer (LOPAP) (Heard, 2008; Sandholm et al. 1990; Kasyutich et al. 2003; Keabian et al. 2005; Cape, 2009; Fuchs et al. 2009; Thalman and Volkamer, 2010; Villena et al. 2011). However, the most commonly employed

65 technique for the measurement of NO<sub>x</sub> species, including for statutory air quality monitoring purposes, is the detection of the chemiluminescence arising from electronically excited NO<sub>2</sub> (NO<sub>2</sub><sup>\*</sup>) formed from the reaction between NO and O<sub>3</sub> (via R1):

70

The intensity of the light emitted via (R2) is in the wavelength 600 – 3000 nm, peaking at ~1200 nm. Chemiluminescent instruments mix sampled ambient air with a reagent stream containing an excess of ozone, to promote the chemiluminescent reaction (see schematic – Figure 1); the resulting emission signal is measured using a photomultiplier tube (PMT), and consists of contributions from NO<sub>2</sub><sup>\*</sup> formed as above, but also potentially from other chemiluminescence processes, detector dark  
75 counts and other noise contributions. Contributions to the measured emission from other species are minimised by using a red filter on the detector to block emission wavelengths below ca. 600 nm, and by employing a background subtraction cycle: chemiluminescent NO<sub>x</sub> monitors commonly acquire a background by increasing the reaction time between NO (from the sampled air) and O<sub>3</sub> (reagent formed within the instrument), using a pre-reactor volume, such that nearly all of the NO present (specifications typically state, in excess of 99%) is converted to NO<sub>2</sub>. The difference in PMT signals between the “online”  
80 and “background” signals is then taken to be proportional to the NO present in the air sample, following the assumption that the abundance of other species which may contribute to the measured signal is not affected by the background cycle.

Chemiluminescent instruments typically alternate between two operation modes – one that directly measures NO and one that measures Σ(NO + NO<sub>2</sub>), by first converting NO<sub>2</sub> to NO. The difference between the two values determines the NO<sub>2</sub> mixing  
85 ratio (if only NO and NO<sub>2</sub> are present). This is most commonly achieved using a molybdenum (Mo) catalyst heated to 300 – 350°C. However, the reduction of other NO<sub>z</sub> species to NO have led to the use of these catalysts in chemiluminescent NO<sub>y</sub> monitors to measure total reactive nitrogen rather than NO<sub>2</sub> (NO<sub>y</sub> = NO<sub>z</sub> + NO<sub>x</sub>; and NO<sub>z</sub> = other reactive nitrogen species catalysed by Mo convertors *e.g.* HNO<sub>3</sub>, HONO, N<sub>2</sub>O<sub>5</sub>, HO<sub>2</sub>NO<sub>2</sub>, PAN, NO<sub>3</sub>, organic nitrates – but not NH<sub>3</sub>) (Navas *et al.*,  
90 1997; Murphy *et al.*, 2007). If atmospheric mixing ratios of NO<sub>z</sub> species are high relative to NO<sub>2</sub> then NO<sub>2</sub> measurements with monitors equipped with Mo catalysts are increasingly inaccurate. This has led to the adoption of photolytic NO<sub>2</sub> conversion stages in research instruments, where a blue light LED convertor is illuminated in a photolysis cell converting NO<sub>2</sub> to NO (Lee  
*et al.*, 2015).

95

The photolytic conversion technique can have greater specificity than the heated Mo catalyst as the photolysis wavelengths may be selected to match the NO<sub>2</sub> photolysis action spectrum, while potential NO<sub>z</sub> interferences for an NO<sub>2</sub> measurement are

thermally unstable and may convert to NO<sub>2</sub> when exposed to heat in the latter approach (Heard, 2008). Despite this, the chemiluminescent analyser with the heated Mo catalyst is the most widely used technique for air quality monitoring of NO and NO<sub>2</sub> worldwide. It is the reference method of measurement specified in the EU directive (BS EN 14211, 2012), providing real-time data with short time resolution for 212 monitoring sites in the UK, including kerbside, roadside, urban background, industrial and rural locations (Air Quality Expert Group, 2004).

### Origins of interferences in chemiluminescent NO<sub>x</sub> measurements

While NO<sub>x</sub> measurements are sometimes perceived to be straightforward and routine, in practice a number of factors are known to affect the accuracy of the levels obtained using chemiluminescence approaches. A detailed account of factors affecting atmospheric NO<sub>x</sub> measurement overall is given elsewhere (e.g. Gerboles *et al.*, 2003; Villena *et al.*, 2012; Reed *et al.*, 2016); here we do not focus upon surface sources/losses but rather upon chemical interferences in chemiluminescent NO<sub>x</sub> analysers, which may arise from the following possible general mechanisms:

1. Collisional quenching of NO<sub>2</sub>\* by an interferent species with a greater collisional efficiency than the bath gas (e.g. air) used for calibration (typically a negative interference, although the magnitude and sign of this depends upon the calibration conditions employed)
2. Conversion of other N-containing species to NO<sub>x</sub> within the NO<sub>2</sub> conversion unit (positive interference)
3. Chemical removal or interconversion of NO and/or NO<sub>2</sub> by an interferent species generated within the instrument (positive or negative interference)
4. Chemiluminescence of other chemical species, which is not fully accounted for during the instrument background cycle (positive interference)

