

Abstract

Lidar backscatter and wind retrievals of the planetary boundary layer height (PBLH) are assimilated into 22 hourly forecasts from the NASA Unified - Weather and Research Forecast (NU-WRF) model during the Plains Elevated Convection at Night (PECAN) campaign on July 11, 2015 in Greensburg, Kansas, using error statistics collected from the model profiles to compute the necessary covariance matrices. Two separate forecast runs using different PBL physics schemes were employed, and comparisons with 6 independent radiosonde profiles were made for each run. Both of the forecast runs accurately predicted the PBLH and the state variable profiles within the planetary boundary layer during the early morning, and the assimilation had a small impact during this time. In the late afternoon, the forecast runs showed decreased accuracy as the convective boundary layer developed. However, assimilation of the doppler lidar PBLH observations were found to improve the temperature and V velocity profiles relative to independent radiosonde profiles. Water vapor was over corrected, leading to an increased differences with independent data. Errors in the U velocity were made slightly larger. The computed forecast error covariances between the PBLH and state variables were found to rise in the late afternoon, leading to the larger improvements in the afternoon. This work represents the first effort to assimilate PBLH into forecast states using ensemble methods.

1 Introduction

The planetary boundary layer (PBL) plays an important role in both weather and climate. This layer is where the Earth's surface interacts with the atmosphere, exchanging heat, moisture and pollutants. The PBL height (PBLH) is central to these interactions and is controlled by the energy flux from the surface. Under certain conditions during daytime it defines the convective boundary layer (CBL) and during nighttime it is the stable (non-convective) boundary layer (SBL). Trace gases and aerosols emitted from the surface are rapidly transported within this layer by turbulent atmospheric motion, and transfer of energy and mass into the free troposphere occurs across an interfacial layer at the top of the PBL. The PBLH is fundamental to weather, climate, atmospheric turbulence and pollution through its role in land-atmosphere interactions and mediation of Earth's water and energy cycles (Santanello et al. 2018). It affects convection in the troposphere, which is generally initiated within the boundary layer and then penetrates

42 the top (Hong and Pan, 1998; Browning, et al. 2007). Thus, accurate knowledge of the
43 PBLH is essential for both weather, pollution and climate forecasting.

44 The PBLH is defined by thermodynamic properties such as a temperature inver-
45 sion or hydrolapse which can be measured by radiosonde. Alternatively, the drop off in
46 aerosol concentration that occurs across the top of the PBL is used, since aerosols are
47 well mixed throughout the PBL (Hicks, et al., 2019). Atmospheric models rely on pa-
48 rameterization schemes to define the structure of the PBL and compute PBLH. These
49 are generally either local mixing schemes that use local turbulent kinetic energy (TKE,
50 Janjic, 1994) or non-local flux schemes (Hong and Pan, 1996). Generally, these PBL pa-
51 rameterizations have systematically higher PBLH relative to observed values (Hegarty
52 et al., 2018), and also have difficulties modeling the growth of the convective layer dur-
53 ing the morning. The variety of definitions of PBLH make it difficult to effectively eval-
54 uate existing models or develop new ones.

55 Observations of PBLH are traditionally made by radiosonde measurements, which
56 have high vertical resolution but are expensive to launch frequently and are thus lim-
57 ited to special experiments and/or ill-timed launches (*e.g.* 00/12 UTC National Weather
58 Service launches) with respect to convective and stable PBL development. Likewise, space-
59 borne measurements of the lower troposphere from passive and active instruments are
60 severely limited in vertical, spatial, and/or temporal resolution (Wulfmeyer et al. 2015).
61 Ground based measurement of PBLH has been proposed for an extensive network of ceilome-
62 ters by adding to the functionality of instruments that were designed for measuring cloud
63 heights (Hicks et al., 2016). The ceilometer measures the time required for a laser pulse
64 to return to a receiver, from which the height of the scattering is determined. The in-
65 tensity of the backscatter is correlated with the density of aerosols at a given height and
66 the PBLH is inferred from the location of the maximum negative gradient of the backscat-
67 ter intensity. Several algorithms employ wavelet transforms to identify the location of
68 the negative gradient (*e.g.* Brooks, 2003; Knepp, *et al.*, 2017). This existing network of
69 ceilometers could be used to create a relatively dense network of frequent PBLH obser-
70 vations, as was recommended by the 2009 study from the National Research Council (NRC,
71 2009) and the Thermodynamic Profiling Technologies Workshop (NCAR, 2012).

