1 Answer to Referee's general comment

We thank the Referee for the detailed and constructive review, it helped us improving the readability and quality of our study.

We agree that the abstract brings many detailed quantitative information and that it is not easy to retain all of them. We have rephrased the part in the abstract where the statistics are provided, and therefore improved the readability. Unfortunately, it is not recommended by the AMT guidelines to include a table in the abstract. However, Table 5 brings exactly what requested by Referee#1 including the information about the portion of troposphere covered by the daytime and nighttime statistics.

2 Answer to Referee's specific comments

During daytime measurements in the lower troposphere, and nighttime measurements in whole troposphere, mean bias are found $\mu = 0.02 \pm 0.1$ K and $\mu = 0.05 \pm 0.34$ K respectively. How would you comment those big errors?

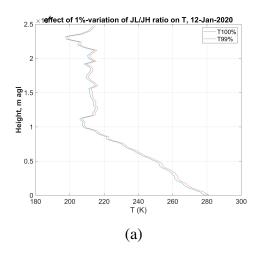

The daytime $\mu = 0.02 \pm 0.1$ K and the nighttime $\mu = 0.05 \pm 0.34$ K are the mean biases along the atmospheric regions where the daytime and nighttime temperature profiles are calculated. Each mean bias is provided with a variability, i.e. the standard deviation of the biases. Based on values of σ of 0.62 K (day) and 0.66 K (night), representing the standard deviation of all differences $\Delta T = T_{\rm ral} - T_{\rm ors}$ over which μ is calculated, a variability of 0.1 K (day) and 0.34 K (night) can be expected.

3 Answer to Referee's Technical corrections

:

- 1. Page 1 Line 18-19 "imperfect subtraction" of the background from the daytime PRR profiles induces a bias of up to 2 K at all heights. In which figure is this represented?
 - The results have not been included in the paper because we deemed that it was out of the scope of the study. However, the sensitivity test of the calculated temperature with respect to a variation of 1% of the ratio J_{low}/J_{high} has been carried out and is shown in figure 1. The plot in panel (b) shows as a change of 1% can induce up to 2 K difference in the lower part of the profile.
- 2. Page 3 Line 3 "Trustworthy references can be provided by co-located radiosondes, satellites or a numerical models." Probably "a" should be removed.

 done

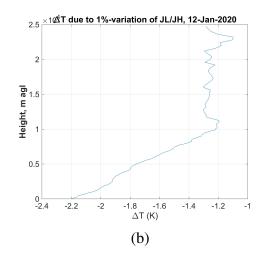

Figure 1: Differences in the calculated temperature induced by a relative change of 1% in the ratio J_{low}/J_{high} .

- 3. Figure 1 (and for all similar graphs) St. dev and median are calculated after averaging, so maybe it should be mentioned at the label.

 The median and St. Dev. have been removed from Figures 1-3 after the technical review.
- 4. Page 4 Line 9-10 "Figures 1 and 2 show the statistical biases of the SRS-C50 and the RS41 with respect to the reference RS92 as a function of height for the day and night-time launches." In order to be better-structured, figures or the SRS-C50, RS41 should be reversed.

 Done
- 5. Page 11 Line 23 "Once the signals corrected, their ratio is used used to retrieve the temperature" the word used should be removed.

 Done.

1 Answer to Referee's general comment

We thank the Referee for the detailed and constructive review provided. We can see that our article is improved by implementing your suggestions.

We appreciate your suggestion to remove the part on cloud supersaturation and to rather put it in a separated publication. We understand that the paper is already long and, even without the supersaturation study, presents already all useful results needed to validate thoroughly the temperature product. Even if the application to a real case of liquid cloud supersaturation is important and provides a direct tool to validate a product that is largely undersampled currently across the scientific community, we agree to remove the chapter on supersaturation. This part will be integrated in a separate publication and submitted as new scientific article.

2 Answer to Referee's specific comments

Sect.1, The last two paragraphs should be combined to avoid repetition. Done.

Sect.3, Page7, Line 8: If only 2 of the 4 telescopes are used for temperature and humidity measurements, what are the other 2 telescopes for?

all four telescopes collect the backscattered signal and transmit it through the REF to the H_2O polychromator. Two mirrors reflects the collected backscattered signal onto the REF and transmit it to the temperature polychromator.

Sect.3, P7, L7: The tilted filter induces polarization effects. Have polarization issues been studied?

Yes. There is a full study that has been conducted, because we are in the process to implement a new depolarization channel. The REF at 9° induces only a negligible depolarisation s. The figure 1 below shows that all signals (p+s) are reflected by the REF without modification.

Sect.3, P8, L6: Please name type and manufacturer of the PMTs.

Done.

Sect.4, P12, L16: Probably, the step width is 0.01 ns?

Indeed!! Corrected, thanks!

Sect.4, P12, L26: The dead times differ significantly. Do you have an explanation? Do you use different PMTs?

Yes each channel has a dedicated PMT. In principle, the dead-time is provided as a specification of the acquisition card (in this case the FastCom P7888), but the PMT, from which the acquisition card gets the number of photons can modify the deadtime significantly.

Sect. 4, P13, L4ff.: Why is this so? At 50-60 km, the 'weaker' (as you say) J_{high} signal should contain only background photons, and so, in theory, background subtraction should be OK.

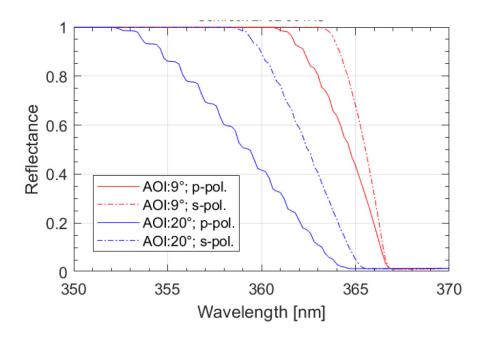

Figure 1: Reflectance for two tilt angles (angle of incidence, AOI) of 9° and 20° ; the half-angle cone of the reflected light is 8.5° . The data are computed by the manufacturer's on-line simulation tool

Yes, "it should", and that is why the standard procedure takes the far range averaged signal and subtract it from the entire signal. However, from a computational point of view, the operation of calculating a mean value (MATLAB in our case) introduces a very small error, due to the not limitless precision of this operation. A slight overestimation or underestimation with respect to the true value generates fractions of percentage-error after subtraction that then cause the temperature to have up to 1 K or 2 K bias.

Sect. 4, P15, Fig. 9 (and others): The temperature profiles are presented starting at 500 (or 600)m. Given the fact that Payerne is at about 450 m asl, this is quite close to the ground and probably within the region of incomplete overlap. At what altitude does RALMO reach full overlap? Do you have instances where an incomplete overlap may have caused measurement errors?

Payerne station is at 491 m a.s.l., RALMO's full overlap occurs at an altitude of ≈ 4000 m. However, the temperature measurement is not really affected by the incomplete overlap in the region 500-4000 m a.s.l. as it is proportional to the ratio $J_{low}(z)/J_{high}(z)$ and both $J_{low}(z)$ and $J_{high}(z)$ have the same overlap function.

Sect. 5, P17, L1ff.: Exclusion of measurements within clouds from the statistics are justified by the attenuation of the signals and the subsequent increase in SNR. Because of the proximity of the elastic line, however, blocking might be an issue as well. Have the authors attempted to measure PRR temperatures in clouds? How well does the double-polychromator setup suppress elastic light in the PRR signals? Up to which backscatter ratio (BSR) can the PRR temperature be considered unaffected by particle scattering? Are there any polarization effects? "

This is a very interesting point. The double-stage temperature polychromator has an

almost 100% efficiency in removing the stray light from the elastic signal. However the extinction coefficient of the PRR signal backscattered from a cloudy volume is so high to impede the transmission of the PRR signal through the cloud and back to the telescope as soon as the cloudy volume is one optical depth above the cloud base $(BSR \approx 5)$.

Sect. 6, P25, L20: The 'clouds' presented are actually extremely thin. Even if the stratus were broken, to obtain a mean BSR of only 4 would mean that most of the integration time there was no cloud at all, or only swollen aerosols were present. Profiles of the cloud optical properties [backscatter coefficient, extinction coefficient, lidar ratio (, and depolarization ratio; but probably not available)] plus RALMO humidity and PRR temperatures would make it possible to assess the measurement situation and the RALMO performance much better. Co-location of maximum RH and BSR sounds a bit suspicious, s. blocking comment above. As already mentioned in the summary, the reviewer recommends to discard this section.

The studied clouds (both cases) are indeed thin liquid stratus (15 Nov 2017) and fair weather cumulus (20 May 2018) clouds. In both cases, the colocated ceilometer detected a cloud base. An opaque cloud detected by the ceilometer starts at about BSR; 2. Both cases showed:

- 1. Pre-cloud formation, with fast growing higroscopicity as a precursor of cloud.
- 2. Already formed cloud.
- 3. blocking by fully-developed cloud

The second stage is the one when supersaturation has its onset at the cloud base. All profiles (backscatter, extinction, humidity...) are available and could be added as ancillary information. However, we have decided as mentioned in the general comment to drop the section on supersaturation as suggested by the Referee. This part will hopefully converge into a cloud microphysics dedicated paper.

Math, equations and running text (all):

- 1. All variables must be in italic. Done
- 2. If not a variable, text must not be italic, e.g.: O₂, N₂, high, low, Stokes, AntiStokes, fit, sig, SB, TD, season, max, ss, ... Done, apart for ss that is a variable.

Figures:

1. Fig. 4: There is no wavelength scale as stated in the caption. corrected

- 2. Fig. 5: Is there a 'degree' symbol after 'to Aerosol & T'? Yes.
- 3. Fig. 5: The depiction of the water vapor spectrum would be more realistic if the steep slope was on the blue shoulder.

Thanks for noticing it, we have corrected the WV spectrum.

4. Fig. 6: There are many more holes in the blocks (at the edges) than explained in the running text. What are they for?

The holes surrounding the fiber's block are not active, are available holders for other potential input/output cables. A full description has been added to the figure's caption.

5. Figs. 10, 11: Use same style for panels left and right. Use same x range for STD in both figures.

Axis x - y of the panels in figures 10-11 have been harmonized.

6. Figs. 14, 16: Harmonize x ranges as much as possible. For instance, use 0-120 for availability in all panels, 0-1 for STD.