Collisional quenching of excited species, mechanism (1), results in a reduction in the chemiluminescence intensity, to an extent dependent upon the pressure, and quenching efficiency – the efficacy with which the quenching species may accept or remove energy from the excited moiety. In the case of electronically excited NO<sub>2</sub>, effective quenching agents have been shown to include H<sub>2</sub>O, CO<sub>2</sub>, H<sub>2</sub> and hydrocarbons (Matthews *et al.*, 1977; Gerboles *et al.*, 2003; Dillon and Crowley, 2018), of which only quenching by water vapour is considered to be significant under most common (ambient air) conditions – sensitivity reductions of up to 8 % have been reported (Steinbacher *et al.*, 2007). Mechanism (2), conversion of other nitrogen-containing species to NO, alongside NO<sub>2</sub>, is a recognised issue with heated Mo converters – interferences between 18 – 100 % have been reported for species such as HONO, HNO<sub>3</sub>, PAN, alkyl nitrates and N<sub>2</sub>O<sub>5</sub> (Dunlea *et al.*, 2007; Lamsal *et al.*, 2008). To address these uncertainties, photolytic converters are now commonly employed in research measurements, although for most routine air quality monitoring, heated Mo converters are still employed. Recently, it has been shown that a further interference can arise within the photolytic converter stage – from the generation of HO<sub>x</sub> radicals through photolysis of photolabile carbonyl species such as glyoxal, forming peroxy radicals promoting NO-to-NO<sub>2</sub> conversion within the instrument (Villena *et al.*, 2012),

resulting in a negative NO<sub>2</sub> interference, which may (under some conditions) exceed the positive interference from retrieval of NO<sub>z</sub> species associated with heated Mo converter instruments i.e. mechanism (3).

The focus of this work relates to mechanism (4): interference in chemiluminescent measurements of NO and NO<sub>2</sub> (using both catalytic and photolytical converters) arising from the chemiluminescence of alkenes in the presence of ozone. Alkene-ozone reactions have received substantial attention as a dark source of HO<sub>x</sub> radicals, and a route to the formation of semi-volatile compounds which contribute to secondary organic aerosol (SOA), particularly for biogenic alkenes such as isoprene and the mono- and sesquiterpenes (e.g. Johnson & Marston, 2008; Shrivastava *et al.*, 2017). Rate constants for ozonolysis reactions depend on alkene structure, and are typically larger for biogenic alkenes. Chemiluminescence from the ozonolysis of 14 short chain species at total pressures of 2 – 10 Torr was first reported by Pitts *et al.* (1972). Excited HCHO, vibrationally excited OH and electronically excited OH in the wavelengths 350 – 520 nm, 700 – 1100 nm and 306 nm, respectively, were the identified chemiluminescent species (Finlayson *et al.* (1974); and indeed has been used to perform field measurements of both ozone and alkenes (e.g. Velasco *et al.*, 2007; Hills and Zimmerman, 1990). This combination – of alkene-ozone reactions giving rise to a chemiluminescent interference signal, and alkene-ozone reactions being sufficiently rapid that alkenes can be appreciably consumed in the background (pre-reactor) cycle, and hence the interference contribution not fully subtracted during the background correction – gives rise to the potential for interference in NO<sub>x</sub> measurements, which is the focus of this study.

## Experimental Approach

Experiments were performed using chamber A of the two 200m<sup>3</sup> simulation chambers of the European Photoreactor (EUPHORE) facility in Valencia, Spain to provide a common, homogeneous air volume for multiple NO<sub>x</sub> analysers to sample from. The EUPHORE chambers are formed from fluorine-ethene-propene (FEP) Teflon foil fitted with housings that exclude ambient light (Wiesen, 2001; Munoz *et al.*, 2011). The chambers are fitted with large horizontal and vertical fans to ensure rapid mixing (timescale 3 minutes). Instrumentation used comprised long-path FTIR (for absolute and specific alkene / VOC measurements), monitors for temperature, pressure, humidity (dew-point hygrometer), ozone (UV absorption) and CO (infrared absorption). NO<sub>x</sub> levels were measured using four independent chemiluminescent monitors, plus (in the case of NO<sub>2</sub>) LP-DOAS absorption spectroscopy – All monitor sampling lines were similar lengths and attached to one inlet sampling from the centre of the chamber.

Monitors 1 and 2 employed heated Mo catalysts, while 3 and 4 used photolytical NO<sub>2</sub> converters (see Table 1). All NO<sub>x</sub> monitors were calibrated (in the range 0 – 100 ppb) at the start and end of the two-week measurement period using a multi-point calibration derived from a primary NO standard (BOC 5 ppm alpha standard, certified to the NPL scale) in addition to single-point calibrations performed on a daily basis. NO<sub>2</sub> calibration was achieved via gas-phase titration using added ozone within

the chamber. In some experiments the calibrations and interference were confirmed with use of the EUPHORE long-path DOAS system to unequivocally identify and quantify NO<sub>2</sub>.