72 Since the ceilometer PBLH observations were not yet available for the campaign
73 we are using, we employ doppler lidar observations made at the PECAN site in Greens-

74 burg, Kansas, to demonstrate the methodology. The data is from a Leosphere WINDCUBE-
75 200S Doppler lidar owned and operated by the University of Maryland, Baltimore County
76 (Delgado et al., 2016). This lidar operates at an infrared wavelength, and hence receives
77 its strongest backscattered signal within the aerosol-laden PBL and is often below the
78 measurement noise floor above the PBL. The Doppler shift of the backscattered signal
79 is used to calculate wind speed as a function of range, which can then be used to pro-
80 duce a multitude of wind and turbulence variables useful for PBL characterization (e.g.
81 vertical velocity variance and signal-to-noise ratio variance). While Doppler lidars and
82 ceilometers are similar in aerosol detection, a Doppler lidar’s additional wind measure-
83 ment capability makes it more broadly applicable and at times more accurate than a ceilome-
84 ter for PBLH measurement. The PBLH algorithm applied for this study combines sev-
85 eral such aerosol and wind variables for PBLH measurement. Each PBLH retrieval in-
86 volves measurement of turbulence intensity, horizontal wind profiles and backscatter in-
87 tensity. The heights of steep gradients in these quantities are determined using empir-
88 ical thresholds and wavelet transform techniques, and the three estimates are combined
89 using fuzzy logic. This is described at length in Bonin et al. (2018). Additional lidar pa-
90 rameters and the application of the algorithm to PECAN data were presented in Car-
91 roll et al. (2019). The PBLH measurements were made from a repeating 25-minute li-
92 dar scan cycle. This Doppler lidar and PBLH algorithm combination are generally well-
93 suited for accurate and precise measurement of the PBLH during the daytime bound-
94 ary layer, nocturnal boundary layer, and morning transition period (Bonin et al. 2018,
95 Carroll et al. 2019). The evening transition is the most challenging for this setup due
96 to due to difficulties in defining a clear mixing layer during the decay of a turbulent day-
97 time PBL (Lothon et al. 2014).

98 The question remaining is how to assimilate these observations into a numerical
99 weather prediction (NWP) model. A number of studies have explored assimilating ther-
100 modynamic profile measurements from lidar (Hu et al. 2019, Coniglio et al. 2019, Degelia
101 et al. 2019) and have shown that this increases the accuracy of model PBLH estimates.
102 But we are interested assimilating the PBLH observations directly because the ceilome-
103 ter network described above will focus on these retrievals, and satellite missions which
104 measure PBLH are also planned. PBLH is a diagnostic variable in NWP parameterized
105 physics models. This means any correction to PBLH will be lost during the model fore-
106 cast unless the PBLH height observation is used to correct state variables such as tem-

107 perature and moisture. This could be done either by creating an adjoint of the PBL pa-
108 rameterization scheme, or through the use of an ensemble Kalman filter which would de-
109 termine the error covariances between PBLH and state variables in the model. The struc-
110 ture of the covariance, and how the state variables are changed by assimilating PBLH,
111 will depend on which PBL scheme is used. We will show how such a system could work
112 by conducting a posteriori lidar PBLH observation impact experiments using forecast
113 fields from a NASA Unified - Weather and Research Forecast (NU-WRF, Lidard-Peters,
114 2015) model runs for one day during the Plains Elevated Convection at Night (PECAN)
115 campaign on July 11, 2015. The assimilation is done on 22 hourly WRF forecast fields
116 throughout the day without cycling the analysis fields back into the model, using two
117 different PBL parameterizations. In this paper, we demonstrate a new and promising
118 method that uses the lidar-based aerosol backscatter and wind derived PBLH to correct
119 model forecasted state variables. The purpose here is to show how ensemble computed
120 error covariance can transfer observational information from PBLH to the state variable
121 profiles.

122 **2 Methodology**

123 The assimilation methodology is based on the ensemble Kalman filter (EnKF)(Evensen,
124 2009), where the analysis state is the estimate with the minimum estimated errors, rel-
125 ative to the given error statistics. It differs from the EnKF in that the analysis is not
126 used as an initial state for the next model forecast. Rather, two existing one day NU-
127 WRF forecasts, with different PBL physics schemes, are used when lidar measurements
128 are available at a single location. These forecasts were produced as a part of the PECAN
129 campaign in 2015, and we reuse them here to demonstrate the assimilation algorithm
130 that we have developed. These were not ensemble forecasts so we cannot build a stan-
131 dard ensemble Kalman filter from them. Instead we use Ensemble Optimal Interpola-
132 tion (EnOI), in which profiles from neighboring model gridpoints are used to obtain an
133 estimate of error statistics (Oke, *et al.*, 2010; Keppenne, *et al.*, 2014). This approach will
134 allow for the construction of the vertical component of covariance, which is needed in
135 order to understand how PBLH can be used to correct atmospheric profiles through the
136 use of profile and PBLH statistics. We use profiles from nearby model grid points and
137 have tested the system with varying numbers of grid points in the ensemble. An ensem-
138 ble Kalman filter would likely give different covariance information, but the basic rela-

139 tionship between the state variable profiles and the PBLH are determined by the model
 140 in the same manner here.