Done

Correspondence: Giovanni Martucci (giovanni.martucci@meteoswiss.ch)

Abstract. The RAman Lidar for Meteorological Observations (RALMO) is operated at the MeteoSwiss station of Payerne (Switzerland) and provides, amongst other products, continuous measurements of temperature since 2010. The temperature profiles are retrieved from the pure rotational Raman (PRR) signals detected around the 355-nm Cabannes line. The transmitter-receiver system of RALMO is transmitter and receiver systems of RALMO are described in detail and the reception and acquisition units of the PRR channels are thoroughly characterized. The FastCom FastCom P7888 card used to acquire the PRR signal, the calculation of the dead-time and the desaturation procedure are also presented. The temperature profiles retrieved from RALMO PRR data during the period going from July 2017 to the end of December 2018 have been validated against two reference operational radiosounding systems (ORS) co-located with RALMO, i.e. the Meteolabor SRS-C50 and the Vaisala RS41. These radiosondes have also been used to perform seven calibrations. The ORS have also served to perform the calibration of the RALMO temperature during the validation period. The maximum bias $(\Delta T_{max} \Delta T_{max})$, mean bias (μ) and mean standard deviation (σ) of RALMO temperature $T_{\rm ral}$ with respect to the reference ORS, $T_{\rm ors}$, are used to characterize the accuracy and precision of $T_{\rm ral}$ in along the troposphere. The ΔT_{max} daytime statistics provide information essentially about the lower troposphere due to lower signal-to-noise ratio. The $\Delta T_{\rm max}$, μ and σ of the daytime differences $\Delta T = T_{\rm ral} - T_{\rm ors}$ in the lower troposphere are are, respectively, 0.28 K, 0.02±-0.1 K and 0.62±-0.03 K, respectively 0.03 K. The nighttime differences suffer a mean bias of $\mu = 0.05 \pm 0.34$ K, a mean standard deviation statistics provide information for the entire troposphere and yield $\Delta T_{\text{max}} = 0.29 \text{ K}$, $\mu = 0.05 \pm 0.34 \text{ K}$ and $\sigma = 0.66 \pm 0.06 \text{ K}$, and a maximum bias $\Delta T_{max} = 0.29 \text{ K}$ over the whole troposphere 0.06 K. The small $\Delta T_{max} \Delta T_{max}$, μ and σ values obtained for both daytime and nighttime comparisons indicate the high stability of RALMO that has been calibrated only seven times over 18 months. The retrieval method can correct for the largest sources of correlated and uncorrelated errors, e.g. signal noise, dead-time of the acquisition system and solar background. Especially the solar radiation (scattered into the field of view from the Zenith angle Φ) affects the quality of PRR signals and represents a source of systematic error for the retrieved temperature. An imperfect subtraction of the background from the daytime PRR profiles induces a bias of up to 2 K at all heights. An empirical correction $f(\Phi)$ ranging from 0.99 to 1, has therefore been applied to the mean background of the PRR signals to remove the bias. The correction function $f(\Phi)$

¹Federal Office of Meteorology and Climatology, MeteoSwiss, Payerne, Switzerland

²Department of Physics and Astronomy, The University of Western Ontario, London, Canada

³Federal Office of Meteorology and Climatology, MeteoSwiss, Payerne, Switzerland (retired)

has been validated against the numerical weather prediction model COSMO suggesting that $f(\Phi)$ does not introduce any additional source of systematic or random error to $T_{\rm ral}$. A seasonality study has been performed to help understanding if the overall daytime and nighttime zero-bias hides seasonal non-zero biases that cancel out when combined in the full dataset. Finally, the validated RALMO temperature has been used in combination with the humidity profiles retrieved from RALMO to calculate the relative humidity and to perform a qualitative study of supersaturation occurring in liquid stratus clouds.

1 Introduction

Continuous measurements of tropospheric temperature are essential for numerous meteorological applications and in particular for numerical weather predictions, for satellite CAL/VAL applications (Stiller et al., 2012; Wing et al., 2018) and for the understanding of climate change. Co-located temperature and humidity measurements allow to calculate the relative humidity, a parameter playing a key role in several thermodynamic processes, such as the hygroscopic growth of condensation nuclei, fog and cloud formation. When considering the thermodynamic processes occurring within a stagnant air mass, a strong increase in relative humidity it is often a precursor of fog, while the onset of supersaturation is linked to a consolidated radiation fog or a cloud forming at the top of a convective layer. Another important thermodynamic parameter is the convective available potential energy (CAPE); the CAPE is directly related to the temperature difference between two layers in the atmosphere. The knowledge of temperature as a function of altitude allows to monitor the atmospheric thermodynamic stability and to diagnose and forecast the onset and intensity of a thunderstorm. Despite its importance in all these processes, the atmospheric temperature is still undersampled in the lower troposphere where the traditional and well established observing systems (e.g., radiosounding, AMDAR, Mode-S, satellites) do not provide continuous measurements. A vertical profile of temperature in the troposphere can be measured efficiently by ground-based remote sensing instrumentation; differently from other technologies, remote sensing is best suited to operate continuously and to satisfy real-time data delivery requirements. Moreover, remote sensing instruments operating continuously for many years ensure long time series of data, which are fundamental for climatology studies. This study focuses on the measurement of the atmospheric temperature done by a LIght Detection And Ranging (LIDAR) instrument. Best known methodologies to retrieve temperature profiles using a LIDAR can be split into four groups of techniques, the differential absorption LIDAR (DIAL), the high spectral resolution LIDAR (HSRL), the Rayleigh and the Raman techniques (Wulfmeyer et al. (2015) and references therein). Measurements with DIAL are based on the dependency of the molecular absorption on the atmospheric temperature, namely oxygen molecules with their constant mixing ratio in the dry atmosphere are used as targets by DIAL to retrieve the temperature profile (Behrendt, 2005; Hua et al., 2005). The HSRL technique uses the Doppler frequency shifts produced when photons are scattered from molecules in random thermal motion; the temperature dependence of the shape of the Cabannes line is used directly for temperature measurements (Theopold and Bösenberg, 1993; Wulfmeyer and Bösenberg, 1998; Bösenberg, 1998). The Rayleigh method is based on the assumption that measured photon-count profiles are proportional to the atmospheric mass-density profile in a atmosphere that behaves like an ideal gas and that is in hydrostatic equilibrium. The mass-density profile is used to determine the absolute temperature profile (Hauchecorne et al., 1991; Alpers et al., 2004; Argall, 2007). The Pure Rotational Raman (PRR) method relies on the dependence of the rotational spectrum on atmospheric temperature (Cooney, 1972; Vaughan et al., 1993; Balin et al., 2004; Behrendt et al., 2004; Di Girolamo et al., 2004; Achtert et al., 2013; Zuev et al., 2017). A combination of the Rayleigh and Raman methods is also possible and allows to extend significantly the atmospheric region where the temperature is retrieved (Li et al., 2016; Gerding et al., 2008). The four methods have the common objective to produce a temperature profile as close as possible to the true atmospheric status. In the attempt of doing that, a reference must be used to calibrate the LIDAR temperature and calculate the related uncertainty. Trustworthy references can be provided by co-located radiosondes, satellites or a-numerical models. A co-located RS can act as reference to calibrate and monitor the stability of a LIDAR system over long periods of time (Newsom et al., 2013). Our study presents a characterization of the radiosounding systems (RS) in use at Payerne and their validation with respect to the Vaisala RS92 certified by the Global Climate Observing System (GCOS) Reference Upper-Air Network (GRUAN). Assimilation experiments using validated Raman LIDAR temperature profiles have been performed, among others, by Adam et al. (2016); Leuenberger et al. (2020). Both studies highlight the big potential of Raman LIDAR to improve numerical weather prediction (NWP) models through data assimilation (DA).

In this study we characterize and validate RALMO temperature profiles and demonstrate the high stability of the system. The paper is organized as follows: In Section 2 we establish the quality of the reference radiosonde data sets. The LIDAR system is described in detail in Section 3 followed by an uncertainty a thorough uncertainty budget estimation in Section 4. In this section all contributions to the total error are quantified and taken into account (dead-time correction, background correction, photon counting error, calibration error). In Sections 5 and 6 we present the statistics of the comparison between LIDAR and radiosondes. Moreover, the validated RALMO temperature has been used in combination with the humidity profiles retrieved from RALMO to calculate the relative humidity and to perform a qualitative study of supersaturation occurring in liquid stratus clouds (Section ??).

The maximum (ΔT_{max}) and mean bias (μ) of the difference (ΔT) of several LIDAR temperature profiles with respect to temporally and spatially co-located radiosonde profiles represent the systematic uncertainty of the LIDAR temperature. The variability of all differences ΔT over the entire dataset yields the random uncertainty (σ) of the LIDAR temperature. In section 5 we present the statistical analysis of the $\Delta T = T_{\rm ral} - T_{\rm ors}$ dataset and we analyze the possibles possible causes of μ and σ over the period July 2017–December 2018. An additional statistical study has been performed splitting the ΔT dataset into seasons to investigate the effect of solar background and its correction function $f(\Phi)$ on the retrieved temperature profiles in terms of μ and σ (Section 6). Moreover, the validated RALMO temperature has been used in combination with the humidity profiles retrieved from RALMO to calculate the relative humidity and to perform a qualitative study of supersaturation occurring in liquid stratus clouds (Section ??) The maximum ($\Delta T_{\rm max}$) and mean bias (μ) of the difference (ΔT) of the LIDAR temperature profiles with respect to the temporally and spatially co-located radiosonde profiles represent the systematic uncertainty of the LIDAR temperature. The standard deviation of all differences ΔT over the entire dataset yields the random uncertainty (σ) of the LIDAR temperature.

2 Validation of the reference radiosounding systems

15

In the framework of the operational radiosonde flight programme, the operational radiosonde is launched twice daily at Payerne at 11 UTC and 23 UTC (in order to reach 100 hPa by 00 UTC and 12 UTC) and provides profiles of humidity (q), temperature (T), pressure (P) and wind (u). In addition to the operational programme, MeteoSwiss is part of the Global Climate Observing System (GCOS) Reference Upper-Air Network (GRUAN) since 2012 with the Vaisala sonde RS92. In the framework of GRUAN, MeteoSwiss has launched from the aerological station of Payerne more than 300 RS92 sondes between 2012 and 2019, contributing significantly to its characterization (metadata, correction algorithms and uncertainty calculation) and to its GRUAN certification (Dirksen et al., 2014; Bodeker and Kremser, 2015). Before being part of GRUAN and since 2005, MeteoSwiss has used the RS92 sonde as *working standard* in the framework of the quality assurance programme of the different versions of the Meteolabor Swiss RadioSonde (SRS). Different versions of the SRS systems were operated at Payerne since 1990, starting from the analog SRS-400 (from 1990 to 2011) getting to the digital sondes SRS-C34 and C50. Starting from 2012, different versions of the SRS-C34 and SRS-C50 have been compared to the RS92 in the framework of GRUAN. In 2014, the Vaisala RS41 (Dirksen et al., 2019) was added to the GRUAN programme where it performed numerous multi-payload flights with the RS92 and the SRS carried under the same balloon.