165

All experiments were performed with the chamber housing closed (i.e. dark conditions,  $j(\text{NO}_2) < 2 \times 10^{-6} \text{ s}^{-1}$ ), at near atmospheric pressure and ambient temperature. For most experiments, humidity was low (dew point ca. -45 ° C). The experimental procedure, starting with a clean flushed chamber, was to add SF<sub>6</sub> (as a dilution tracer), followed by successive aliquots of various alkenes and in certain cases additional species (H<sub>2</sub>O and CO), whilst recording the measured NO and NO<sub>2</sub> levels, over periods of 1-3 hours. For some systems, ozone was added at the end of the experiment – under such dark, high O<sub>3</sub> conditions we can be confident that negligible NO could actually be present in the chamber (e.g. from wall sources) and hence that any “NO” signal observed by the monitors was unequivocally an interference response (as any NO remaining would be rapidly consumed by reaction with O<sub>3</sub>). The potential interferant species investigated were cis-2-butene (C2B), trans-2-butene (T2B), tetra-methyl ethylene (2,3-dimethyl-butene or TME), α-terpinene, limonene, methyl chavicol (estragole) and terpinolene, with 4 – 5 additions of 20 – 50 ppb in each case, together with single- or dual-point interference measurements for ethene, propene, isobutene, isoprene, α-pinene, β-pinene and myrcene. Repeat experiments were performed for trans-2-butene, terpinolene and α-terpinene under conditions of increased humidity (up to ca. 30% RH). Alkene mixing ratios introduced into the chamber are given in Table S1. Propene, cis-2-butene and trans-2-butene were supplied by The Linde Group (purity > 99%); isobutene (purity > 99%) and terpinolene (purity > 85%) from Fluka Analytical; and TME (purity > 98%), isoprene (purity > 99%), limonene (purity > 97%), α-pinene (purity > 97%), β-pinene (purity > 97%), α-terpinene (purity > 85%), estragole (purity > 98%) and myrcene (purity > 99%) from Sigma Aldrich. All reagents were used as supplied.

175

180

### Data Analysis

The limit of detection (LOD) for each instrument was determined under the actual experimental conditions, as three times the standard deviation of the NO and NO<sub>2</sub> signal recorded each day from the empty chamber prior to the start of experiments (i.e. before addition of any reactants). The mean LODs determined for NO and NO<sub>2</sub> are shown in Table 1. These LOD values are higher than those quoted by the manufacturers for monitors 1-4 (typically 2-100 ppt) but accurately reflect the actual performance of the instruments as used during these experiments. In the analysis which follows, in order to confirm that any change in measured NO and NO<sub>2</sub> mixing ratio for each alkene addition was not due to noise or drift and therefore signal, the readings were compared to the experimentally determined LOD for each instrument. Only if the measured change was greater than the experimentally determined LOD were these readings used for determining an interference. The interference due to the VOC was determined by means of linear regression (least squares fit), with slopes and their uncertainty and Pearson’s correlation coefficients calculated in IGOR (see Tables 2 and 3).

190

## 195 Results

Figures 2-4 give the measured VOC mixing ratios and the retrieved “NO” and “NO<sub>2</sub>” measurements by the four monitors during the experiment for selected alkenes, along with the regression analysis for determining the interference levels. Spikes in NO and NO<sub>2</sub> mixing ratios observed after an alkene addition (*e.g.* Fig. 4) arise from sampling close to the addition point prior to the initial period of mixing in the chamber (~ 3 min) and were disregarded in the analysis. The slow decay of alkene and “NO<sub>x</sub>” mixing ratios following each addition arises from dilution effects (with a first order rate constant of  $\sim 5.7 \times 10^{-5} \text{ s}^{-1}$ , derived from the decay of SF<sub>6</sub>).

From Figures 2-4, a clear and systematic response from the monitors to the presence of  $\alpha$ -terpinene, terpinolene and trans-2-butene was observed, with the magnitude varying between the monitors. In addition to the alkenes shown in Figures 2-4, significant interference effects were also observed for cis-2-butene, TME and limonene for some of the monitors, as summarised in Tables 2 and 3. No interference was observed, within detection uncertainty, for ethene, propene, isobutene,  $\alpha$ -pinene,  $\beta$ -pinene, myrcene or methyl chavicol in any of the monitors. For isoprene, no statistically significant interference was observed for monitors 1-3, while monitor 4 observed a very small positive interference of  $0.035 \pm 0.001\%$  (NO channel) and  $0.076 \pm 0.002\%$  (NO<sub>2</sub> channel).

210

For the alkenes where significant interference was observed, in general a positive interference was observed for NO and a negative interference for NO<sub>2</sub> by monitors 1-4 (Tables 2 and 3), with the exception of TME, where a negative NO interference was observed by monitor 3 (and is discussed later). Generally, for monitor 4 a positive NO interference, and a mixture of both positive and negative NO<sub>2</sub> interferences, was observed. Overall, while the magnitude of interference differed between the monitors, the same trend in the interference was observed, with  $\alpha$ -terpinene having the largest interference effect, followed by terpinolene, TME/trans-2-butene, cis-2-butene and limonene.