141 The two NU-WRF simulations use the Mellor–Yamada–Janjic (MYJ)[Mellor and
 142 Yamada, 1974, 1982; Janjic, 2002] and Mellor-Yamada-Nakanishi-Niino level 2.5 (MYNN)
 143 [Nakanishi and Niino, 2009] which are local 1.5 and 2.5 order turbulence closure schemes
 144 respectively. The PBLH in each of these models is estimated using the total kinetic en-
 145 ergy (TKE) method. The NU-WRF forecast state variables are temperature (T), mois-
 146 ture (Q) and velocity (U,V), and we define the forecast vector $\mathbf{x}^f = [T^f \ Q^f \ U^f \ V^f \ (PBLH)^f]$,
 147 where we have combined PBLH with the state variables to enable the covariance calcu-
 148 lation between them. The forecast runs are initiated from the NOAA global forecast sys-
 149 tem (GFS) reanalysis interpolated to the local domain of 30-48N and 84-110 W, with
 150 220×220 lat/lon and 54 vertical levels, at 0 UTC. At this time, the initial state has as-
 151 similated all of the convential and satellite observations globally. The two WRF fore-
 152 cast experiments start at 0 UTC, and are run for 22 and 23 hours for the MYJ and MYNN
 153 experiments, respectively. We use an ensemble of the 20×20 nearest gridpoints, so that
 154 all of the ensemble members are within about 30 km of the lidar observations (since the
 155 grid spacing is about 3 km). Generally, larger ensembles using gridpoints farther away
 156 will result in larger forecast error covariance because the geographic variability. So this
 157 ensemble size was chosen as a balance between ensemble size and geographic localiza-
 158 tion. The forecast standard deviation for PBLH on the chosen ensemble was around 27
 159 m at 22 UTC.

160 The forecast error covariance, \mathbf{P}^f is defined as

$$\mathbf{P}^f = \langle (\mathbf{x}^f - \mathbf{x}^t)(\mathbf{x}^f - \mathbf{x}^t)^T \rangle \quad (1)$$

161 where the summation is over the grid points $i = 1, N_{lon}$, $j = 1, N_{lat}$ and \mathbf{x}^t is the (un-
 162 known) true state, on the discrete model grid. We only assimilate the observation $y^o =$
 163 $PBLH = H(\mathbf{x}^f)$ where H is the non-linear observation operator. The analysis equa-
 164 tion is

$$\mathbf{x}^a = \mathbf{x}^f + \mathbf{K}(y^o - H(\mathbf{x}^f)) \quad (2)$$

165 where the gain matrix, \mathbf{K} is defined by:

$$\mathbf{K} = \mathbf{P}^f \mathbf{H}^T (\mathbf{H} \mathbf{P}^f \mathbf{H}^T + (\sigma^o)^2)^{-1}, \quad (3)$$

166 σ^o is the observation error standard deviation supplied with the lidar retrievals, and is
 167 determined from the combined uncertainty of the vertical velocity variance, velocity gra-
 168 dient and backscatter gradient. Generally, when these quantities change rapidly at the
 169 top of the PBL, then the estimated error is small. The error estimates are larger when
 170 (during the evening), the gradients are much more gradual. \mathbf{H} is the linearized obser-
 171 vation operator for PBLH. Because the PBLH is related to the state variables via the
 172 two PBL physics schemes, determining \mathbf{H} would require linearizing the PBL physics at
 173 every analysis time. Rather, here we use the EnOI described above to get:

$$\mathbf{P}^f \mathbf{H}^T \approx \langle (\mathbf{x}^f - \mu_{\mathbf{x}}^f) (H(\mathbf{x}^f - \mu_{\mathbf{x}}^f))^T \rangle \quad (4)$$

174 and

$$\mathbf{H} \mathbf{P}^f \mathbf{H}^T \approx \langle H(\mathbf{x}^f - \mu_{\mathbf{x}}^f) (H(\mathbf{x}^f - \mu_{\mathbf{x}}^f))^T \rangle \quad (5)$$

175 where $\mu_{\mathbf{x}}^f$ is the mean forecast state of the ensemble of profiles. See Houtekamer and
 176 Zhang (2016) for a review of ensemble Kalman filter techniques.

177 We expect the correlation between the air mass within the PBL and the free tro-
 178 posphere to drop away rapidly, because of limited interactions between them. We found
 179 that this can cause errors in the analysis profiles if error covariance and PBLH is allowed
 180 to continue into the troposphere. To reduce these errors we have added an exponential
 181 decay starting at the model level closest to the PBLH (k_{PBLH}) to define a vertical lo-
 182 calization factor:

$$C_{loc} = exp \left[-\alpha \left(\frac{k - k_{PBLH}}{k_{PBLH}} \right)^2 \right] \quad (6)$$

183 where k is the model level and $\alpha = 8$ is an experimentally determined factor. This en-
 184 sures that the covariance between the PBLH and the state variables becomes small within
 185 a couple of model levels into the free troposphere.