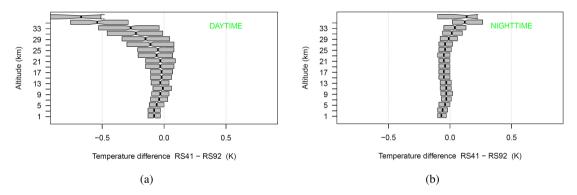

Figure 1. Temperature deviation of the RS41 with respect to the RS92 calculated from the GRUAN multi-payload flights dataset during 2015/06 - 2018/12. The boxes are centered in the mean bias and span the $25^{th} - 75^{th}$ percentile range. Statistics are based on 58 flights at 11 UTC (Fig.1a) and 59 at 23 UTC (Fig.1b).

During the studied period, two different operational radiosounding systems (ORS) have been launched regularly at 11 UTC and 23 UTC, the SRS-C50 (February 2017- March 2018) and the Vaisala RS41 (March-December 2018). Thanks to the multi-sensor flights performed with the SRS-C50, the Vaisala RS41 and the Vaisala RS92, the SRS-C50 and RS41 have been validated by the GRUAN-certified RS92. Figures 1 and 2 show the statistical biases of the RS41 and the SRS-C50 with respect to the reference RS92 as a function of height for the day and night-time launches. The differences have been co-added into altitude boxes of 2 km and the profiles have been sampled every 30 s starting from 15 s after launch. The boxes in the plots have boundaries at the 25th and 75th percentile and are centered (black dot in each box) in the mean value bias.

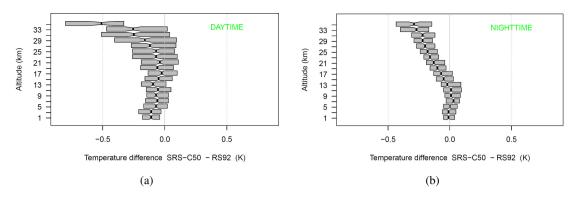

Figure 2. Temperature deviation of the SRS-C50 with respect to the RS92 calculated from the GRUAN multi-payload flights dataset during February–December, 2018. The boxes are centered in the mean bias and span the $25^{th} - 75^{th}$ percentile range. Statistics are based on 25 flights at 11 UTC (Fig.2a) and 26 at 23 UTC (Fig.2b).

The RS41 and the SRS-C50 show an overall negative bias during both day and night never exceeding $-0.1\,\mathrm{K}$ along the whole troposphere. Only in the mid-stratosphere, above $30\,\mathrm{km}$, the daytime biases reach $-0.5\,\mathrm{K}$. In the framework of our study, the region of interest for the temperature profiles measured by RALMO is the troposphere and, more rarely, the UTLS (upper troposphere and lower stratosphere, $\approx 0\text{-}14\,\mathrm{km}$). In this region, as the statistic show, the two ORS perform very well. For the daytime comparisons (11 UTC), the mean bias of the RS41 over the region 0-14 km is $-0.05\,\mathrm{K} \pm 0.03\,\mathrm{K}$ with a mean standard deviation of $0.15\,\mathrm{K} \pm 0.05\,\mathrm{K}$. For the nighttime comparisons (23 UTC), the mean bias of the SRS-C50 for daytime (11 UTC) show a mean bias over the region 0-14 km of $-0.08\,\mathrm{K} \pm 0.02\,\mathrm{K}$ and a mean standard deviation of $0.19\,\mathrm{K} \pm 0.09\,\mathrm{K}$. For the nighttime comparisons (23 UTC), the mean bias of the SRS-C50 over the region 0-14 km is $-0.01\,\mathrm{K} \pm 0.02\,\mathrm{K}$ with a mean standard deviation of $0.13\,\mathrm{K} \pm 0.04\,\mathrm{K}$.

The comparisons with the RS92 show that for both ORS the daytime differences undergo a larger variability along the 0-14 km vertical range compared to the nighttime statistics. The main reason for the larger variability is that, during the daytime flights, the RS92 and the two ORS undergo different exposure to the solar radiation, which causes a different response of the thermocouple sensors. The effect on the thermocouple becomes larger with the altitude as the solar radiation increases with height. All RS are corrected by the manufacturer for the effects of solar radiation on the thermocouple sensors. However, different manufacturers use different radiation corrections, which contributes to the statistical broadening of the differences at all levels. The overall (11 UTC and 23 UTC) performance of the two ORS in terms of bias with respect to the reference RS92 is summarized in figure 3. The distribution and mean value of the differences confirm that in the first 15 km the two ORS remain well below the -0.1 K-bias. The RS41 shows closer values to the RS92 than the SRS-C50 especially in the stratosphere. The better statistics of the RS41 should be interpreted also in light of the fact that the RS92 and the RS41 are both manufactured by Vaisala.

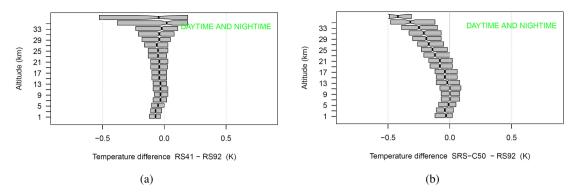

Figure 3. Overall temperature deviations at 11 and 23 UTC of the RS41 (Fig. 3a) and the SRS-C50 (Fig. 3b) with respect to the reference sonde RS92. The interpretation of the graphics is the same as for the previous figures.

3 The RAman LIDAR for Meteorological Observations - RALMO

RALMO was designed and built by the École Polytechnique Fédérale de Lausanne (EPFL) in collaboration with MeteoSwiss. After its installation at the MeteoSwiss station of Payerne (N $46^{\circ}48.0'$, E $6^{\circ}56.0'$, 491 m a.s.l.) in 2007 it has provided profiles of q, T and aerosol backscatter (β) in the troposphere and lower stratosphere almost uninterruptedly since 2008 (Brocard et al., 2013; Dinoev et al., 2013). The T data during the 2008-2010 period are unexploited due to low quality of the analog channel. RALMO has been designed to achieve a measurement precision better than 10% for q and 0.5 K for T with a 30 min integration time and to reach at least 5 km during daytime and 7 km during nighttime in clear-sky conditions. RALMO uses high-energy emission, narrow receiver's field of view and a narrow-band detection to achieve the required daytime performance. The data acquisition software has been developed to ensure autonomous system's operation and real-time data availability. RALMO's tripled Nd:YAG laser emits 400 mJ per pulse at 30 Hz and at 355 nm. A beam expander expands the beam's diameter to 14 cm and reduces the beam divergence to 0.09 mrad ± 0.02 mrad. The returned signal is an envelope of the 355 nm elastic- and Raman-backscattered signals, i.e., PRR, water vapour, oxygen, nitrogen and Rayleigh. Next, the Raman lidar equation (RLE) for the PRR signal is presented along with the detailed description of how RALMO selects the high and low quantum shift wavelengths used in the RLE to retrieve the temperature.

15 3.1 Pure Rotational Raman Temperature

Raman LIDAR measurements of the atmospheric temperature rely on the interaction between the probing electromagnetic signal at wavelength (λ) emitted by the LIDAR and the molecules of O_2 and N_2 encountered along the probing path. In addition to the Rayleigh light backscattered by the aerosols and molecules at the same frequency as the incident light, the O_2 and N_2 molecules return a frequency-shifted Raman signal back to the LIDAR's receiver. The Raman-backscattered signal is shifted in frequency due to the rotational and vibrational Raman effect. In this study only the pure rotational part of the spectrum around the Rayleigh frequency (*Cabannes* line) is detected by RALMO and analyzed (Fig. 4).

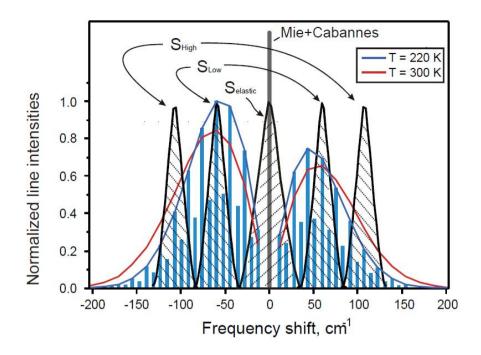

Figure 4. Temperature dependence of the Stokes Stokes and Anti-Stokes Anti-Stokes pure-rotational Raman spectrum of N₂ calculated at 220 K and 300 K. The intensity of the spectral lines are in normalized relative units. The wavelength scale is for frequency shift on the x-axis refers to a laser's wavelength of 355 nm. The total intensity of the high and low quantum-shifted PRR channels is the summation of the single line intensities underneath the bell-shaped black curves.

The Raman LIDAR equation, RLE, yields the intensity of the PRR signal S_{PRR} :

$$S_{\text{PRR}}(z) = \frac{C}{z^2} O(z) n(z) \Gamma_{\text{atm}}^2(z) \left(\sum_{i=O_2, N_2} \sum_{J_i} \tau(J_i) \eta_i \left(\frac{\text{d}\sigma}{\text{d}\Omega} \right)_{\Pi}^i (J_i) \right) + B$$
 (1)

The received S_{PRR} signal measured over the time t is a function of the altitude z; C is the LIDAR constant; O(z) is the geometrical overlap between the emitted laser and the receiver's field of view; n(z) is the number density of the air; $\Gamma_{atm}(z)$ is the atmospheric transmission; $\tau(J_i)$ is the transmission of the receiver for each PRR line J_i ; η_i is the volume mixing ratio of nitrogen and oxygen; $(\frac{d\sigma}{d\Omega})^i_\Pi(J_i)$ is the differential Raman cross section for each PRR line J_i and B is the background of the measured signal. Air mainly contains oxygen and nitrogen ($\approx 99\%$) whose ratio remains fairly constant in the first 80 km of atmosphere, so η_i can be regarded as a constant in eq. 1. The LIDAR constant C depends on the overall efficiency of the transceiver (transmitter and receiver) system including the photo multipliers (PMT) efficiency, on the area of the telescope, and on the signal's intensity. The full expression of the differential Raman cross section for single lines of the PRR spectrum can be found in the reference book chapter by Behrendt (2005).

3.2 Temperature polychromator of RALMO

The two-stage temperature polychromator, hereafter referred to as PRR polychromator, represents the core of the the signal selection. The PRR polychromator separates several pure-rotational Raman spectral lines and isolates elastic scattering consisting of Rayleigh and Mie lines (*Cabannes* line).