215

The addition of water (RH ca. 30%) led to the observed NO and NO<sub>2</sub> interference for trans-2-butene, terpinolene and  $\alpha$ -terpinene decreasing by 30–60% as shown in Tables 2 and 3. The addition of CO resulted in an increase in the NO interference observed for TME from below the LOD to 0.7% for monitors 1 and 2 while monitors 3 and 4 exhibited a larger interference increase (Table 2).

220

## Discussion

### Interference effects on retrieved NO abundance

Positive NO interferences were observed for those alkenes which react most rapidly with ozone, and hence will be present within the monitor reaction chamber at different levels in the measurement and background modes. This interference is

225

attributed to chemiluminescent emission following the alkene-ozone reaction, and may be attributed to a combination of two factors: formation of excited products in the alkene-ozone reaction which emit chemiluminescence, coupled with the significant removal of some alkenes during the instrument background phase compared with the measurement phase, through their reaction with (elevated levels of) ozone within the instrument, *i.e.* mechanism (4) outlined above.

230

Possible origins of this signal are the production of excited HCHO, vibrationally excited OH and electronically excited OH (*e.g.* Finlayson *et al.*, 1974). While the long-pass filters used in chemiluminescence NO<sub>x</sub> monitors should preclude emission from electronically excited species, vibrationally excited OH produced through the hydroperoxide mechanism is known to emit in the 700 – 1100 nm wavelength range (Finlayson *et al.*, 1974; Schurath *et al.*, 1976; Hansen *et al.*, 1977; Toby, 1984), and would be detected as NO<sub>2</sub>. The long-pass filters used in the chemiluminescence NO<sub>x</sub> monitors in this study are not reported in their respective user manuals, but typically block light below *ca.* 600 nm, while typical PMT response characteristics are between 400 – 950 nm (Jernigan, 2001). Any chemiluminescence signal in the 600 – 950 nm wavelength range can therefore cause a potential interference.

235

240

The difference in the interference effect among monitors may then reflect differences in the conditions (*e.g.* ozone abundance, pressure, residence time) within the reaction cell and filter specifications. The relative magnitudes of the positive interference signals observed between the different monitors are consistent with this picture, as the reaction chamber pressure is much lower for monitors 3 and 4 (*ca.* 1 – 10 Torr) compared with monitors 1 and 2 (*ca.* 300 Torr) leading to greater collisional quenching. Similarly, addition of H<sub>2</sub>O, which would be expected to efficiently accept vibrational energy from OH radicals (Gerboles *et al.*, 2003), was found to substantially reduce the apparent interference. In the experiments with higher humidity, a reduced interference (factor of *ca.* 2, see Table 2) was observed for all NO experiments for all instruments except for TME for the photolytic converters, where an increase was observed. There is currently no recommended relative humidity under which calibrations should be performed for any of the instruments or within EU and EPA guidelines (AQEG, 2004; USEPA, 2002). However, the installation of permeation driers at the sample inlet should (in principle) reduce the impact of different H<sub>2</sub>O / relative humidity levels upon quenching of NO<sub>2</sub> or other species and are a common feature of most modern samplers (AQEG, 2004).

245

250

### **Interference magnitude: kinetic and structural effects**

The most significant effects are the large positive NO interferences observed for the monoterpenes;  $\alpha$ -terpinene and terpinolene, within monitors 1, 3 and 4. The criteria for an alkene to display such a positive interference (*i.e.* via mechanism 4) are that it reacts with ozone to produce suitable excited products which exhibit a chemiluminescent signal at appropriate wavelengths. In addition, the alkene must have a sufficiently rapid reaction with ozone that its mixing ratio is substantially reduced during the instrument background phase compared with the measurement phase, precluding the correct subtraction of

255

the interference signal. The reaction rate constants for many alkenes with ozone are well known, allowing the calculation of a kinetic interference potential (KIP) ranking for this second factor, and is calculated by Eq 1.

260

$$KIP = 100 \times \left( 1 - \exp \left( -k' t \times \frac{k(\text{Alkene} + \text{O}_3)}{k(\text{NO} + \text{O}_3)} \right) \right) \quad (\text{Eq. 1})$$

where  $k' = k[\text{O}_3]t$  and  $\frac{[\text{NO}]}{[\text{NO}]_0} = 0.01$  (*i.e.* 1% of NO left after reaction with excess  $\text{O}_3$ ); see Supplementary Information for  
265 calculation details. The calculated KIP are shown in Table 4 as the percentage of a given alkene's potential chemiluminescent signal which would *not* be subtracted in the standard background cycle, under the assumption that the background cycle conditions ( $\text{O}_3$  mixing ratio, residence time) would be sufficient to remove 99% of NO present.

This ranking does not reflect the precise (relative) interference which is observed, as it neglects structural features which will  
270 affect the yield (and state *i.e.* electronic or vibrationally excited) of the chemiluminescent products from the ozonolysis reaction – but is consistent with the trend and relative magnitudes for the substantial positive interferences shown in Tables 2 and 3. For example, a lack of interference is observed for myrcene and limonene, both of which exhibit terminal C=C bonds (see Table 4), and after reaction with ozone lead to the production of the  $\text{CH}_2\text{OO}$  Criegee intermediate (CI) which subsequently decomposes or undergoes rearrangement to form small yields of OH (Alam *et al.*, 2011). The ozonolysis of internal alkenes  
275 such as *cis*- and *trans*-2-butene produce the  $\text{CH}_3\text{CHOO}$  CI which predominantly decomposes via the vinyl hydroperoxide mechanism forming larger yields of OH (Johnson and Marston, 2008; Alam *et al.*, 2013). Such chemically formed OH that produces a detectable signal may also be augmented by contributions from  $\text{HO}_2$  and  $\text{RO}_2$ , converted into OH within the instrument by reaction with NO – especially in the  $\text{NO}_2$  channel of photolytic converter instruments.