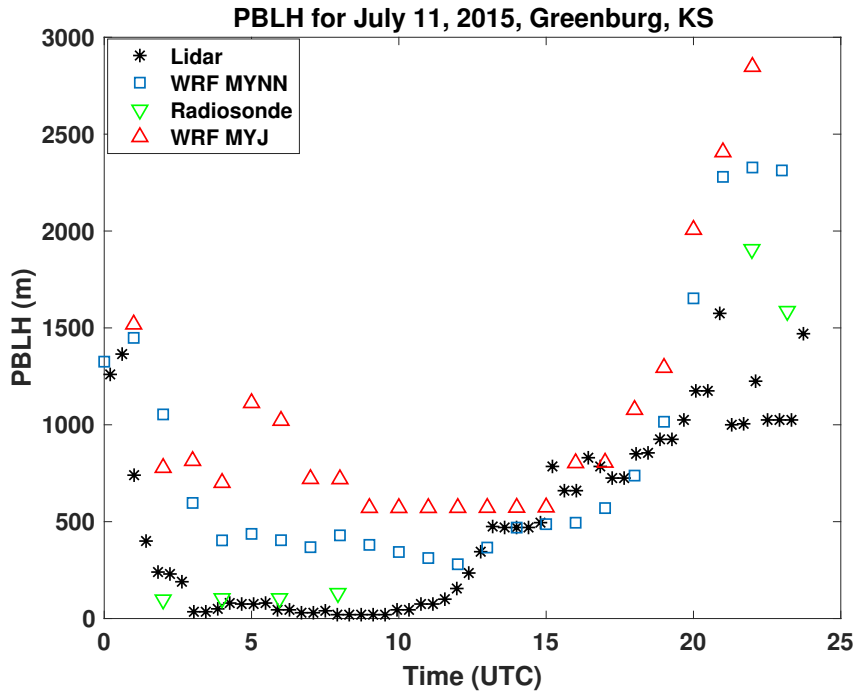

186 This system is solved at each hour using the nearest lidar profile observation in time,
 187 and the resulting analysis fields are compared to radiosonde profiles when the latter are
 188 also available. There are 22 or 23 analyses (for each forecast run), and 6 times where com-
 189 parison with radiosonde profiles are made. We focus on the impact of the assimilation
 190 on the state variables T, Q, U and V rather than the PBLH because only the state vari-
 191 ables would be retained by a forecast.

3 Results

The NU-WRF simulations, taken from existing forecast runs used for the PECAN campaign (Santanello *et al.*, 2019) are initialized using a National Center for Environmental Prediction (NCEP) Global Forecast System (GFS) reanalysis. The two forecast runs were conducted using MYJ PBL physics (2-22 UTC) and MYNN (2-23 UTC) on July 11, 2015. Lidar PBLH observations were made every 25 minutes on that day in Greensburg, KS (37.6 N, 99.3 W), while balloon soundings were launched from that location 6 times as part of the Plains Elevated Convection At Night (PECAN; Gerts *et al.* 2017). Figure 1 shows the PBLH during that day, derived from the two NU-WRF forecasts, lidar observations and soundings. We have determined the sounding PBLH using the parcel method (Holzworth, 1964), which defines the top as the height where the potential temperature first exceeds the ground temperature. The lidar PBLH (black *, derived using the method reported in Bonin, 2018) closely matches the radiosonde estimates (green triangles) in the late evening to early morning (2-7 UTC), while it is somewhat lower in the afternoon. The two NU-WRF forecasts differ from the observations depending on the time of day. In the early morning and early afternoon the MYJ forecasts (red triangles) both are higher than the observations, then rise less than the lidar observations in the late morning and early afternoon (12-17 UTC, there are no radiosonde measurements to compare to here) before rising much higher than the observations in the late afternoon (18-24 UTC).

Since we are primarily interested in the impact of the assimilation on state variables within the boundary layer, in Figures 2 and 3 we plot the RMS difference between the model and the independent (unassimilated) radiosonde profiles from the surface to roughly the top of the boundary layer in the late afternoon. This corresponds to the first 8 layers, or about 800 mb. We use a fixed number of layers so as to make the comparisons of the RMS differences consistent during the day, rather than computing the RMS over a different number of layers as the PBL grows during the day. For the temperature forecast, the RMS difference would be

$$RMS(t_a) = \left[\frac{1}{8} \sum_{i=1}^8 (T_i^f - T_i^{sonde})^2 \right]^{1/2} \quad (7)$$

c

Figure 1. PBLH vs UTC time for July 11, 2015 for lidar backscatter (black *), WRF model - MYJ (red triangles), WRF model - MYNN (blue squares), and radiosonde observations using parcel method (green triangles).

220 where t_a is the analysis time and $i = 8$ is the model level at the top of the PBL in the
 221 late afternoon. Figures 2 and 3 show the RMS differences with the radiosonde profiles
 222 throughout the day for the forecasts (blue x) and analyses (red squares) for potential tem-
 223 perature (upper left), water vapor mixing ratio WV (upper right) and the U (lower left)
 224 and V (lower right) components of velocity.