The PRR signal from the O_2 and N_2 atmospheric molecules is collected by four parabolic high-efficiency reflecting mirrors each one with diameter of 30 cm. The mirrors have dielectric reflection coating with R > 99% for the vibrational Raman wavelengths and R > 96% for the elastic and pure-rotational Raman for both cross and parallel polarized light. Nine-degrees tilted Semrock Razor Edge Filters (REF) are installed just below the focal points of two of the four mirrors (Fig. 5a). The REF are long-wavelength pass filters and have a cut-off wavelength at 364 nm (Fig. 5b). The ro-vibrational Raman scattering from the atmospheric H_2O , O_2 and N_2 is transmitted by the REF onto the optic fibers placed above the REF at the exact focal distance of the parabolic mirrors. The elastic (Rayleigh and Mie) and PRR scattering are reflected by the tilted REF onto 0.4-mm optic fibers and transmitted to the PRR polychromator.

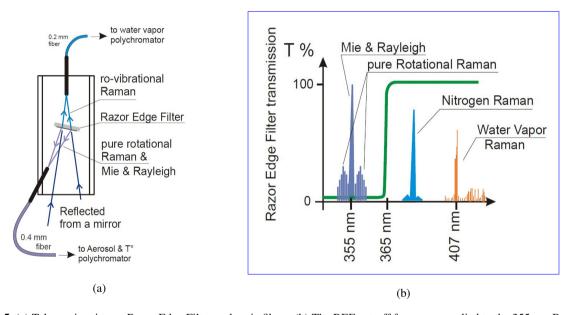

Figure 5. (a) Telescopic mirrors, Razor Edge Filter and optic fibers. (b) The REF cut-off frequency applied to the 355-nm Raman spectrum

The two optic fibers transmitting the PRR and the elastic signals enter the temperature polychromator through the first fibers' block shown in Figure 6. The fibers are fixed into the fiber's block ensuring no or negligible temperature and mechanical-induced drifts of the fiber alignment with respect to the other optical elements inside the polychromator (detailed in Fig. 7). The outline of the two fibers' blocks Cartesian coordinates system in figure 6a shows the position of the input, output and intermediate fibers (from stage-1 to stage-2) as a function of their abscissa-ordinate, x - y, positions. At x = 21.5 mm, the input fibers, coming from the mirrors, are located at the y = 20 mm and y = 24 mm, the output "elastic" fibers are located at y = 18 mm and y = 22 mm. The two output elastic signals are then transmitted through the fibers and combined together just

before entering the PMT installed outside the polychromator's box (PMT R12421P Hanamatsu). The two input fibers transmit the PRR and the elastic signals onto an aspheric lens with focal length of 300 mm and diameter of 150 mm. The two signals are then transmitted through the lens onto a reflective holographic diffraction grating with groove density 600 grooves/mm oriented at a diffraction angle of 48.15° with respect to the axis of the lenses in a *Littrow* configuration. The two input signals (one from each mirror) are diffracted by the grating polychromator and separated into high- and low quantum number lines from both *Stokes* and *Anti-Stokes* Stokes and Anti-Stokes parts of the Raman-shifted spectrum. Two groups of four spectral lines are then diffracted, i.e. J_{high}^{Stokes} , $J_{high}^{AntiStokes}$, J_{low}^{Stokes} , J_{high}^{Stokes} , $J_{high}^{AntiStokes}$, J_{high}^{Stokes} , J

Signals J_{low} and J_{high} J_{low} and J_{high} are sums of the respective Stokes and anti-Stokes lines for nitrogen and oxygen. The eight J-signals diffracted by the polychromator are then re-focused by the aspheric lens onto the *intermediate* fibers positioned at the y-ordinates y=18 mm and y=22 mm and at the x-abscissae x=18.93 mm, x=20.075 mm, x=22.925 mm, x=24.07 mm.

The eight Stokes and Anti-Stokes J-signals are transmitted through the *intermediate* fibers into the second fibers' block (Fig. 6b) and subsequently transmitted along an optical path almost identical to the one in stage-1. Differently from stage-1, the eight J-signals are recombined by the diffraction grating polychromator into two groups of total J-signals (J_{high} and J_{low}). The general outline of the two-stage PRR polychromator is shown in Fig. 7.

The total J-signals are focused by the aspheric lens onto the output fibers positioned in the fibers' block in Fig. 6b at the same x-abscissa x=21.5 mm and at the y-ordinates, y=24.5 mm ($J_{high}J_{high}$), y=21.5 mm ($J_{high}J_{high}$), y=19 mm ($J_{tow}J_{low}$) and y=16 mm ($J_{tow}J_{low}$). The output fibers transmit the four J_{high} and $J_{low}J_{high}$ and J_{low} signals from the two mirrors to two separate PMT boxes installed outside the polychromator's unit. Inside each PMT box two J-signals are combined by an imaging system made by two lenses focusing onto a common spot. This last recombined signal is then divided by a beam splitter into two signals, one at 10% and the other at 90% of the intensity, which are focused onto two independent PMTs. A total of four signals are then obtained at the end of the receiver chain, i.e., $J_{high}^{10\%}$, $J_{high}^{90\%}$, $J_{low}^{10\%}$ and $J_{low}^{90\%}$ and $J_{low}^{90\%}$

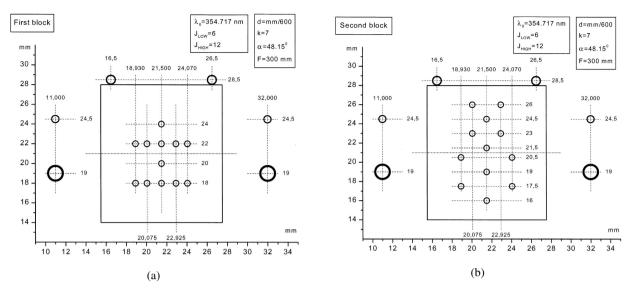

Figure 6. The outline of the two fibers' blocks shows the positions of the input, output and intermediate (afrom stage-1 to stage-2) Telescopic mirrors fibers as a function of the *abscissa-ordinate*, Razor Edge Filter and x - y Cartesian's coordinates. (a) Two optic fibers transmitting the PRR and the elastic signal enter the temperature polychromator through the first fibers' block. (b) The REF cut-off frequency applied eight Stokes and Anti-Stokes J-signals are transmitted through the intermediate fibers into the second fibers' block. The eight J-signals are recombined by the diffraction grating polychromator into two groups of total J-signals (J_{bigh} and J_{low}) and sent to the 355-nm Raman spectrum output fibers. Holes shown outside the fiber's block are not fibers' holders.

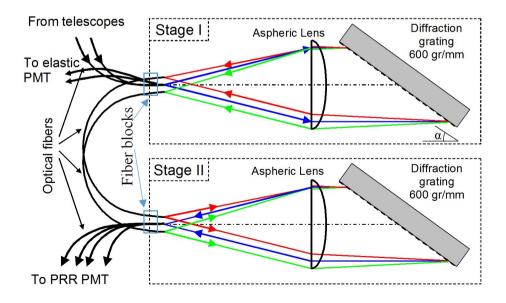

Figure 7. Optics block diagram of PRR polychromator

3.3 PRR channel acquisition system

The acquisition of RALMO's PRR channels have been migrated in August 2015 from the Licel acquisition system to the FAST ComTec P7888 (FastCom). The Model P7888 Series is one of the fastest commercially available multiple-event time digitizer with four inputs (one for each PRR channel) with very short acquisition system's dead-time and consequently minimum saturation effects of the photon-counting channels. Compared to the Licel acquisition system, FastCom acquires the PRR channels solely in photon counting mode, with higher range resolution and with about twice shorter dead-time, τ . The FastCom acquisition system acquires two low-transmission channels ($\frac{J_10\%}{high}$, $\frac{J_10\%}{J_00\%}$, $\frac{J_10\%}{J_00\%}$, and two high-transmission channels, ($\frac{J_10\%}{high}$, $\frac{J_10\%}{J_00\%}$, $\frac{J_10\%}{J_00\%}$, and two high-transmission channels, ($\frac{J_10\%}{high}$, $\frac{J_10\%}{J_00\%}$, $\frac{J_10\%}{J_00\%}$). Most photon-counting acquisition systems are limited in performance by the dead-time τ , i.e. the minimum amount of time in which two input signals may be resolved as separate events. Whenever two consecutive photons impinge on the detector with separation time $t < \tau$ the system counts only one event. Certain type of acquisition systems can be corrected for the underestimation induced by τ , the correction of the PRR signals measured by the FastCom system is presented in the section 4.

4 Retrieval of $T_{\rm ral}$ and calculation of the uncertainty

The high and low-frequency-shifted S_{PRR} signals have the expression given in eq.(1). In order to use them to retrieve the temperature profile, eq.(1) shall be corrected for the dead-time and the background. Once the signals are corrected, their ratio is used used to retrieve the temperature from eq.(3) scaled by two coefficients A and B. The atmospheric temperature is then obtained from the calibration of eq.(3) with respect to T_{ors} and the determination of A and B. The calibrated temperature is then provided along with its uncertainty. Table 3 summarizes the vertical and temporal resolution of the S_{PRR} signal at different stages of the data processing. The vertical resolution of T_{ral} is not constant with the altitude and depends on the calculated total random uncertainty in eq.(6). A Savitzy-Golay digital filter with polynomial degree K=1 is applied to the T_{ral} profiles to degrade the sampling resolution and reduce the sampling noise. The adopted procedure and the definition of the obtained vertical resolution are compliant with the NDACC (Network for the Detection of Atmospheric Composition Change) recommendations detailed in the work by Leblanc et al. (2016). The initial and highest resolution is $\delta z_{max} = \delta z_{max}$

4.1 Correction of S_{PRR}

15

The PRR signals are corrected for the systematic underestimation of the true photon-counting signal (dead-time) and for the offsets (instrumental and solar). The first correction is then for the acquisition system's dead-time τ . The low-transmission channels $\frac{J_{low}^{10\%}}{J_{high}^{10\%}}$ and $\frac{J_{low}^{10\%}}{J_{low}^{10\%}}$ do not become saturated and are used as reference channels to identify the saturation

Table 3. Spatial and temporal resolution of S_{PRR} signals and T_{ral}

level	δt in min	$\delta z_{ m min}$ in ${ m m}$	$\delta z_{ m max}$ in m
raw S_{PRR}	1	2.4	2.4
corrected S_{PRR}	1	2.4	2.4
$T_{ m ral}$	30	400	30

of the high-transmission channels $J_{high}^{90\%}$ and $J_{low}^{90\%}$ $J_{high}^{90\%}$ and $J_{low}^{90\%}$. Assuming that the PMTs and the associated electronics obey the non-paralyzable assumption (Whiteman et al., 1992), we have studied the departure from the constant ratio $J^{10\%}/J^{90\%}$ as a function of τ . We have applied a method based on the non-paralyzable condition (Newsom et al., 2009) to a year of data and have calculated τ for all the cases when the saturation clearly affected the high-transmission channels $J^{90\%}$.