280 The relationship between the KIP (Table 4) and measured NO interference (Tables 2 and 3) is illustrated in Figure 5 and can be used for predicting the potential interference of a given alkene to the NO signal from a kinetic perspective. For example,  $\alpha$ -humulene has a KIP of 94.54% which could give rise to a 1.7%, 2.4% or 10.2% NO interference for monitors 1, 3 and 4, respectively. This estimate is, however, based on the rate constant of  $\alpha$ -humulene alone and does not include any structural features such as the presence of terminal and non-terminal C=C bonds.

## 285 **Explanation of the interference observed for $\text{NO}_2$**

The above discussion considers only the interference effect arising from alkene chemiluminescent emission; further measurement impacts are also evident in the (negative) interferences apparent for other species / monitors in Tables 2 and 3.

Inspection of Tables 2 and 3 shows smaller positive interferences, and some negative interferences, from alkenes in the NO<sub>2</sub> measurements.

290

NO<sub>2</sub> measurements using chemiluminescence approaches are usually obtained by measuring NO<sub>x</sub> (*i.e.*  $\Sigma(\text{NO} + \text{NO}_2)$ ), after passing the sampled air through an NO<sub>2</sub> converter) and subtracting the (independently determined) NO contribution. If the actual interference signal (additional chemiluminescence) during the NO<sub>x</sub> measurement mode arises solely from mechanism (4), ozonolysis chemiluminescence, then this would be expected to match that in the NO mode (subject to the alkene abundance not being altered in the NO<sub>2</sub> conversion stage and if the detection conditions for the NO and NO<sub>x</sub> phases are identical), and consequently would not affect the retrieved NO<sub>2</sub> mixing ratio. Monitors 1, 2 and 3 used a single detection cell, alternating between NO and NO<sub>2</sub> (NO<sub>x</sub>) modes, and so measured the NO<sub>2</sub>\* chemiluminescence signal under identical conditions (optical arrangement, filtering, pressure). The observed negative interference for NO<sub>2</sub> therefore may have arisen due to removal of alkene by the Mo catalyst within the monitors.

300

For monitor 1 (TE 42i-TL), the negative interference observed for NO<sub>2</sub> was the same magnitude as observed for the positive interference for NO, including the experiments with H<sub>2</sub>O and CO (see Fig. 6 and Tables 2-3). This response is thought to arise as a consequence of the calculation methodology, combined with removal of alkenes during the NO<sub>2</sub> conversion by the Mo catalyst:

305

There are three modes of operation in monitor 1 (TE 42i-TL) – NO measurement, NO<sub>2</sub>/NO<sub>x</sub> measurement and background (pre-reactor) measurement, given by Eq 2-4 respectively:

310

$$sNO = sNO_{real} + X_i \quad (\text{Eq 2})$$

$$sNOx = sNOx_{real} + yX_i \quad (\text{Eq 3})$$

$$sP = fX_i \quad (\text{Eq 4})$$

where  $sNO$  and  $sNOx$  are the NO and NO<sub>x</sub> signals produced by the chemiluminescence monitor, respectively,  $sNO_{real}$  and  $sNOx_{real}$  are the ‘real’ NO and NO<sub>x</sub> signals,  $X_i$  denotes the interference alkene  $i$ ,  $y$  is the fraction of the interferant (alkene)  $X_i$  remaining after the Mo convertor,  $sP$  denotes signal at the pre-reactor and  $f$  is the fraction of  $X_i$  remaining after the pre-reactor. The mixing ratios of NO, NO<sub>2</sub> and NO<sub>x</sub> are given by:

315

$$[NO] = \frac{sNO - sP}{cNO} \quad (\text{Eq 5})$$

$$[NO] = \frac{(sNO_{real} + X_i) - fX_i}{cNO} \quad (\text{Eq 6})$$

$$[NO] = \frac{(sNO_{real} + (1 - f)X_i)}{cNO} \quad (\text{Eq 7})$$

$$[NO_x] = \frac{sNO_x - sP}{cNO_x} \quad (\text{Eq 8})$$

$$[NO_x] = \frac{(sNO_{x_{real}} + yX_i) - fX_i}{cNO_x} \quad (\text{Eq 9})$$

$$[NO_x] = \frac{(sNO_{x_{real}} + (y - f)X_i)}{cNO_x} \quad (\text{Eq 10})$$

$$[NO_2] = \frac{[NO_x] - [NO]}{CE} \quad (\text{Eq 11})$$

$$[NO_2] = \frac{(sNO_{x_{real}} + (y - f)X_i)}{cNO_x \times CE} - \frac{(sNO_{real} + (1 - f)X_i)}{cNO \times CE} \quad (\text{Eq 12})$$