225 During the night (2-9 UTC), the assimilation has a relatively smaller impact on
 226 the potential temperature RMS differences (upper left) in the early morning (6 and 8
 227 UTC), and the two forecasts have similar accuracy. By late afternoon (22 and 23 UTC,
 228 note that the MYJ forecast stops at 22 UTC) the radiosonde comparisons show that the
 229 assimilation reduces RMS differences in the potential temperatures by around $1.5K$ for
 230 MYJ and $2K$ for MYNN. The water vapor mixing ratio (upper right) also has little im-
 231 pact from the assimilation between 2 and 8 UTC, but at 22 UTC (the next radiosonde
 232 profile) the RMS difference for both MYJ and MYNN analysis increase by at least $1.5 \times$
 233 $10^{-3} kg/kg$ in the late afternoon. The U-velocity profiles (lower right) show small dif-
 234 ferences between the MYJ and MYNN through 8 UTC (3 a.m. local time) and the as-
 235 similation increases the RMS differences with radiosonde profiles by nearly $1m/2$ start-
 236 ing at 22 UTC for both models. The V-velocity profiles (d) begin to differ between MYJ
 237 and MYNN for the forecasts at 8 UTC ($0.5m/2$ decrease), and assimilation also decreases
 238 the RMS differences with radiosondes in late afternoon by $1.5 - 2m/s$.

239 We would like to understand why there is a smaller impact during night time and
 240 early morning, whereas there are decreases in the RMS differences in temperature and
 241 V velocity and increases in moisture and U velocity in the late afternoon. To this end,
 242 we plot the forecast, analysis and radiosonde profiles (T, Q, U and V) at 4 UTC (11 p.m.
 243 local time) and 22 UTC (5 p.m. local time) in Figures 4-7. At 4 UTC, (Figures 4,5) these
 244 clearly indicate that there are small corrections made by the assimilation, as the red and
 245 blue profiles closely overlap. But it also shows that the profiles (particularly tempera-
 246 ture and moisture) more accurately follow the radiosonde profiles (except for the U ve-
 247 locity above the PBL), meaning that there is less room for improvement to the forecast
 248 state. In contrast, Figure (1) shows that the forecast PBLH (particular MYJ) is quite
 249 a bit higher than the lidar observation at 4 UTC. In the late afternoon (Figures 6, 7)
 250 indicate that there are large differences between the forecast and radiosonde profiles for

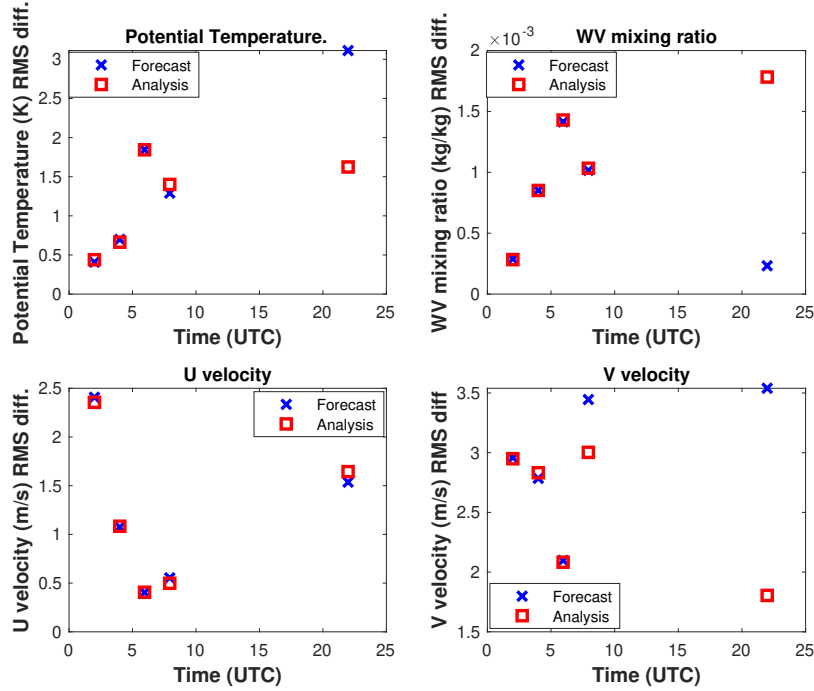

Figure 2. RMS difference for lowest 8 layers, vs. time of forecast (blue x) and analysis (red square) with radiosonde profiles for potential temperature (upper left), water vapor (upper right), U velocity (lower left) and V velocity (lower right).