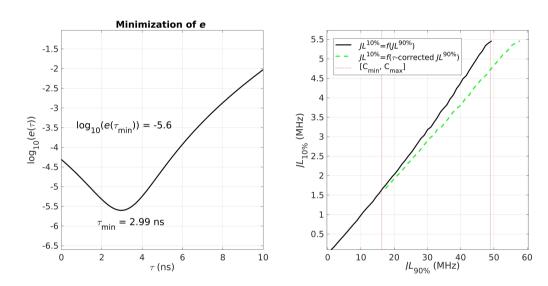

Figure 8. Dead-time calculation and correction of the high-transmission channel $J^{90\%}$. The left panel shows the minimization of the *distance* vector $e(\tau_i)$ in terms of τ_i yielding the deadtime $\tau=2.99$ ns. The right panel shows the saturated $J^{10\%}=f(J_{desat}(\tau=0))$ (solid black), the desataturated linear relation $J^{10\%}=f(J_{desat}(\tau_{min}))$ $J^{10\%}=f(J_{desat}(\tau_{min}))$ (dashed green) and the count-rate domain $[C_{min},C_{max}]$ $[C_{min},C_{max}]$ (dashed red)

As soon as the saturation has its onset, the ratio $J^{10\%}/J^{90\%}$ ceases to be constant and the saturated $J^{90\%}$ yields smaller count rates than the true ones. When the $J^{90\%}$ is desaturated using the correct τ , it gives the τ -corrected signal $J_{desat}(\tau) = J^{90\%}/(1-\tau J^{90\%})$. One thousand linear fits $J^{10\%} = f(J_{desat}(\tau_i))$ are performed with τ_i varying within the interval $\tau_i \in [0 \text{ ns}-10 \text{ ns}]$ at steps of 0.1 ns = 0.01 ns. The linear fits $J^{10\%} = f(J_{desat}(\tau_i))$ are performed over a temporal interval of 30 min and a vertical range defined by the count rates within the maximum range 0.5 MHz to 50 MHz, respectively C_{min} and $C_{max}C_{min}$

and C_{\max} . For each linear fit we calculate the value $e(\tau_i)$ that provides the distance in the count-rate domain between $J^{10\%}$ and $f(J_{desat}(\tau_i))$ as a function of τ_i . The minimization of $e(\tau)$ with respect to τ_i determines the value of the acquisition system's dead-time $\tau_i = \tau_{\min} \in \tau_i = \tau_{\min} \in [0 \text{ ns} \cdot 10 \text{ ns}]$ for each channel. The obtained value $\tau_{\min} \tau_{\min}$ is used to desaturate $J^{90\%}$ and to reestablish the constant ratio $J^{10\%}/f(J_{desat}(\tau_{\min})) = constant J^{10\%}/f(J_{desat}(\tau_{\min})) = constant J^{10\%}/f(J_{desat}(\tau_{\min})) = constant$. Figure 8 shows an example of calculation of $\tau_{\min} \tau_{\min} = \tau_{\min} = 3 \text{ ns}$. On the right panel, the uncorrected and the τ -corrected relations are shown. The uncorrected relation $J^{10\%} = f(J_{desat}(\tau = 0))$ (solid black) departs from the linear relation $J^{10\%} = f(J_{desat}(\tau_{\min}))$ $J^{10\%} = f(J_{desat}(\tau_{\min}))$ (dashed green) as soon as the count rates exceed the lower bound $C_{\min} C_{\min}$ (dashed red). Applying this method to a year of data and collecting more than hundred cases we have determined the mean dead-times $\tau_{jh} = 1.4 \text{ ns}$ and $\tau_{jl} = 3 \text{ ns}$ for J_{high} and J_{low} , respectively. The desaturated J_{high} and J_{low} J_{high} and J_{low} are further corrected for the background and the procedure is described hereafter.

The electronic and solar background must be subtracted from S_{PRR} before retrieving T_{ral} . While the electronic background is stable and does not undergo daily or seasonal cycles, the solar background changes in intensity with the position of the sun Φ (the angle between the zenith and the centre of the Sun's disc). We have found that subtracting the mean value of the far-range signal ($z \in [50\text{-}60]$ km) from S_{PRR} , (subtraction of term B from eq. 1) causes a systematic negative bias with respect to T_{ors} of about 1 K at all altitudes z during daytime. A relative change of 1% in the ratio $\frac{1}{100} \frac{1}{100} \frac{1}$

$$f(\Phi) = 1 - 0.01 \cdot \frac{\cos \Phi}{\cos \Phi_{\min}} \delta_{\Phi}, \quad \delta_{\Phi} \equiv 1 \quad \text{for} \quad 0 \le \Phi < \pi/2, \quad \delta_{\Phi} \equiv 0 \quad \text{for} \quad \pi/2 \le \Phi < 2\pi$$
 (2)

If uncorrected, the retrieved daytime $T_{\rm ral}$ suffers a bias at all heights with respect to $T_{\rm ors}$. The bias is largest when $\Phi = \Phi_{\min}^{day} \Phi = \Phi_{\min}^{day}$. The correction $f(\Phi)$ is applied only to the background of $J_{high}J_{high}$. The intensity of $J_{high}J_{high}$ is generally lower than J_{low} . J_{low} at all atmospheric temperatures (see Sect. 4), and so is also its signal-to-noise ratio (SNR). Even a small error of $\approx 1\%$ when subtracting B from $J_{high}J_{high}$ has a major impact on its SNR; $f(\Phi)$ corrects the imperfect subtraction of B from J_{high} J_{high} and minimizes the daytime bias of $T_{\rm ral}$ with respect to $T_{\rm ors}$ almost perfectly.

4.2 Estimation of total random uncertainty

Once B_{corr} is subtracted from the τ -corrected S_{PRR} , the deviation of T_{ral} from T_{ors} depends only on how precisely eq. (3), derived from the RLE, represents the true atmospheric temperature at the altitude z and time t. The random uncertainty does not

account then for the error induced by the saturation and the background, which are considered as purely systematic. The high-frequency-shifted, $J_{high}J_{high}$, and low-frequency-shifted, $J_{low}J_{low}$, signals in the Stokes and anti-stokes Q-branches depend on the temperature of the probed atmospheric volume (Fig. 4). The ratio of the S_{PRR} intensities $Q(z) = J_{low}(z)/J_{high}(z)$ is a function of the atmospheric temperature T at the distance z. Based on the calculations shown by Behrendt (2005) and for systems that can detect independent J-lines in each channel, the relationship between T and Q would take the form of eq. (3) with the *equals* sign. The approximation sign in eq. (3) indicates that the detection system detects more than one J-line and thus brings an inherent error. The calibration coefficients A and B are a-priori undetermined and can be determined by calibration of T_{ral} with respect to T_{ors} .

$$T_{\rm ral} \approx \frac{A}{B + \ln Q}.$$
 (3)

The coefficients A and B are determined calibrating $T_{\rm ral}$ with respect to $T_{\rm ors}$. The coefficient A has units in Kelvin as eq. (3) is not normalized for the standard atmospheric temperature (Behrendt and Reichardt, 2000). The linear relation y = A/(x+B) is used, where x is the ratio Q and y is the reference temperature $T_{\rm ors}$. The mean error on $T_{\rm ors}$ for both the RS41 and SRS-C50 is $\approx -0.04 \pm 0.15$ K at 11 UTC and 23 UTC between 0 and 14 km (section 2). Due to the very small error on $T_{\rm ors}$, we can calculate the uncertainty U_{fit} U_{fit} of the fitting model only in terms of the fitting parameters' errors σ_A and σ_B (eq. 4). As it will be shown in the next section, the covariance σ_{AB} of A and B is very close to zero (< 10^{-3}), thus σ_A and σ_B can be treated as statistically independent and used to calculate U_{fit} U_{fit} from the first-order Taylor's series of propagation of fitting parameters' uncertainties.

$$U_{\underline{fit}_{\infty}^{\text{fit}}} = \frac{1}{(B + \ln Q)} \left[\sigma_A^2 + \frac{A^2 \sigma_B^2}{(B + \ln Q)^2} \right]^{\frac{1}{2}},\tag{4}$$

 U_{fit} U_{fit} is not the only error source, a second contribution to the total uncertainty comes from the fact that S_{PRR} is acquired by a photon-counting system and is affected by the measurement's noise that can be calculated using standard *Poisson* statistics. The error σ_J for *Poisson*-distributed data is equal to the square root of the S_{PRR} signals, $\sigma_{J_{low}} = \sqrt{J_{low}}$ and $\sigma_{J_{high}} = \sqrt{J_{high}}$. In eq. (5), coefficients A and B can be regarded as independent from the noise on S_{PRR} , as the contribution of it is already included in σ_A and σ_B in eq.(4).

$$U_{\underline{sig} \text{ sig}} = \frac{A}{(B + \ln Q)^2} \left[\frac{1}{J_{\text{high}}} + \frac{1}{J_{\text{low}}} \right]^{\frac{1}{2}}.$$
 (5)

The total uncertainty of the calibrated $T_{\rm ral}$ is a *type B* uncertainty (for Guides in Metrology, 2008) and is the sum of the independent error contributions U_{fit} and $U_{\rm sig}$ $U_{\rm fit}$ and $U_{\rm sig}$.

$$U_{T} = \sqrt{U_{\text{fit}}^{2} + U_{\text{sig}}^{2}} = \sqrt{\frac{1}{(B + \ln Q)^{2}} \left[\sigma_{A}^{2} (B + \ln Q)^{2} + A^{2} \left(\sigma_{B}^{2} + \frac{1}{J_{\text{high}}} + \frac{1}{J_{\text{low}}} \right) \right]}.$$
 (6)

4.3 Calibration of S_{PRR}

For a very stable system like RALMO, calibrations can be performed once every few months to compensate for any occurring drift of the detection system's sensitivity and/or efficiency. Calibrations of RALMO are performed using eq. (3) in clear-sky conditions during nighttime to remove the effect of solar background and have a larger vertical portion of $T_{\rm ral}$ available for calibration (the daytime profiles have normally a lower cut-off altitude). Figure 9 shows a case of RALMO calibration, the green-shaded area represents $\pm 2U_T$ (k=2).