320

where  $c$  is the ‘span factor’ and  $CE$  represents the conversion efficiency. If we assume  $cNO_x \approx cNO \approx c$ , then

$$[NO_2] = \frac{(sNO_{x_{real}} + (y - f)X_i) - (sNO_{real} + (1 - f)X_i)}{c \times CE} \quad (\text{Eq 13})$$

From Eq 13, it may be seen that if  $y = 1$  (*i.e.* if the interferant – alkene – abundance is not affected by passage through the Mo converter), then there would be no interference observed in the retrieved  $NO_2$ , while if the interferant species is subject to removal during passage through the converter, then  $y < 1$  and a negative interference would be observed. Molybdenum oxide catalysts have been reported to efficiently isomerise alkenes at temperatures between 300 – 400 °C, (Wehrer *et al.*, 2003) and are also effective catalysts for the epoxidation of alkenes (Shen *et al.*, 2019). The observed small negative interference effects (for monitors 1 and 2, the Mo converter units), in the absence of significant sampled  $NO_x$ , may reflect partial removal of the alkene on the converter.

The negative  $NO_2$  interference apparent for monitors 3 and 4 (photolytic converter instruments) is more difficult to rationalise (as no Mo catalyst is present). Under ambient conditions, where  $NO_x$  is present, mechanism (3) may occur as outlined below. In reality, the conversion efficiency for photolytic converters is substantially lower than 100% (Reed *et al.* 2016), as a consequence of both the finite photolysis intensity achievable, and occurrence of the  $NO + O_3$  back reaction. If the instrument calibration factor for  $NO_x$  is not equal to that for  $NO$  (see Eq 12), or if alkene was removed in the convertor stage, then this

335

will lead to different interferences for NO and NO<sub>2</sub>, as CE is also (significantly) less than 1. This trend is apparent in the values shown in Table 3, in particular for the instruments fitted with photolytic convertors. However, in the absence of sampled NO<sub>x</sub> the observed less-positive or even negative NO<sub>2</sub> interference suggests that less alkene is present in the NO<sub>x</sub> mode. Direct  
340 photolysis of alkenes is unlikely to cause such a change, considering the photolytic converter wavelength envelope, but photolytic production of HO<sub>x</sub> radicals (which then react with the alkene) may be responsible.

Monitor 4 (AQD) used independent NO<sub>2</sub>\* detection channels; tests were conducted using both channels for cis-2-butene and terpinolene systems, and revealed significant differences between the two detectors (*ca.* 40% lower interference response for  
345 NO in the NO<sub>2</sub> detection channel). With two independent detection channels, NO<sub>2</sub> may be determined from the NO<sub>x</sub> measurement by either subtracting the NO level obtained from the NO channel (method (a)), or via the difference in signal observed in the NO<sub>2</sub>/NO<sub>x</sub> channel when turning the photolysis lamp on and off (method (b)). Under method (a), as employed for cis-2-butene and terpinolene, a lower positive interference from alkene chemiluminescence results, as a consequence of the difference in the detection cell conditions (results marked \* in Table 3), while under method (b), as employed for the other  
350 alkenes studied here with the AQD system, the interference (from mechanism 4 alone) should cancel out (results marked # in Table 3).

### **Effect of quenching by the alkenes**

The data presented in Figures 2-4 and Tables 2 and 3 show both negative and positive interferences while mechanism 4 alone would be expected to result in positive interference signals for NO for all alkenes. We therefore conclude that additional  
355 mechanisms are occurring. Under the conditions of these chamber experiments, retrieval of additional NO<sub>y</sub> species can be precluded (the chamber wall source of HONO has been characterised and shown to produce ppt levels of HONO under the dark, dry conditions of these experiments (Zador *et al.*, 2005) and would be equally present for all experiments). We attribute the negative (or reduced positive) interference effects to a combination of mechanisms (1) and (3): quenching of excited OH (produced by alkene+ozone reaction) by alkenes – electron rich alkenes have been shown to be effective quenchers (Gersdorf  
360 *et al.*, 1987; Chang and Schuster, 1987) - and generation of HO<sub>x</sub> radicals within the instrument following on from the ozonolysis reaction.

The alkene-ozone reactions are known to produce OH, HO<sub>2</sub> and RO<sub>2</sub> radicals both directly (e.g. Johnson and Marston, 2008), following the photolysis of other alkene-ozone reaction products (e.g. carbonyl compounds), and through OH-alkene reactions.  
365 Peroxy radicals promote the conversion of NO to NO<sub>2</sub>, altering the abundance of both species (the formation of NO<sub>x</sub> reservoirs such as nitric acid and organic nitrates will also occur, but will be negligible on the timescale of operation of most instruments).

The ozonolysis of TME results in the production of OH with close to unity yield (IUPAC, 2018) and if taking into account the above mechanism (4) only, might be expected to exhibit a large interference in NO mode. Table 2 shows no interference for

370 monitors 1 and 2 (Mo convertor units) and negative and positive interferences for monitors 3 and 4 (photolytic convertor units) respectively, and so is hard to rationalise (for NO mode). The addition of CO as a scavenger for OH led to an increase in the NO signal for all monitors. A possible origin of this signal is the chemiluminescence production of the excited intermediate HOCO (from reaction of vibrationally excited OH, from the ozonolysis of TME, with CO), which has a temperature and pressure dependent rate of reaction, (Atkinson *et al.*, 2006; Li and Francisco, 2000) and is consistent with the larger NO signal  
375 in the photolytic monitors (Table 2).