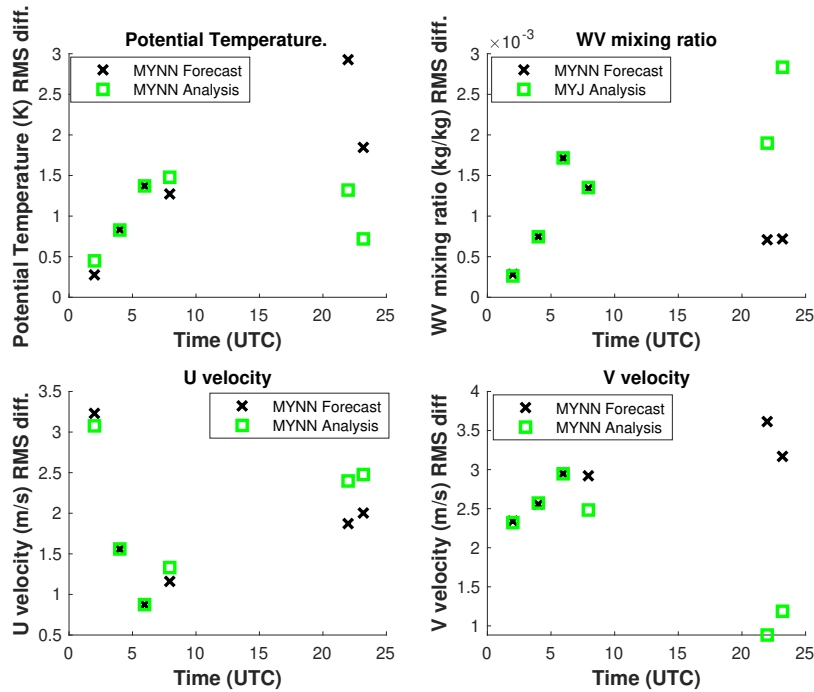

Figure 3. Same as Figure 2, but for MYNN PBL model, with forecast (black x) and analysis (blue square).

251 all of the state variables, and the forecast PBLH values differ substantially from the li-
 252 dar measurements as well. The correction to to the forecast profiles generally pushes the
 253 analyses towards the independent radiosonde profiles, particularly for temperature and
 254 V velocity.

255 So the forecasts that that predicted both PBLH and state variables with relatively
 256 greater accuracy in the early morning were not corrected, while the less accurate after-
 257 noon forecast was drawn towards the independent radiosonde measurements. The as-
 258 similation also made changes to the vertical velocity (W) in the afternoon, but there is
 259 no independent data to compare with so we have not included it.

260 The WV profile is shown to be increased by the assimilation (since WV and PBLH
 261 are negatively correlated and higher PBLH corresponds to lower WV levels in the PBL
 262 models), but the analysis overshoots the radiosonde WV profile, hence causing the in-
 263 crease in the water vapor RMS difference in Figures 2 and 3. Compared to temperature,
 264 WV is highly variable in time and space and it has been shown in the past that slanted
 265 balloon trajectories under estimate the WV present (Demoz et al 2006; Crook, 1996).
 266 The U velocity difference with the radiosonde is larger for the analysis, but this correc-
 267 tion is more difficult because the differences (at least for MYJ) are both positive and neg-
 268 ative and the PBLH observation only contains a single piece of information. The V ve-
 269 locity is, on the other hand, greatly improved by the assimilation. These analysis pro-
 270 files in show that, for this one analysis time, the assimilation is pushing the state vari-
 271 ables in the proper direction for temperature, V velocity and moisture, though the mois-
 272 ture correction overshoots the readiosonde profile. The reason for these corrections to
 273 the state variable profiles is that the error covariance between PBLH and each state vari-
 274 able, $\mathbf{P}^f \mathbf{H}^T$, can be computed from the ensemble of profiles that was collected from the
 275 model grid. The forecast PBLH for each profile was computed using the full PBL physics,
 276 and therefore contains the essential correlation information between these variables.

277 The increasing differences between PBLH and profile forecasts from early morn-
 278 ing to late afternoon only partly explain the much larger impact of the assimilation at
 279 22 UTC. We can also analyze this by plotting the error covariance between PBLH and
 280 each of the state variables, seen in Figure 8 at different times during the day. The co-
 281 variance with temperature is always positive, and grows by a factor of 4 by late after-