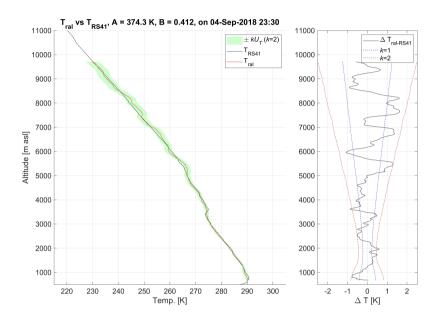

Figure 9. RALMO temperature profile calibrated by the ORS RS41. The left panel shows T_{RS41} (solid black) and T_{ral} (solid red) with the confidence interval (green shading) corresponding to $kU_T(k=2)$. The right panel shows the differences $\Delta T_{ral-RS41}$ within the U_T k-boundaries for k=1 (dashed blue) and k=2 (dashed red).

The calibrated $T_{\rm ral}$ results from the integration of 30 $\tau-$ and B-corrected $S_{\rm PRR}$ profiles ($\delta t=30\,{\rm min}$) into eq. (3). At a given atmospheric altitude z during the time interval $\delta t,\,U_T(z)|_{\delta t}$ is made of the single contributions $U_{sig}(z,t)$ and $U_{fit}(z,t)$. $U_{sig}(z,t)$ and $U_{fit}(z,t)$. $U_{sig}(z,t)$ can be regarded as independent with respect to time; on the other hand, the errors $U_{fit}(z,t)U_{fit}(z,t)$, depend on the atmospheric processes occurring within the layer $[z-\delta z/2,z+\delta z/2]$ during the time interval $[t-\delta t/2,t+\delta t/2]$ and are, a-priori, not statistically independent. By assuming that all errors in eq. (6) are statistically independent, we assume that the off-diagonal elements of the variance-covariance matrix are all zero. By doing so, $U_T(z)|_{\delta t}$ could be underestimated by an amount equal to the non-zero covariance terms, including the covariance σ_{AB} . A method to assess the exhaustiveness of the theoretical error U_T is to calculate how many points in the vector $\Delta T = T_{\rm ral} - T_{\rm ors}$ fall within the interval $[-k\sigma, +k\sigma]$ and check if they are compatible with the Gaussian probability levels 68.3%, 95.5% and 99.7% for k=1,2,3, respectively. As it is shown in the right panel of figure 9, almost all points along the vector $T_{\rm ral} - T_{\rm ors}$ fall within the

interval $[-2\sigma, +2\sigma]$, i.e. the 98.1%. For k=1 the percentage falls slightly below the expected level for a Normal distribution with only 61.2% of the points within $[-\sigma, +\sigma]$. Between July 2017 and December 2018, a total of seven calibrations have been performed (three SRS-C50 and four Vaisala RS41). The mean percentage of points over all performed calibrations is 65.1% for k=1, 97.9.1% for k=2 and 99.98% for k=3. These values seem to confirm an overall exhaustiveness of U_T with a slight underestimation of 3.2% at k=1. The list of calibrations is shown in Table 4. For each calibration, the table lists the date and end time of the calibration, the calibration coefficients A and B used in the fitting model eq. (3), the errors σ_A and σ_B , the covariance σ_{AB} and the ORS used to calibrate $T_{\rm ral}$. As to further support the assumption of zero covariance of the coefficients A and B, all covariances σ_{AB} in the table are smaller than 1.71×10^{-3} . Between two consecutive calibrations performed at times t_i and t_{i+1} the coefficients $A(t_i)$ and $B(t_i)$ are used to calibrate all profiles $T_{\rm ral}$ during the time interval $t \in [t_i, t_{i+1}]$.

10 5 Validation of PRR temperature

More than 450 profiles $T_{\rm ral}$ (245 nighttime, 215 daytime) have been compared to $T_{\rm ors}$ and assessed separately for daytime and nighttime based on the bias and standard deviation (σ) of the differences $\Delta T = T_{\rm ral} - T_{\rm ors}$ over the period 1^{st} of July 2017- 31^{st} of December 2018. Two criteria to select the cases for the dataset have been used:

- 1. Only cases with no precipitation and no low clouds or fog are retained.
- 15 2. Only cases with $\Delta T < 5 \,\mathrm{K}$ are retained.

Criterion 1 is performed setting a threshold for minimum cloud base, h_b , at $1000 \,\mathrm{m}$ (a.g.l.), for any values of $h_b < 1000 \,\mathrm{m}$ T_{ral} is not retrieved. Whenever $h_b > 1000 \,\mathrm{m}$, the cut-off altitude will correspond to h_b . Indeed, above h_b , the SNR drops abruptly and $U_T(z) \gg 1 \,\mathrm{K}$. For this reason, especially during winter, when long-lasting stratus clouds occur in the altitude range 1 km to 4 km, the nighttime and daytime T_{ral} is profiles are limited in range to the altitude h_b (or are is not calculated if $h_b < 1000 \,\mathrm{m}$). Criterion 2 is performed setting a threshold at 33% of the number of elements along the profile ΔT exceeding 5 K. If more

than 33% of the elements along ΔT exceed the threshold, the whole $T_{\rm ral}$ is rejected and not included in the statistics. For any value below the threshold, the outliers are removed from $T_{\rm ral}$. This is justified by the fact that exceedances counting more than 33% are caused by temporary misalignment of the transceiver unit. On the other hand, exceedances well below the threshold can always occur (especially in the higher part of the profile) due to low SNR or unfiltered clouds. In Table 5 we present a summary of the statistical parameters characterizing the daytime and nighttime differences ΔT that will be discussed in detail in the following sections. The dataset ΔT is described in terms of maximum mean bias $\Delta T_{max}\Delta T_{max}$, average mean bias μ , standard deviation σ and maximum availability $N_{max}N_{max}$ of the differences ΔT along the atmospheric range.

Table 5. Summary of the statistical parameters of the day and night ΔT dataset

night						
$\Delta T_{ m max}$	μ	σ	$N_{ m max}$	range		
$0.24\mathrm{K}$	$0.05 {\pm}~0.34\mathrm{K}$	$0.66\pm0.06\mathrm{K}$	244	0.5-10 km		
day						
$\Delta T_{ m max}$	μ	σ	$N_{ m max}$	range		
$0.25\mathrm{K}$	$0.02 {\pm}~0.1\mathrm{K}$	$0.62 {\pm}~0.03\mathrm{K}$	212	0.5-6 km		

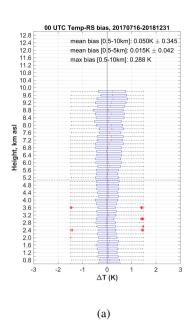

Besides a global validation we also present and discuss the seasonal statistics in order to better characterize the system performance.

0 5.1 Nighttime temperature statistics

The nighttime $\Delta T_{max} \Delta T_{max}$, μ , σ and $N_{max} N_{max}$ of ΔT are are the metric to assess the accuracy and precision of T_{ral} with respect to T_{ors} . Figure 10 shows $\Delta T_{max} = \Delta T_{max} = 0.24 \,\mathrm{K}$, $\mu = 0.05 \pm 0.34 \,\mathrm{K}$, $\sigma = 0.66 \pm 0.06 \,\mathrm{K}$ and $N_{max} = 244 \,\mathrm{M}$ over the tropospheric region $0.5 \,\mathrm{km}$ to $10 \,\mathrm{km}$.

In addition to the uncertainty assessment performed in section 4.3, the exhaustiveness of the theoretical total uncertainty 15 U_T can be further assessed comparing U_T with σ . The mean value of U_T along the troposphere and over the seven nighttime calibrations is $\overline{U}_T = 0.64 \, \text{K}$, the mean nighttime standard deviation averaged over the tropospheric column in figure 10 is $\overline{\sigma} = 0.66 \, \text{K}$. The two 1 - k uncertainties are then fully compatible.

The nighttime ΔT data are characterized by values of μ and σ smaller than 1 K, with minimum values in the lower troposphere from 0 km to 5 km. It is indeed in the lower troposphere, where σ is ≈ 0.6 K, i.e. 0.1 K larger than the 0.5 K requirement for data assimilation into the numerical weather prediction COSMO forecasting system (Fuhrer et al., 2018; Klasa et al., 2018, 2019). In order to achieve a successful assimilation of $T_{\rm ral}$ into COSMO, the overall impact of the assimilation shall correspond to an improvement of the forecasts without increasing the forecasts' uncertainty. Assimilation of high-SNR, well-calibrated $T_{\rm ral}$ into numerical models leads to the improvement of the forecasts. In the study by Leuenberger et al. (2020), the

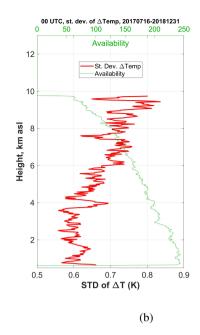

Figure 10. Nighttime bias and standard deviation (STD) of ΔT over the period July 2017-December 2018. In fig. 10a, on each box of 200 m vertical span, the central mark indicates the median, and the left and right edges of the box indicate the 25^{th} and 75^{th} percentiles, respectively. The whiskers extend to the most extreme data points not considered outliers, and the outliers are plotted individually and shown by the '+' symbol. The thick red curve in Fig. 10b shows the vertical profile of standard deviation (thick red) STD calculated over the altitude-decreasing number of ΔT points (thin green).

authors assimilate, amongst other data, temperature and humidity profiles from RALMO showing the beneficial impact on the precipitation forecast over a wide geographical area.

5.2 Daytime temperature statistics

During daytime, the retrieved temperature profiles are limited in range to about $6 \, \mathrm{km}$. Figure $11 \mathrm{a}$ and $11 \mathrm{b}$ show the bias ΔT and the standard deviation σ , respectively. The $\Delta T_{\max} \Delta T_{\max}$, μ , σ and $N_{\max} N_{\max}$ of the daytime ΔT over the lower troposphere $(0.5\text{-}6 \, \mathrm{km})$ are $0.25 \, \mathrm{K}$, $0.02 \pm 0.1 \, \mathrm{K}$, $0.62 \pm 0.03 \, \mathrm{K}$ and 212, respectively. The data availability goes rapidly to zero above $5 \, \mathrm{km}$. The daytime T_{ral} profiles have been corrected for the solar background by $f(\Phi)$, which proves to be very efficient in removing the noon bias with respect to T_{ors} . To ensure that the correction $f(\Phi)$ does not introduce any additional bias during the daily cycle, we have compared T_{ral} with the temperature calculated by the COSMO model. More than three months of clear-sky 24-hour $T_{\mathrm{ral}} - T_{\mathrm{cos}}$ differences have been collected yielding a mean daily cycle at the level $1.4 \, \mathrm{km}$ to $1.7 \, \mathrm{km}$ a.s.l.. The comparison in Fig. 12 shows that RALMO does not suffer any systematic daily Φ -dependent bias.