## Conclusion

The interference in chemiluminescence NO<sub>x</sub> measurements from alkenes has been systematically investigated using four commercially available monitors. Varying degrees of interference in the NO and NO<sub>2</sub> signals were observed for all monitors investigated, attributed to a combination of mechanisms 1, 3 and 4, particularly the incomplete subtraction of  
380 chemiluminescence from the products of alkene-ozone reactions, manifest due to significant removal of the alkene during the instrument background cycle. Monoterpenes,  $\alpha$ -terpinene and terpinolene, exhibit the largest interferences followed by 2,3-dimethyl-2-butene (TME) and trans-2-butene, in line with the calculated Kinetic Interference Potential, KIP (see Table 4). The KIP can be used as a crude indicator for a potential interference of an alkene to a NO signal, but have large margins of error as they do not take into account the variation in the yield of chemiluminescent products and other instrumental differences.  
385 The alkene interference observed with enhanced RH conditions also indicates the need to accurately calibrate chemiluminescence NO<sub>x</sub> analysers under actual sampling conditions.

The NO interferences from alkenes among the monitors investigated in this study ranges from 1 to 11%. The varying responses exhibited by the different monitors reflect differences in the conditions within the instrument (ozone abundance, pressure and  
390 residence time) within the reaction cell and filter specifications. The magnitude of the NO and NO<sub>2</sub> interferences not only vary with different alkenes and commercial monitors, but will also be dependent upon sampling environments (and with ambient NO<sub>x</sub> and alkenes concentrations). Notably, in these experiments the alkene abundance is high compared with most ambient air samples – consequently internally generated OH will react essentially exclusively with the alkene, which may not reflect ambient sampling – but which we do not expect to impact the conclusions reached with respect to mechanism 4, interference  
395 in retrieved NO levels. Further research to explore these impacts, and other parameters (*e.g.* H<sub>2</sub>O abundance), is urgently needed. The chemiluminescence from monoterpene ozonolysis should also be investigated to identify emission spectra of possible interfering species; given the varying OH yields and energetics from the ozonolysis of different alkenes, their intensity of emission are likely to vary. A combination of selective long-pass filters and detector characteristics can then be exploited within chemiluminescence NO<sub>x</sub> monitors to eliminate such interferences with similar emission spectra to NO<sub>2</sub>\*.

400

Mixing ratios of NO<sub>x</sub> vary from > 100 ppb in some urban areas, *e.g.* Marylebone Road (Carslaw *et al.* 2005), < 300 ppt in biogenic environments (Hewitt *et al.* 2010) and < 35 ppt in remote areas (Lee *et al.* 2009). For typical urban environments where alkene mixing ratios are relatively low (< 2 ppb *e.g.* von Schneidmesser *et al.* 2010) the interferences identified here are not likely to be significant (~ 1% of the NO signal). However, for biogenic environments where monoterpenes and sesquiterpenes, which react rapidly with ozone, are abundant, the interference could be significantly larger. For example, average mixing ratios for isoprene (~ 1 ppb), 5 monoterpenes (~ 220 ppt), 3 short chain alkenes (~ 240 ppt) and NO (0.14 ppb) were measured within a south-east Asian tropical rainforest (Jones *et al.*, 2011). Using the relationship between KIP and NO interference an overestimation of NO levels of up to 58% would result, with very significant implications for prediction of other atmospheric chemical processes involving NO<sub>x</sub>. Given that NO<sub>x</sub> mixing ratios are relatively small in biogenic and remote environments, these interferences could lead to their substantial overestimation. Such alkene interference may contribute to the relatively high NO and low NO<sub>2</sub> reported in the tropical rainforests at night, which could not otherwise be accounted for (Pugh *et al.* 2011).

Within indoor environments, NO<sub>x</sub> primarily arises from outdoor sources or indoor combustion sources (Young *et al.*, 2019). Typically, in the absence of a known indoor combustion source, indoor NO levels are low (*ca.* 13% of outdoor levels) with NO<sub>2</sub> comprising the majority of the NO<sub>x</sub> (Zhou *et al.*, 2019). There are multiple sources of alkenes indoors, such as fragranced volatile personal care products (Nemafollahi *et al.*, 2019; Yeoman *et al.*, 2020) and cleaning products (Kristenson *et al.*, 2019), resulting in very much larger levels than NO<sub>x</sub> (McDonald *et al.*, 2018; Kristenson *et al.*, 2019). Consequently, monoterpenes are among the most ubiquitous VOC reported for indoor air, with the main species including, linalool,  $\alpha$ -pinene,  $\beta$ -myrcene and limonene (Krol *et al.* 2014; Nematollahi *et al.* 2019). Peak limonene mixing ratios may be a factor of *ca.* 50 higher indoors than outdoor environments (Colman Lerner *et al.*, 2012). Although monoterpenes,  $\alpha$ -pinene, myrcene and limonene show no significant NO interferences in chemiluminescence NO<sub>x</sub> monitors, other fast reacting monoterpenes (with O<sub>3</sub>) such as  $\alpha$ -terpinene and terpinolene which are not generally reported in the literature, exhibit quite large interferences and may lead to very substantial overestimations in indoor NO<sub>x</sub> measurements. Monoterpene mixing ratios in indoor environments can be further enhanced by cleaning activities (Singer *et al.*, 2006; Kristenson *et al.*, 2019; Weschler and Carslaw, 2018). Indoor  $\alpha$ -terpinene and  $\alpha$ -pinene mixing ratios have exceeded 10 and 68 ppb, respectively (Singer *et al.*, 2006; Brown *et al.*, 1994). These relatively large monoterpene mixing ratios may lead to substantial interferences in chemiluminescence NO<sub>x</sub> monitors; their incorrect retrieval as measured “NO<sub>x</sub>” will impact assessments of indoor air chemistry, indoor air quality and hence health.