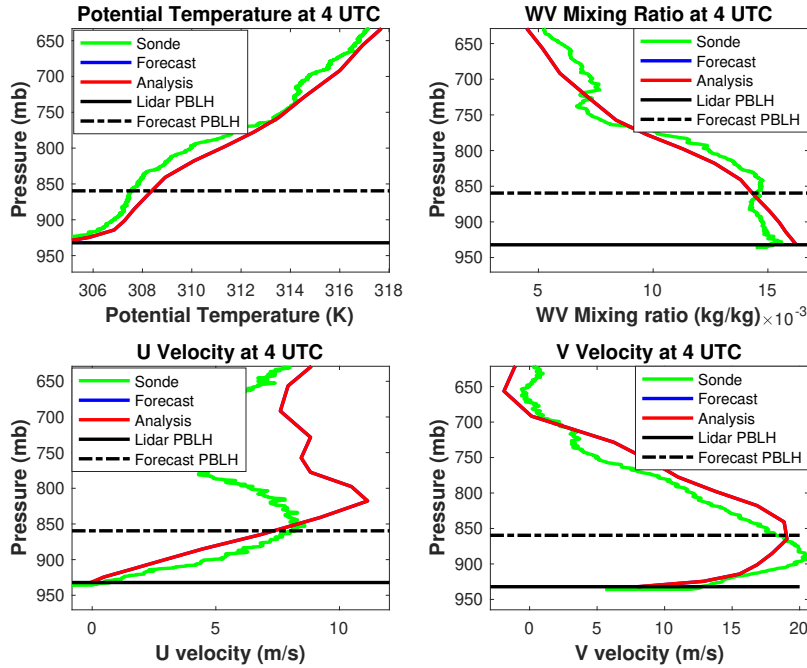

Figure 4. Profiles from radiosonde (green), forecast (blue) and analysis (red) for potential temperature (upper left), water vapor mixing ratio (upper right), u-velocity (lower left) and v-velocity (lower right) at 4 UTC, July 11, 2015 in Greensburg, KS. The model uses the MYJ physics parameterization.

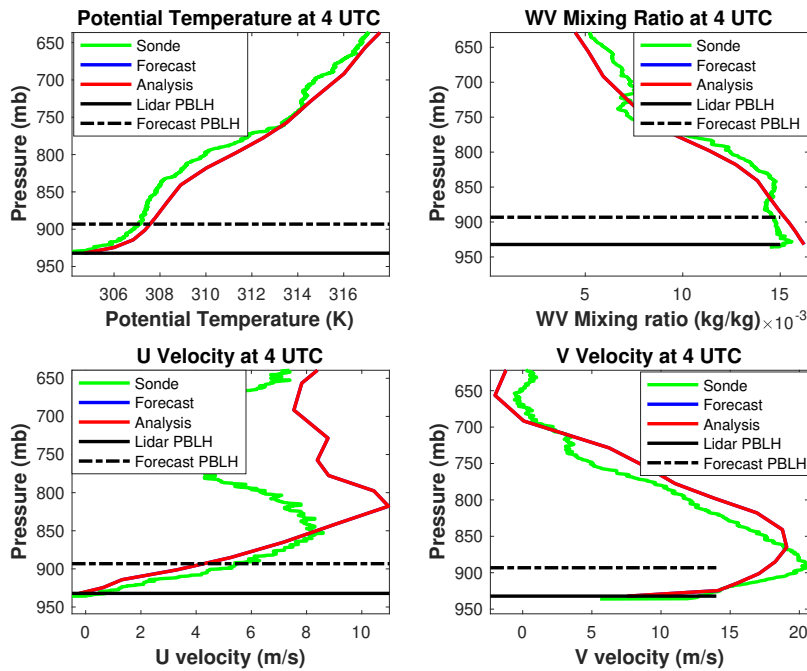

Figure 5. Same as figure 4 except using MYNN model.

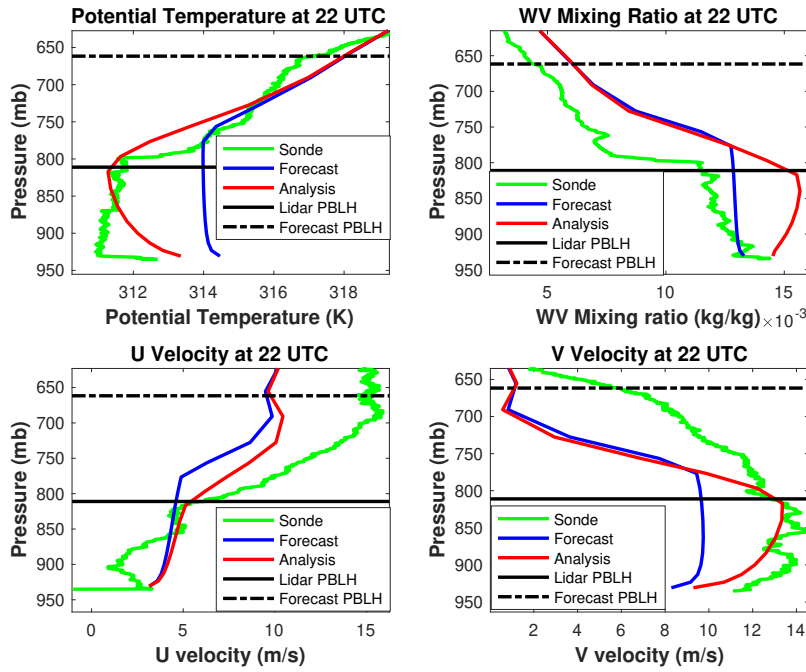

Figure 6. Same as figure 4 except using except at time 22 UTC.