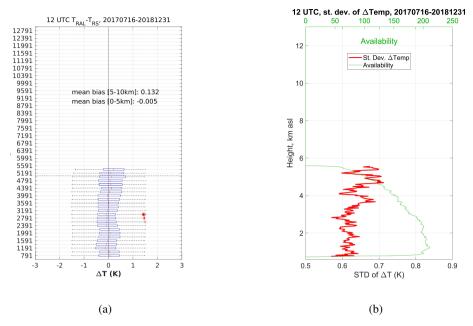

Figure 11. Daytime bias and standard deviation (STD) of ΔT over the period July 2017-December 2018. In fig.11a, on each box of 200 m vertical span, the central mark indicates the median, and the left and right edges of the box indicate the 25^{th} and 75^{th} percentiles, respectively. The whiskers extend to the most extreme data points not considered outliers, and the outliers are plotted individually and shown by the '+' symbol. Fig.11b shows the vertical profile of standard deviation (thick red) calculated over the altitude-decreasing number of ΔT points (thin green).

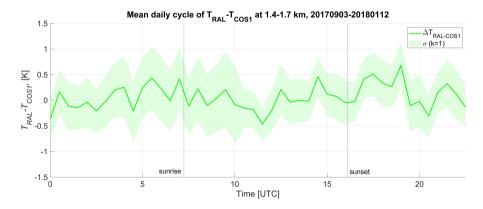

Figure 12. RALMO-COSMO-1-Differences between RALMO and COSMO temperature at 1400-1700 m asl during Sept. 2017-Jan. 2018. The green shading accounts for the k=1 standard deviation of the differences. The dashed vertical lines show the sunrise and sunset time on 12 Jan 2018, the mean daily cycle shows that no artefacts are introduced by the application of $f(\Phi)$ during daylight.

6 Seasonality study

In order to study the seasonal effects on μ and σ , the ΔT dataset has been divided into seasons. The four seasons are defined as it follows: summer, from 1^{st} of June to 30^{th} of August, autumn from 1^{st} September to 30^{th} of November); winter from 1^{st} of December- 15^{th} of March; Spring from 16^{th} of March to 31^{st} of May. Because of the less favourable conditions in winter due to precipitation and low clouds, only few temperature profiles are available during this period. Additionally, during winter 2018, from January till mid-March, RALMO measurements have been stopped for about 80% of the time due to maintenance works. The results are summarized in Tables 6 and 7 in terms of μ , σ and maximum availability N_{max} over the lower tropospheric range 0 km to 6 km for daytime and over 0 km to 10 km for nighttime. With the only exception of winter, the other seasons have enough profiles to perform a statistical analysis and to draw quantitative conclusions about the contribution of each season to the overall values μ and σ .

6.1 Seasonal daytime temperature statistics

The seasonal daytime μ and σ profiles are analyzed to understand if sources of systematic errors other than SB-SB affect the retrieved $T_{\rm ral}$. The seasonal profiles are shown in Fig. (13) and (14) and summarized in Table 6. Due to the less favourable weather conditions and the maintenance works, the winter statistics count only 8 profiles. The statistical characterization of the winter dataset can then only be qualitative. Summer and spring are the seasons with the minimum values of Φ at noon, during these two seasons $T_{\rm ral}$ is most affected by SBSB. If uncorrected for $f(\Phi)$, the noon $T_{\rm ral}$ suffers a negative mean bias of about 2 K at all heights (not shown here). Summer counts more than twice the number of cases in the spring dataset, nevertheless for both seasons the values of μ are compatible with a zero bias within their uncertainties (both $\sigma = 0.64$ K). Despite the less favourable weather conditions compared to spring and summer, autumn is the season with most cases and this is because there are two autumn seasons in the dataset. Likewise Like spring and summer, also autumn has μ compatible with the zero-bias within its uncertainty. Through the four seasons the mean σ spans from 0.4 K to 0.65 K.

Table 6. Seasonal mean bias μ , standard deviation σ and TD-maximum availability N_{max} at 12 UTC

season	μ [K]	σ [K]	$N_{ m max}$
	0.5 -	– 6 km a.	s.1.
summer	+0.03	0.64	74
autumn	+0.005	0.61	102
winter	+0.24	0.41	8
spring	-0.03	0.64	31

Fig. (13) suggests that $T_{\rm ral}$ is not affected by any obvious systematic error ($\mu \simeq 0 \in [-\sigma, +\sigma]$) and no seasonal cycle appears in the statistics. From the perspective of the statistical validity of the studied data, any sub-sample chosen randomly from the total $T_{\rm ral}$ dataset can be described by the same μ and σ that characterizes ΔT .

Differently from the Fig. (13), the σ profiles in Fig. (14) show different behaviors in summer-autumn and in winter-spring. The σ -profiles in Figs. (14a) and (14b) undergo a decoupling between the lower and upper part of the profile with inversion point slightly higher in autumn. An increase in σ with height is something expected and can be explained with the decreased data availability and the decreased SNR due to the increasing large distance from the laser emission lidar's telescope. However, the abrupt increase in spread σ at ≈ 3 km in summer and at ≈ 4.5 km in autumn is more related to the atmospheric dynamics than to the SNR. In summer, the transition between the boundary layer and the free troposphere is a region of high variability in terms of temperature and humidity. The alternating cold downdrafts and warm updrafts engendered by the overall fair weather conditions and the continuous development of thermals through the boundary layer (Martucci et al. (2010)) cause a large variability of $T_{\rm ral}$ at ≈ 3 km, which translates into large σ -values. In autumn, the thermal activity at the top of the boundary layer is less pronounced than in summer, on the other hand, a temperature inversion linked to the formation and dissipation of stratus clouds above Payerne occurs at ≈ 4.5 km causing larger discrepancies in the comparison with $T_{\rm ors}$.

15 6.2 Seasonal nighttime temperature statistics

At nighttime, $f(\Phi)$ has no impact on the temperature retrieval and the seasonal statistics can reveal sources of systematic error other than the <u>SB-SB</u> causing $|\mu| > 0$. The separation into seasons, helps understanding if the overall zero-bias shown in Fig. 10 hides seasonal non-zero biases that cancel out when combined in the full dataset. Compared to daytime cases, the availability of the nighttime dataset is higher including the one of winter cases that allows now to perform a statistical analysis. Indeed, the number of cases in the nighttime dataset is 245, versus 215 in the daytime. All seasonal μ values are compatible with the zero bias along the troposphere within $[-\sigma, +\sigma]$. Likewise Like the daytime seasonal statistics, also the nighttime do not reveal any obvious source of systematic error. The mean μ and σ in the troposphere are summarized in Table 7.

Table 7. Seasonal mean bias μ , standard deviation σ and \overline{TD} -maximum availability N_{max} at 00 UTC

season	μ [K]	σ [K]	Nmax
	0.5	6-6 km	a.s.l.
summer	+0.11	0.66	77
autumn	+0.02	0.65	118
winter	+0.18	0.60	19
spring	+0.08	0.64	31

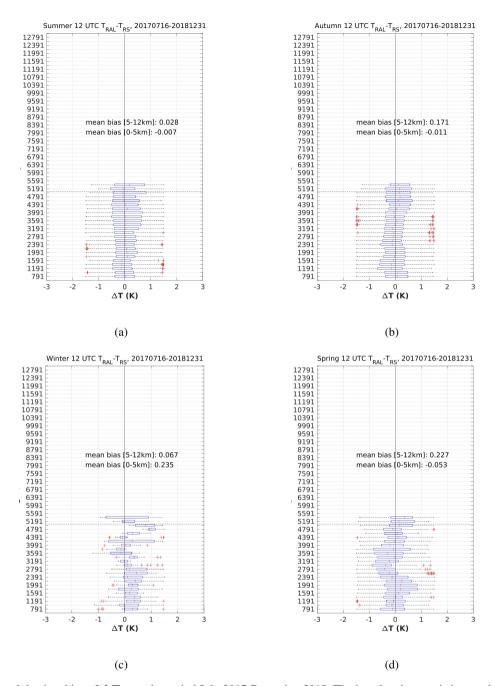

Figure 13. Seasonal daytime bias of ΔT over the period July 2017-December 2018. The boxplot characteristics are the same as in Fig. 10 and Fig. 11, but restricted over the seasonal periods. Based on the definition of seasons provided in the text, panel 13a shows the summer data, panel 13b shows the autumn data, panel 13c shows the winter data, panel 13d shows the spring data.

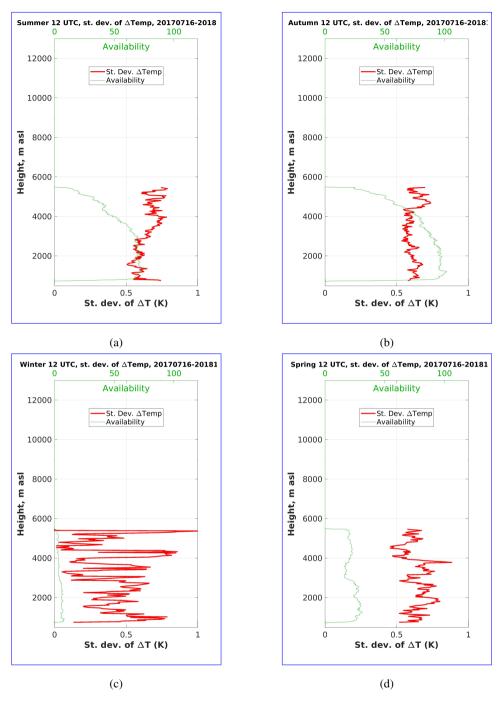

Figure 14. Seasonal daytime standard deviation (STD) of ΔT over the period July 2017-December 2018. The vertical profiles of standard deviation (thick red) are calculated over the altitude-decreasing number of ΔT points (thin green). Based on the definition of seasons provided in the text, panel 14a shows the summer data, panel 14b shows the autumn data, panel 14c shows the winter data, panel 14d shows the spring data.

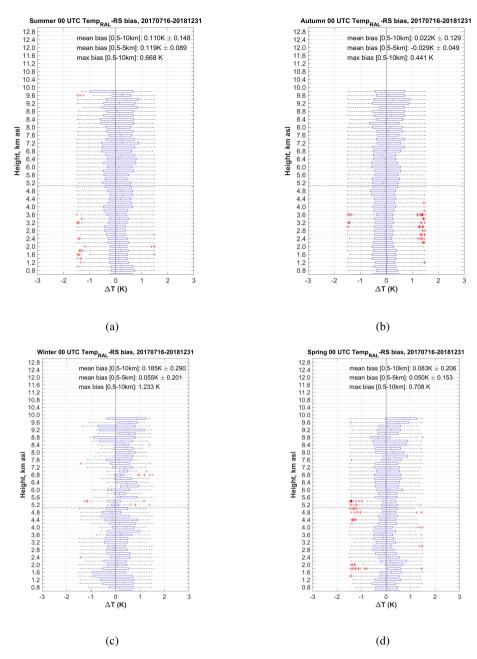

Figure 15. Seasonal nighttime bias of ΔT over the period July 2017-December 2018. The boxplot characteristics are the same as for Fig. 10 and Fig. 11, but restricted over the seasonal periods. Based on the definition of seasons provided in the text, panel 15a shows the summer data, panel 15b shows the autumn data, panel 15c shows the winter data, panel 15d shows the spring data.