## Data Availability

Experimental data are available in the Eurochamp database, [www.eurochamp.org](http://www.eurochamp.org), from the H2020 EUROCHAMP2020 project, GA no. 730997

## Author Contributions

435 MSA, WJB and JDL conceived and planned the experiments. MSA, JDL, MV, AM and MR performed the experiments. LRC, LJK and MSA performed the data analysis. LRC, LJK, MSA, CF and WJB contributed to data investigation and curation. MSA wrote the original draft manuscript and all co-authors contributed to reviewing and editing the paper.

## Competing Interests

The authors declare that they have no conflict of interest.

## 440 Acknowledgements

This work was funded in part through the UK Natural Environment Research Council (NERC) project “ICOZA: Integrated Chemistry of Ozone in the Atmosphere” (NE/ K012169/1) and by the EUROCHAMP-2 Transnational access project “NOxINT: NOx analyser interference in chemically complex mixtures“ (E2-2010-05-26-0033) . Part of this work has received funding from the European Union’s Horizon 2020 research and innovation programme through the EUROCHAMP-2020  
445 Infrastructure Activity under grant agreement No. 730997. CEAM is partly supported by the IMAGINA-Prometeo project (PROMETEO2019/110) and by Generalitat Valenciana. In addition, we thank Eva Clemente for their work in these experiments.

Table 4: Kinetic ranking of interference potential: the percentage of the potential chemiluminescent signal from ozonolysis of a given alkene which would not be removed by a standard instrument background cycle, under conditions (ozone mixing ratio, residence time) which would remove 99% of the NO sampled. Rate constants are taken from Calvert et al. (2000);  $k_{(NO+O_3)} = 1.90 \times 10^{-14} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  (298 K). NB: this ranking does not include variations in the yield of chemiluminescent products with alkene structure, which will modulate the values given. Species marked \* are investigated in this study.

Species	$k_{(\text{Alkene}+O_3)}$ (298 K) / $\text{cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$	Kinetic Interference Potential (%)	No. of C=C bonds	No. of terminal C=C bonds
Ethene	$1.58 \times 10^{-18}$	0.04 *	1	1
1-Butene	$9.64 \times 10^{-18}$	0.23	1	1
2,3-dimethyl-1-butene	$1.00 \times 10^{-17}$	0.24	1	1
Propene	$1.01 \times 10^{-17}$	0.24 *	1	1
1-pentene	$1.06 \times 10^{-17}$	0.26	1	1
Isobutene	$1.13 \times 10^{-17}$	0.27 *	1	1
Isoprene	$1.28 \times 10^{-17}$	0.31 *	1	1
2-methyl-1-butene	$1.30 \times 10^{-17}$	0.31	1	1
$\beta$ -pinene	$1.50 \times 10^{-17}$	0.36 *	1	1
$\alpha$ -cedrene	$2.80 \times 10^{-17}$	0.68	1	0
3-carene	$3.70 \times 10^{-17}$	0.89	1	0
$\alpha$ -pinene	$8.66 \times 10^{-17}$	2.08 *	1	0
cis-2-butene	$1.25 \times 10^{-16}$	2.98 *	1	0
cis-3-hexane	$1.44 \times 10^{-16}$	3.43	1	0
trans-3-hexane	$1.57 \times 10^{-16}$	3.73	1	0
$\alpha$ -coapene	$1.58 \times 10^{-16}$	3.76	1	0
trans-2-butene	$1.90 \times 10^{-16}$	4.50 *	1	0
Limonene	$2.00 \times 10^{-16}$	4.73 *	2	1
2-carene	$2.30 \times 10^{-16}$	5.42	1	0
2-methyl-2-butene	$4.03 \times 10^{-16}$	9.31	1	0
Myrcene	$4.70 \times 10^{-16}$	10.77 *	3	2
2,3-dimethyl-2-butene	$1.13 \times 10^{-15}$	23.96 *	1	0
Terpinolene	$1.90 \times 10^{-15}$	36.90 *	2	0
$\alpha$ -humulene	$1.20 \times 10^{-14}$	94.54	3	0
$\beta$ -carophyllene	$1.20 \times 10^{-14}$	94.54	2	1
$\alpha$ -terpinene	$2.10 \times 10^{-14}$	99.38 *	2	0