Figure 7. Same as figure 6 except using MYNN model.

282 noon near the surface. The covariance with WV is mostly negative and grows by roughly
 283 a factor of 5, while the covariance with the two components of velocity oscillate between
 284 positive and negative and shows less consistent growth. Thus, the largest impact of as-
 285 simulation on temperature and moisture occurs in late afternoon while more limited ve-
 286 locity corrections are largely constrained by the correlations determined by the ensem-
 287 ble of model forecast states.

Figure 8. Covariance $\mathbf{P}^f \mathbf{H}^T$ between PBLH and temperature (upper left), water vapor (upper right), U velocity (lower left) and V velocity (lower right), at times 4, 8, 22 and 23 UTC, for PBL physics model MYHH.

4 Conclusions

288 These offline data assimilation experiments indicate that assimilating ground based
 289 lidar backscatter and wind measurements of PBLH into a regional NWP model will likely
 290

291 lead to corrections to profiles within the PBL, particularly when this approach is applied
292 to an EnKF assimilation system with cycling. Using two NU-WRF forecasts over a pe-
293 riod of one day with different PBL physics models, we show how the state variables, T,
294 WV, U and V can be corrected using an assimilation system with ensemble based er-
295 ror covariances. During the night and early morning the assimilation has relatively lit-
296 tle impact on the state variables, but by late afternoon the temperature field is drawn
297 closer to independent radiosonde measurements. We have shown that the lack of data
298 impact early in the day is due to the relatively higher accuracy of the model and lack
299 of correlation between the forecast PBLH and temperature profiles at that time. Later
300 in the day, when the model is less accurate in predicting the growth of the boundary layer,
301 the data begins to draw the analyses mostly toward the independent radiosonde profiles.
302 The assimilation over corrected the water vapor mixing ratio in the direction of radiosonde
303 data, and this could likely be tuned in an assimilation system. And it corrected the the
304 V velocity component by a smaller amount, and reduced differences with the radiosonde
305 profiles for the V velocity. These corrections are the result of ensemble computed error
306 covariances between the PBLH and the state variable profiles within the PBL. The re-
307 sults here indicate that this approach has some potential to be used in a forecast sys-
308 tem in a way that that the PBLH observational information could be carried forward
309 in time so as to impact the forecast accuracy within the PBL. An additional value of as-
310 simulating PBLH is its close connection with the PBL scheme used in the model. The
311 covariances between PBLH and the different state variables are defined through the PBL
312 physics scheme. This has an impact on the corrections made to the profiles within the
313 PBL, which can be used as another way to evaluate the physics parameterizations. For
314 example, the MYJ and MYNN result in analysis profiles that differ, particularly in WV
315 in the late afternoon. And the differences in response to assimilation are an indication
316 of how the two different PBL schemes affect the covariance between PBLH and the state
317 variables. However, a full evaluation would require that the assimilation be implemented
318 into a cycling data assimilation system.

319 This work is intended only to demonstrate a necessary first step in terms of how
320 ensemble statistics can help to constrain profiles within the PBL by assimilating PBLH
321 observations. A more complete demonstration of this approach will require the construc-
322 tion of an EnKF, and run over many days with a variety of weather patterns, including
323 significantly warmer(cooler) and wetter(drier) days. This is needed to show how the as-

324 simulated PBLH observations will impact future forecasts within the PBL. In addition,
325 an EnKf will involve spatial covariances in both horizontal and vertical directions, and
326 will allow for both inflation and horizontal localization. This will enable further tuning
327 of the system to optimize the analysis state relative to the independent radiosonde ob-
328 servations. The PBLH assimilation within the EnKF framework could be done in any of
329 numerous existing enKF assimilation systems that connect with WRF, including NU-
330 Wrf (Lidard-Peters *et al.*, 2015) and WRF-DART (Anderson *et al.*, 2009).

331 **5 Acknowledgments**

332 B. Demoz was funded by National Science Foundation award (AGS-1503563) to
333 the University of Maryland, Baltimore County and through NOAA Cooperative Science
334 Center in Atmospheric Sciences and Meteorology, funded by the Educational Partner-
335 ship Program at NOAA in collaboration with Howard University.

336 **6 Data Sets**

337 PECAN (https://data.eol.ucar.edu/master_list/?project=PECAN\verb) data are
338 archived by NCAR/EOL, which is funded by NSF. The forecast and analysis fields pro-
339 duced for this work are stored at <https://alg.umbc.edu/pecan/>.

340 **7 Competing Interests**

341 The authors declare that they have no conflict of interest.

342 **8 Author Contributions**

343 Andrew Tangborn built the assimilation system, with input from Jeffrey Anderson on
344 the algorithm. Belay Demoz and Brian Carroll provided the lidar observations. Joseph
345 Santanello provided background information on PBL physics. All of the authors contributed
346 to writing and revising the paper.