The nighttime cases undergo different dynamics than the daytime cases. The absence of solar radiation removes almost all convection in the boundary layer and minimizes the variance of the temperature at the top of the nocturnal and residual layers. Consequently, no sharp increase of σ is detected at specific levels during any of the seasons. The σ -profiles increase in value with height as a response to the drop of the SNR due to the distance from the emission.

5 7 Measurement of supersaturation in liquid stratus clouds Future applications

A reliable real-time measurement of the temperature in the troposphere along with a reliable measurement of the humidity allows to calculate trustworthy profiles of relative humidity. A validation of the relative humidity measured by RALMOhas been performed by Navas-Guzmán et al. (2019). The authors have characterized the relative humidity (RH) measured by RALMO using a similar procedure like for the temperature, finding that The validated $T_{\rm ral}$ is used to calculate the relative humidity using the humidity profiles also provided by RALMO. The relative humidity product has been validated in a parallel work by Navas-Guzmán et al. (2019) that shows that in the first $\frac{2 \text{ km}}{2 \text{ km}}$ the RH suffers a mean systematic and random error of $\Delta \text{RH} = +2\% \pm 6\%$ RH.

Case of 15 Nov. 2017. Top panel: RH supersaturation in a liquid stratus cloud (thick contours show the zone in the cloud where supersaturation occurs). Bottom panel: total backscatter ratio (contour lines show zones where the cloud has the largest backscatter ratio).

When studying eases of cloud supersaturation a great accuracy is needed, especially when the supersaturation is assessed at the cloud base or inside a fog layer where the supersaturation is at its onset value. Previous studies (Hudson et al. (2010); Martucci and O'De) show that for different types of The validated RH can be used to perform, amongst others, studies of supersaturation of water vapour in liquid stratus cloudsforming within continental (polluted) or marine (clean) air masses, the characteristic values of supersaturation span between 0.1 % to > 1 %, respectively. In this sense, we cannot use here the RH measurements quantitatively, as the RH relative erroris bigger than the expected maximum supersaturation. However, this limitation does not prevent to perform a qualitative study about the occurrence of supersaturation in liquid clouds. The two case studies presented in Figures ?? and ?? show the temporal evolution of the RH and the total back-scattering ratio (BSR) for two liquid stratus clouds. The RH time series shown in the Figures ?? and ?? have maxima co-located in time and space with the maxima of the BSR (Figs. ?? and ??), i.e. where the actual stratus clouds are located. A LIDAR cannot measure through a fully developed liquid cloud as the laser becomes totally extinct after 2-3 optical depths above the cloud base ($\approx 100-150$ m penetration). For this reason, normally, the retrieved profiles from a ground-based LIDAR refer strictly to the lower part of the stratus cloud. The cloud cases presented here, are not completely opaque stratus and so they allow a partial LIDAR return from higher altitudes above the cloud. In Fig. ??, the observed maxima along the RH profiles for the case of 15th of November 2017 occur during 21:30-22:00 UTC and between 860 m and 950 m. The RH maxima during these temporal and spatial intervals reach RH= 102.16% at 21:30 UTC and RH= 102.53% at 22:00 UTC, by correcting the RH for its mean bias in the first 2 km $(\Delta RH = +2\%)$, the resulting supersaturation is in the range ss = 0.16 - 0.53%. These values of ss are typical for continental warm stratus cloud and, although qualitative, fit very well the expected microphysical scenario.

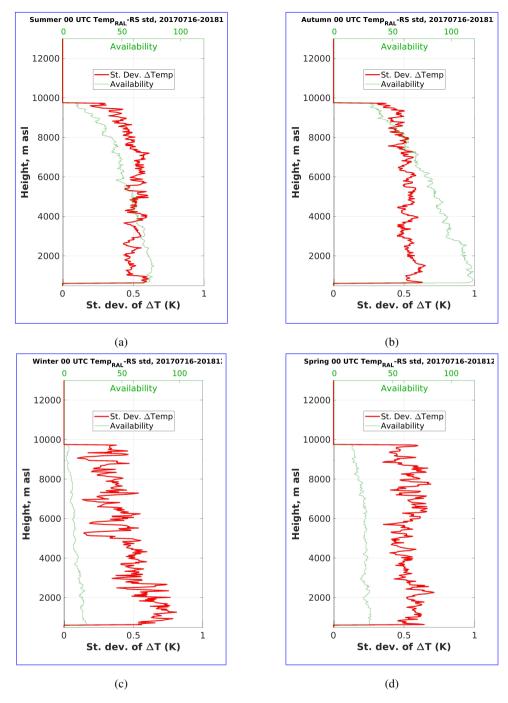

Figure 16. Seasonal nighttime standard deviation (STD) of ΔT over the period July 2017-December 2018. The vertical profiles of standard deviation (thick red) are calculated over the altitude-decreasing number of ΔT points (thin green). Based on the definition of seasons provided in the text, panel 16a shows the summer data, panel 16b shows the autumn data, panel 16c shows the winter data, panel 16d shows the spring data.

Case of 20/May/2018. Top panel: RH supersaturation in a liquid stratus cloud (thick contours show the zone in the cloud where supersaturation occurs). Bottom panel: total backscatter ratio (where the cloud has the largest backscatter ratio).

The case of the 20^{th} of May 2018 in Figure ?? shows the convective growth of the boundary layer above Payerne from the late morning till the central hours of the day. At the top of the developing convective boundary layer, fair-weather cumulus clouds form starting from very low altitude above the ground before 11:00 UTC and reaching ≈ 2 km between 14:00 UTC and 15:00 UTC. The RH (Fig. ??) reach local maxima of supersaturation correspondingly to the maxima in BSR (Fig. ??). By performing the same qualitative analysis as for the previous case, the supersaturation is observed at 11:30 UTC between 830 m and 1160 m asl (ss = 100.43% - 102.32%) and at 14:00 UTC between 1400. As future work, we will investigate the supersaturation corrected for the RH systematic error, of a large statistical dataset of liquid clouds above Payerne across different seasons and years. The possibility to study supersaturation is critical to disentangle the microphysics of liquid clouds and 1520 m asl (ss = 102.25% - 102.93%). Correcting the RH for its mean bias in the first 2 km, the resulting supersaturation is achieved only at its high-end for the first event with ss = 0.32% and results in the range of values ss = 0.25% - 0.93% for the second-event better predict the amount of liquid water within the cloud.

8 Conclusions

More than 450 LIDAR temperature profiles have been compared to the temperature profiles measured by the reference radiosounding system at Payerne at 11 UTC and 23 UTC during 1.5 years (July 2017-December 2018). The reference radiosounding systems (SRS-C50 and Vaisala RS41) have been validated by the GRUAN-certified Vaisala RS92 sonde in the framework of the quality assurance programme carried out at Payerne. A semi-empirical modification has been developed and applied to the background correction procedure to reduce a the daytime bias. The temperature profiles retrieved from RALMO PRR data show an excellent agreement with the reference radiosounding system during both daytime and nighttime in terms of maximum bias $(\Delta T_{max} \Delta T_{max})$, mean bias (μ) and standard deviation (σ) . The $\Delta T_{max} \Delta T_{max}$, μ and σ of the daytime differences $\Delta T = T_{\rm ral} - T_{\rm ors}$ over the tropospheric region 0.5–6 km are 0.28 K, 0.02 ± 0.1 K and 0.62 ± 0.03 K, respectively. The nighttime ΔT dataset is characterized by a mean bias $\mu=0.05\pm0.34$ K and $\sigma=0.66\pm0.06$ K, while ΔT is smaller than $\Delta T_{max} = 0.29 \Delta T_{max} = 0.29 \text{K}$ at all heights over the tropospheric region 0.5–10 km. We further have compared the lidar data against model output and found no daytime temperature data against the temperature predicted by the COSMO model and found that there was no dependence of the bias nor and the standard deviation and on the diurnal cycle. This result let us conclude that essentially the same data quality is achieved for at day and night. A seasonality study has been performed to help understanding if the obtained overall daytime and nighttime zero-bias hides seasonal non-zero biases that cancel out when combined in the full dataset. The study reveals that all independent seasonal contributions of μ are compatible with the zero-bias within their uncertainty. In general, the seasonal datasets confirm the fact that sub-sampling the total ΔT dataset, the sub-samples can still be described by the same μ and σ . The validated $T_{\rm ral}$ has then been used to calculate the relative humidity using the humidity profiles also provided by RALMO. The relative humidity product has been validated in a parallel work by Navas-Guzmán et al. (2019) that shows that in the first 2 km the RH suffers a mean systematic and random error of $\Delta RH = +2\% \pm 6\%$ RH. The validated RH data have been used to perform a qualitative study to assess the supersaturation of water vapour in liquid stratus clouds measured by RALMO. Two cases have been investigated and the observed supersaturation values, once corrected for the RH systematic error, found compatible with the values characteristics for continental liquid stratus clouds (ss = 0.16 - 0.53%). The possibility to study supersaturation is critical to disentangle the microphysics of liquid clouds and better predict the amount of liquid water within the cloud.

We have shown that RALMO temperature profiles the temperature profiles obtained from the PRR RALMO data meet the OS-CAR breakthrough uncertainty requirement of 1 K for high resolution NWP (https://www.wmo-sat.info/oscar/requirements). Combined with the water vapor measurements measurements the Raman lidar has a high potential to improve NWP through data assimilation as we have demonstrated recently (Leuenberger et al., 2020) and MeteoSwiss plans to assimilate the Raman lidar in Payerne operationally in the near future.

Acknowledgements. This work has been supported by the Swiss National Science Foundation (project no. PZ00P2 168114) entirely by the Federal Office of Meteorology and Climatology, MeteoSwiss through the Swiss Government. Two projects have most contributed through the years to improve the quality of the RALMO data, the Global Climate Observing System (GCOS) Reference Upper-Air Network (GRUAN) and Network for the Detection of Atmospheric Composition Change (NDACC). We thank the École Polytechnique Fédérale de Lausanne (EPFL) who co-designed and built RALMO.
